synthesizes the acetylcholine; Buffelli et al., 2003). The results showed that when axons containing normal levels of ChAT co-innervated junctions with axons that had subnormal amounts, the subnormal axons typically occupied smaller territories. This result is consistent with the idea that axons that have the greatest number of synaptic branches may be at a disadvantage because they cannot maintain sufficient resources to drive postsynaptic cells as well as axons with fewer branches.

Summary

Structural studies of synapse elimination at the neuromuscular junction have provided a number of clues as to how and why branches are pruned. One important insight is that synapse elimination at individual neuromuscular junctions may be part of a larger-scale circuit optimization. This optimization may be occurring to ensure that all the connections that are maintained into adulthood are sufficiently strong that they can consistently drive the postsynaptic cell to threshold. Perhaps such an optimization requires axons to forfeit some of their synaptic connections to ensure that the ones that remain have sufficient resources to be consistently efficacious.

A ROLE FOR INTERAXONAL COMPETITION AND ACTIVITY

A number of lines of evidence suggest that the loss of synapses is the consequence of competition. The word *competition*, however, has many different meanings, and which of these definitions is most relevant to synaptic development is an area of some debate (Lichtman & Colman, 2000; Ribchester, 1992; Ribchester & Barry, 1994). In broad terms, competition occurs when more than one individual (in this case, more than one axon) is capable of having the same fate (e.g., sole occupation of a neuromuscular junction), and the probability of having that fate is related inversely to the number of such individuals. The point of defining competition so broadly is to emphasize that competition does not imply what kind of mechanism drives the outcome; even lotteries, where winners are picked by random, are competitions. Synapse elimination occurring on muscle fiber cells or cerebellar Purkinje cells is thought to be competitive because there is always only one axon remaining at the completion of the process, and therefore more than one axon cannot share the same fate.

Importantly, which particular axon is maintained does not seem to be preordained. There is no evidence of an extensive molecular specificity that uniquely matches each motor axon to an exclusive subset of muscle fibers or each climbing fiber to a matching set of Purkinje cells. Moreover, if there were some molecular blueprint, one might expect some stereotypy in that pattern between the same muscle in different individuals. However, painstaking axon tracing of all the motor units in a single muscle has revealed a complete lack of similarity in the organization of axons in many instantiations of the identical muscle (including in the left and right side of the same animal), arguing that no molecular patterning is establishing the particular wiring diagram. But if it is a competition that explains the variable outcomes, how is this competition being driven? Competitive mechanisms range from situations where the contestants interact with each other directly (e.g., a sumo wrestling match) to mechanisms where the contestants have little or nothing to do with each other, and a third party (a judge) decides the outcome (e.g., competition for a Pulitzer Prize). Evidence in the neuromuscular system suggests that synaptic competition may be more akin to the latter alternative, with the muscle fiber playing the role of judge.

Neuromuscular System

In 1970, Paul Redfern (1970) published the first physiological report of synapse elimination. He found that rat diaphragm muscle fibers were innervated by several motor neurons in the first postnatal week, but this multiple innervation was short lived; by two weeks of age, all muscle fibers were singly innervated (Fig. 19.1). At the time, he suggested that the extra innervation may be explained by the presence of motor neurons that project to a muscle in early life but subsequently undergo *cell death*. A few years later, this idea was shown to be incorrect when the tension elicited by activating single motor axons was shown to drop precipitously over the same period of early postnatal life, indicating that synapse elimination was accompanied by motor unit branch trimming rather than wholesale motor neuron loss (an event that occurs in the prenatal period) (Brown et al., 1976). Brown and colleagues also made the important point that because all neuromuscular junctions ended up with exactly one innervating axon, the elimination process was likely explained by interaxonal competition—otherwise all axons should leave a neuromuscular junction, or more than one converging axon should persist into adulthood. These two seminal reports stimulated many investigators to seek an understanding of the underlying mechanisms. Much of this effort has focused on the role of activity in synapse elimination. Many lines of evidence show that modifying neuromuscular activity has a large effect on synapse elimination (Thompson, 1985). However, it has remained unclear how activity might mediate interaxonal competition, as conflicting evidence suggested that either active (Ridge & Betz, 1984) or, surprisingly, inactive axons (Callaway, Soha, & Van Essen, 1987) are

at an advantage. At first glance, it may seem improbable that inactive axons could outcompete active ones (a result that is opposite to one discussed later, on the effects of monocular deprivation in visual system synapse elimination). Callaway et al. (1987) argued that the way muscles are used, the axons that are recruited most infrequently were the ones that in adults had the largest motor units. If their large sizes resulted from less branch trimming during development, then inactive axons might indeed have the advantage in synaptic competitions. Further complicating matters is the fact that the total number of axons innervating the muscle does not appear to change (Brown et al., 1976). This constancy implies that no individual axon's activity pattern could be considered *the* worst, because all axons maintain some neuromuscular junctions and thus all axons must outcompete other axons at some junctions.

Other experiments have questioned whether activity is even necessary for synapse elimination. For example, after reinnervation of adult muscle, evidence has been obtained showing that electrically silent inputs can displace other electrically silent inputs (Costanzo, Barry, & Ribchester, 2000). Moreover, in some cases, the presence of activity does not invariably lead to neuromuscular synapse elimination (Costanzo, Barry, & Ribchester, 1999).

As these conflicting experimental results demonstrate, the role of activity in synapse elimination is not easily summarized. One way to obtain a clearer idea of the role of activity is to view "activity" not as one phenomenon but as several different influences—for example:

- Synaptic competition may be affected by the relative efficacy (i.e., amplitude of the postsynaptic potential) of different axons attempting to drive the postsynaptic cell to threshold, with the most powerful input being favored.
- Alternatively, the firing frequency of an axon (i.e., action potentials per second) may have a negative impact, especially if the axon has a large arbor and thus insufficient resources to maintain efficacious synaptic transmission throughout its terminal branches.
- Finally, activity may affect the electrical properties of the postsynaptic cell or cell region, either encouraging synapse elimination (via postsynaptic activity) or preventing it by encouraging synapse formation (via the absence of postsynaptic activity) (Fig. 19.12).

Perhaps the most attractive hypothesis is that difference in activity between axons is critical for synapse elimination to occur. Indeed, because an axon has many synaptic release sites impinging on one postsynaptic cell, which do not seem to compete with themselves, interaxonal activity differences may be a crucial element of the competition. An experiment in which one part of a neuromuscular junction was desynchronized from the rest by silencing its acetylcholine receptors with alpha bungarotoxin (Box 19.1) examined how activity differences might give rise to synapse elimination. Focal postsynaptic silencing at one site within an otherwise normally active adult neuromuscular junction induced synapse withdrawal from the silenced site (Fig. 19.13). Postsynaptic silencing of an entire neuromuscular junction, however, did not cause synapse loss. These results suggested that synaptic activity at some synaptic sites can induce synaptic destabilization of other sites if they are not active at the same time. This view of the way activity modifies synaptic connections is related to the well-known theory of plasticity: *Hebb's postulate* (Hebb, 1949; see Chapter 52). Although Hebb argued that inputs that are consistently active when the postsynaptic cell is active are strengthened, this idea is the logical obverse: synapses that consistently fail to excite the postsynaptic cell when the cell is being activated are eliminated (Lichtman & Balice-Gordon, 1990; Stent, 1973). How might active synaptic sites destabilize silent ones? One suggestion is that active synapses generate two kinds of postsynaptic signals: one that protects them from the destabilizing effects of activity and one that punishes other inputs that are not active at the same time (Fig. 19.14). The physical basis of these protective and punishment signals remains unclear. Since neurotransmitter receptors are sometimes permeable to calcium, and the activity-induced depolarization can also raise intracellular calcium levels, one idea is that calcium signaling serves one or both of these roles.

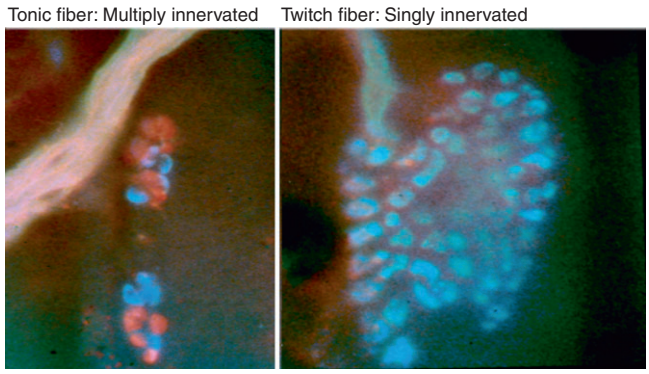

FIGURE 19.12 **Postsynaptic cells that don't fire action potentials don't undergo synapse elimination.** Photomicrographs of multiply and singly innervated snake muscle fibers. The singly innervated neuromuscular junctions are on twitch muscle fibers that have voltage-sensitive sodium channels. The multiply innervated neuromuscular junctions are found on tonic muscle fibers that do not have regenerative potentials. Labeling of different axons with different colors was accomplished by activity-dependent fluorescent labeling of axon terminals. *From Lichtman, Wilkinson, and Rich (1985).*

This view of the role of activity implies that if all axons were firing synchronously, then synapse elimination would not occur, which is exactly the conclusion reached using a regeneration model for synapse elimination (Busetto, Buffelli, Tognana, Bellico, & Cangiano, 2000). Interestingly, during the period of naturally occurring synapse elimination, there appears to be a switch from

BOX 19.1

α-BUNGAROTOXIN

A number of different dyes, stains, and markers are useful in revealing synaptic structure and function. Some of the more powerful have been borrowed from nature. Many toxins and poisons bind to specific proteins. One example is the snake toxin a-bungarotoxin (α-btx). This toxin is a constituent of the venom of a *Krait* snake of the species *bungarus*. The lethality of α-btx is the consequence of its ability to bind to the α subunits of nicotinic AChRs in skeletal muscle cells of vertebrates (with a few notable exceptions: snakes, mongooses, and hedgehogs). Because α-btx is an irreversible competitive antagonist of the AChR, its binding thus paralyzes and suffocates the prey. Researchers have taken advantage of this snake toxin to study many aspects of the AChR. For example, α-btx was used to purify AChRs from *Torpedo* membranes. Furthermore, the toxin can be conjugated to radioactive markers or to fluorescent molecules that can be seen in the microscope to stain receptors on muscle cells to determine their distribution, stability, and motility in the membrane. Because the toxin binds essentially irreversibly to the receptor in the muscle fiber membrane, receptors can be labeled once and then their behavior followed over time. This approach has provided substantial evidence about the stability of synaptic regions on muscle fibers, the lifetime of receptors in the membrane at the junctional sites, and how AChRs move within the plane of the membrane. For studies of synapse elimination in particular, the toxin also has been used to selectively inactivate some regions of a synapse by "puffing" it locally over a small region of a junction.

synchronous to asynchronous activity patterns (Buffelli, Busetto, Cangiano, & Cangiano, 2002; Personius & Balice-Gordon, 2001). It has been suggested that a gradual loss of electrical coupling among motor neurons may be the reason synapse elimination begins. This hypothesis was tested in mice that lack a gap junction protein (connexin 40) in which motor neuronal electrical coupling is reduced. In $Cx40^{-/-}$ muscles, synapse elimination was significantly accelerated, suggesting that asynchronous firing of neurons enhances synapse elimination (Personius, Chang, Mentis, O'Donovan, & Balice-Gordon, 2007).

Such an activity-based mechanism for synapse elimination would tend to pit the synchronously active synaptic terminals of one axon on a given postsynaptic cell (a *synaptic "cartel"*) against the terminals of other axons contacting the same target cell. In this way an axon's terminals on one postsynaptic cell cannot compete against themselves but rather serve as a competitive unit vying against the cartels of other axons.

Visual Cortex

Classic studies on the visual system by Hubel and Wiesel were the first to suggest that competition in fact was driving synaptic reorganization in the developing brain (Hubel & Wiesel, 1963; Hubel, Wiesel, & LeVay, 1977). In most species of young mammals, input neurons to layer IV in the visual cortex can be activated by inputs driven from both the left eye and the right eye—that is, they are driven binocularly. Subsequently, however, in many species, cortical input neurons become strongly dominated by either the right or left eye, but not both (Fig. 19.15). In agreement with this physiological result, the terminal arbors of the geniculocortical axons from the two eyes overlap in early postnatal life (Hubel et al., 1977; but see Horton & Hocking, 1996). However, with time, their projections appear to resolve into a striking pattern of alternating stripes known as *ocular dominance columns* (Fig. 19.15). This anatomical result was based on anterograde transneuronal transport of radioactive amino acid that was injected into one eye and passed through the thalamus to label the eye-specific axons in the optic radiation (Hubel et al., 1977). Despite the remarkable clarity of these stripes, their functional significance is not well understood, and in some mammals, such as rodents and new world monkeys, ocular dominance columns are absent (Horton & Adams, 2005; Livingstone, 1996).

During development, the ocular dominance columns' organization is less obvious because there is overlap in the thalamic inputs driven by the right and left eye to layer IV. Anatomically as development proceeds, each eye's columns become narrower and eventually almost nonoverlapping (especially in primates). Even though the narrowing in the widths of right and left eye ocular dominance columns is likely due to the loss of axonal branches in overlapping regions (Antonini & Stryker, 1993), this retraction of branches should not be taken to mean that the total number of thalamo-cortical synapses in layer IV is decreasing during this period. Similar to the peripheral nervous system, the axons associated with each eye elaborate many new synapses that more than compensate numerically for the lost connections of the withdrawing axons (Crowley & Katz, 2000; Erisir & Dreusicke, 2005). In other words, the process of ocular dominance column formation is one in which individual arbors lose synaptic connections with some targets but gain connections with others. Thus elimination restricts the neuronal population that is directly driven by each eye, but the synaptic

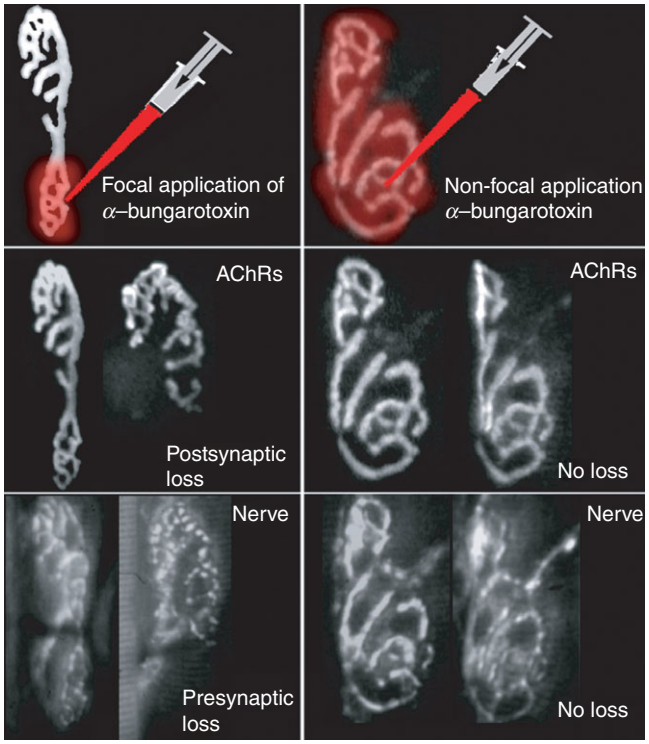

FIGURE 19.13 **An experimental test of the role of postsynaptic activity in synapse elimination.** If axons converging on the same postsynaptic cell were competing based on their efficacy in activating the postsynaptic cell, then locally blocking synaptic transmission at one axon's synaptic site should lead to its elimination and the maintenance of the other unblocked inputs. In this test, focal blockade of neuromuscular transmission was accomplished by applying saturating doses of α-bungarotoxin with a fine glass pipette (upper panels, red) to a neuromuscular junction in a living mouse. The AChR sites (middle panels) and the nerve terminals (lower panels) were viewed at the time of blockade and several times over the next few weeks. Following focal blockade (left panels), progressive loss of the nerve terminal staining and AChRs (arrows) was observed in regions previously saturated with α-bungarotoxin. However, when the entire neuromuscular junction was blocked (right panels), there was no loss. These results argue that active postsynaptic synaptic sites can cause the disassembly of inactive sites. *Adapted from Balice-Gordon and Lichtman (1994).*

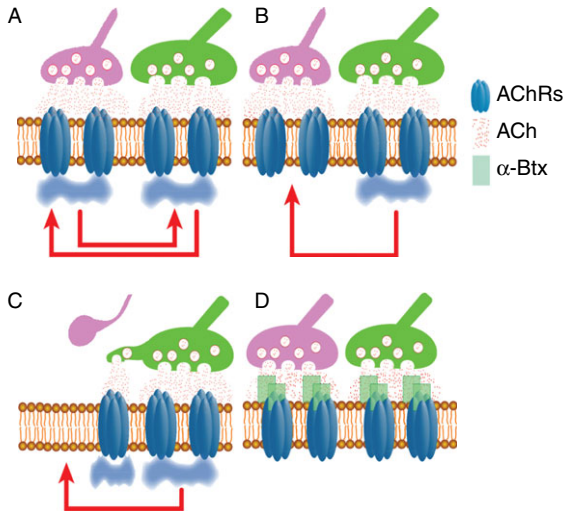

FIGURE 19.14 **Putative mechanism for a postsynaptic role in synapse elimination.** Postsynaptic receptor activation may elicit two opposing signals within a muscle fiber. One consequence of receptor activation is a "punishment" signal (here designated as red arrows) that causes destabilization of synaptic sites. Receptor activation may also generate a "protective" signal (here designated as blue clouds) that locally prohibits the punishment signals from destabilizing synapses in the vicinity of where receptor activation recently occurred. (A) When all the receptors are activated synchronously, as might occur before birth when motor neurons are electrically coupled (Personius & Balice-Gordon, 2001), there is no synaptic destabilization (due to protective blue clouds everywhere). (B) However, later in development, when two inputs are activated asynchronously, the active synaptic sites at any time point are protected (i.e., the synaptic sites beneath the active green axon are protected by a local blue cloud), whereas the asynchronously activated synapses (i.e., the synaptic sites under the pink axon) are not protected. (C) This asynchrony allows the more powerful input to destabilize the weaker one. This destabilization can lead to nerve and postsynaptic disappearance and/or nerve withdrawal, followed quickly by takeover of its former synaptic sites by the remaining axon, which would restabilize the site. (D) If all synaptic sites are inactive, as might occur with α-bungarotoxin application that inactivates nicotinic AChRs, then there are no blue clouds to protect synaptic sites, but also no red arrows to destabilize them. Thus synaptically silent and synchronously active synaptic sites (see panel A) do not undergo synapse elimination. *Idea adapted from Jennings (1994).*

addition strengthens the influence of one eye on the regions of cortex it continues to drive.

The most interesting aspect of this segregation is that the gradual removal of overlap in the two eyes' input streams leading to equally sized ocular dominance columns is not inevitable. Hubel and Wiesel showed that during a developmental *critical period* in early postnatal life, the widths of these columns can be dramatically and permanently changed by alterations in the relative amounts of visual experience in the two eyes. In particular, the outcome of the segregation can be radically skewed in favor of one eye if the activity of the other eye is decreased (e.g., by patching one eye). This monocular deprivation results in larger columns for the open eye and smaller columns for the deprived eye (Fig. 19.15). Once the critical period of sensitivity is passed (approximately the seventh postnatal week in kittens, the tenth week in ferrets, and the twentieth week in rhesus monkeys), the widths of the ocular dominance columns are fixed and no longer subject to shifts based on visual experience. Remarkably, even long-term monocular deprivation (of decades or more) apparently has little effect on the width of ocular dominance columns if the visual deprivation is begun after the critical period is over (approximately six years in humans; Keech & Kutschke, 1995). For example, in human patients in which one eye was removed for surgical reasons in adulthood or late childhood, postmortem analysis of the visual cortex indicated that eye removal has little or no effect on the width of the ocular dominance columns dominated by

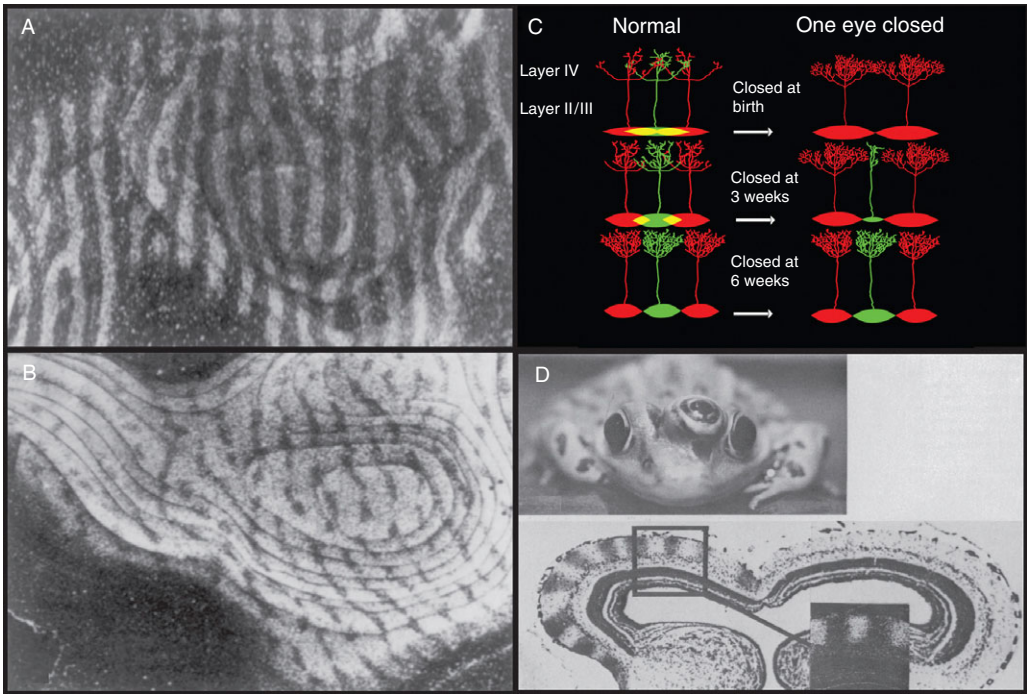

FIGURE 19.15 **Synapse elimination in the visual system.** (A) Ocular dominance columns of the neonatal monkey primary visual cortex in layer IVC, revealed by injecting [^{3}H]-proline into the vitreous of one eye. Light stripes (columns) represent sites containing the anterograde transported ^{3}H-amino acid from the injected eye. Dark regions are occupied by axons driven by the other eye. (B) Monocular deprivation by lid suture of one eye (2 weeks after birth for a period of 18 months) resulted in the shrinkage of the columns representing the deprived eye (dark stripes) and an expansion of the columns of the nondeprived eye (light stripes). (C) A schematic representation of ocular dominance column development represents the way in which a gradual segregation ocular dominance column could lead to the end of the critical period and progressively more modest effects of monocular deprivation as development ensues. (Top) At birth the afferents from the two eyes (red and green ovals) overlap completely in layer IV, and thus each eye is capable of maintaining inputs everywhere. At this young age, monocular deprivation would allow the nondeprived eye to remain in all parts of layer IV so that the entire cortex would be dominated by the red inputs. (Middle) In nondeprived animals, the two sets of afferents become progressively more segregated with age, meaning that by three weeks there would be regions of layer IV that are exclusively driven by the red or, as shown, green afferents. Once an eye's inputs are removed from a territory, it can no longer reoccupy that territory when the other eye is silenced. Hence monocular deprivation (that begins at three weeks) will spare a small strip of the inactive eye's territory (in this case the green regions). (Bottom) Once segregation is complete then monocular deprivation has no effect and the critical period is over. (D) A remarkable example showing how interactions between two eyes can cause segregation was found in frogs in which a third eye is implanted (at the tadpole stage) next to one of the eyes and projects with the native eye to the same optic tectum (ordinarily each frog tectum is monocular). After injection of H^3-proline into the normal eye, one optic tectum of a three-eyed frog shows dark and light bands strikingly similar to the ocular dominance columns observed in monkeys (D). *A–C adapted from Hubel et al. (1977); D from Constantine-Paton and Law (1978).*

the removed eye (Horton & Hocking, 1998). What might account for this dramatic change in sensitivity?

One idea is that during the critical period, thalamic afferents driven by the two eyes *compete* for control of the cortical neurons that they share temporarily. If each eye has the same average amount of activity, each ended up with similar amounts of cortical territory. However, if there were imbalances between the eyes in terms of visual experience, the outcome tipped the segregation in favor of one eye over the other. The skewing that resulted from depriving one eye of vision was due both to additional losses in the connections driven by the inactive eye (shrinking its ocular dominance columns) and to additional maintenance of the connections from the normally active nondeprived eye (maintaining its columns at the wider width it had at an earlier age) (Fig. 19.15). Ordinarily, each eye's afferents would relinquish its connections with approximately half of its postsynaptic target cells in visual cortex. Furthermore, binocular eye closure during the critical period appears to have far less serious effects than monocular occlusion. These results support the idea that synapse elimination is due to an activity-mediated competitive interaction between the connections driven by the two eyes. Because binocular deprivation has less dramatic effects on ocular dominance columns than monocular deprivation, here, as at the neuromuscular junction, active synaptic inputs seem to play a role in destabilizing inactive inputs.

Though these conclusions appear straightforward, the roles of activity in cortical refinements may need reevaluation as new investigations show that the mechanisms may be more complicated than originally imagined. In studies

of the rodent visual system, evidence suggests roles for both activity-dependent and -independent factors in developmental axonal refinements. Although mice lack ocular dominance columns, they do have a binocular cortical region that becomes progressively smaller as development proceeds. This shrinkage can be shifted with monocular deprivation during a critical period (Antonini, Fagiolini, & Stryker, 1999). This system has been used to show an important role of inhibitory circuits in both the establishment and maintenance of the critical period (Hensch, 2005). For example, deletion of the gene for glutamic acid decarboxylase, the enzyme that is responsible for the synthesis of the inhibitory neurotransmitter, GABA, prevents visual cortical refinements (Fagiolini & Hensch, 2000). Interestingly, these refinements can be reinitiated at any age by injecting GABA receptor agonists such as benzodiazepines into visual cortex. Thus intracortical inhibitory circuitry may be sufficient to trigger the opening or closure of the critical period in mice (Hensch, 2004; Hensch et al., 1998).

In mouse visual cortex, it has also been possible to study the sharpening of the retinotopic map in early postnatal life. The small receptive fields seen in adult visual cortex emerge from shrinkage of receptive field size in development (Issa, Trachtenberg, Chapman, Zahs, & Stryker, 1999). Activity plays a complex role in this sharpening; the effects of deprivation of formed vision (by lid suture) are different than the effects of pharmacological blockade or enucleation (Smith & Trachtenberg, 2007). A contralateral eye that is sensing light through a sutured lid impedes the refinement of the open eye's central projection, whereas either an open, or completely silent, contralateral eye does not. This result suggests that when inputs are synchronous (i.e., both eyes open), the activity-mediated refinements that shrink receptive fields occur more efficiently than when the same cortical neurons are receiving inputs with different activity patterns (i.e., in an animal with one open and one sutured eye). On the other hand, when one eye is entirely silent (i.e., by enucleation or pharmacological blockade), then the refinement of the open eye's inputs can still occur because in this case, there is no competing activity pattern from another eye. Thus some kinds of refinements may be mediated by cooperative interactions between the two eyes rather than competitive ones. One recent trend is that experiments that might have previously been interpreted strictly in terms of activity-mediated competition between different axons (à la Hubel and Wiesel) are now recast in terms of *homosynaptic* mechanisms of potentiation and depression or mechanisms of *synaptic homeostasis* (see Chapter 52). These newer frameworks for thinking about critical periods suggest that many different regulatory mechanisms working simultaneously may help to ensure that the right numbers and kinds of synapses survive the period of developmental refinements.

Thalamus

Separation of the inputs from the two eyes occurs twice in the visual system. Prior to the emergence of cortical ocular dominance columns, eye input to the lateral geniculate nucleus of the thalamus segregates into layers rather than columns. In embryonic cats, axon terminals of ganglion cells from the two eyes overlap extensively within the lateral geniculate nucleus before gradually segregating to form the characteristic *eye-specific* layers by birth. As in the cortex, this refinement process involves both the retraction of axonal branches from inappropriate regions of the geniculate nucleus and the elaboration of processes within the correct eye layer (Shatz, 1990). Physiological studies support anatomical observations that geniculate neurons initially are driven binocularly but maintain the axonal input from only one eye at maturity (Shatz, 1990). There is also a dramatic change in the convergence of retinal ganglion cell input to thalamic neurons related to a shrinkage in receptive field size (Chen & Regehr, 2000; Tavazoie & Reid, 2000) (Fig. 19.16).

It is likely that *spontaneous activity* as opposed to actual visual experience is important in the segregation of retinogeniculate connections in the thalamus. This view is based on the fact that in cats, ferrets, and monkeys, the eye-specific layers are established well before the retina is sensitive to light and is dependent on the spontaneous activity

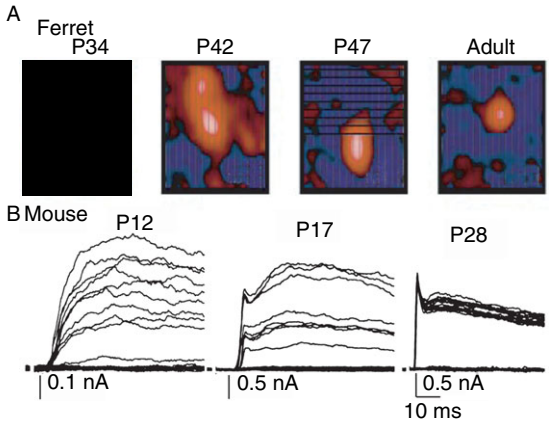

FIGURE 19.16 **Synapse elimination in the lateral geniculate nucleus of the thalamus.** (A) In the ferret lateral geniculate nucleus, receptive fields of geniculate neurons are larger and much more diffuse at one month of age than those receptive fields observed in adult neurons. Red regions represent the receptive field map of geniculate neurons that correspond to areas excited by bright stimuli. Note that red areas become smaller as development proceeds. The shrinkage in the receptive field is likely to result from the elimination of the convergence of multiple retinal afferents onto each geniculate neuron (B). At P12 in mouse, multiple retinogeniculate axons are recruited as stimulation intensities to the bundle of axons is increased (see also Fig. 19.1C). At P17 there are fewer steps, and after P28, only one or two inputs innervate each geniculate neuron (i.e., no steps in the evoked-synaptic currents are seen even though optic nerve stimulation is increased). *(A) Adapted from Tavazoie and Reid (2000). (B) Adapted from Chen and Regehr (2000).*

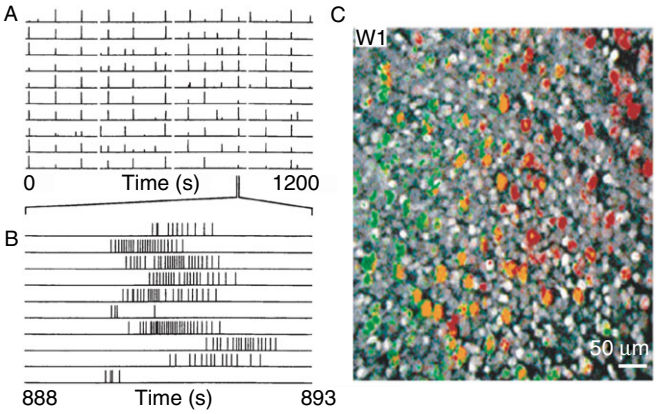

FIGURE 19.17 **Immature retinal ganglion cells show correlated patterns of activity.** (A) Using an array of extracellular recordings, rhythmic bursts of action potentials (indicated by vertical lines) are synchronized between neighboring retinal ganglion cells before eye opening in ferret. (B) Action potential bursts expanded in time scale show that each burst corresponds to ten or more action potentials. (C) Using calcium indicators it has been possible to observe waves of neuronal activity in immature retinal ganglion cells (pseudo-colored image). In this example, a wave of neuronal activity propagates through the retina. Pseudo-colored cells indicating the temporal firing pattern of retinal ganglion neurons; cells in green fire before yellow ones, and lastly red cells. *(A, B) from Meister, Wong, Baylor, and Shatz (1991). (C) from Wong (1999).*

of these inputs. What information may be contained in the spontaneous activity patterns of immature retinas that could lead to eye-specific lamination? Electrophysiological recordings and Ca^{++} imaging studies demonstrate that each immature retina generates correlated propagating *waves* (Fig. 19.17), which have no preferred direction of propagation and that occur periodically, about once a minute. It is possible that retinal waves contain temporal and spatial cues that guide activity-dependent refinement of retinogeniculate connections. For example, because waves are generated independently in each retina, activities from the two eyes are unlikely to be coincident, while nearby retinal ganglion cells in the same eye would tend to have similar spontaneous activity patterns. Asynchrony between the inputs of the two eyes could account for the segregation of inputs into different eye-specific layers in the thalamus. Since ocular dominance column formation is initiated before birth, the spontaneous patterns of activity from the two eyes could be responsible for the eye-specific pathways throughout the visual system. Moreover, because the waves ensure that nearby retinal ganglion cells are better synchronized than more distant cells, geniculate neurons are able to gauge neighbor relationships in the retina by their sequential activation. This feature could be useful for refinements of the retinotopic map in both thalamus and cortex. Pharmacological blockade of retinal waves during the period of eye-specific segregation prevents the emergence of these layers, suggesting that activity from the retinas is involved (Wong, 1999). However, these activity patterns must be only part of the story: the laminar organization of the lateral geniculate is stereotyped from animal to animal, suggesting that other developmental mechanisms are also at play.

Cerebellum

A particularly clear example of synapse elimination in the developing CNS is the *climbing fiber input* onto cerebellar Purkinje cells. Climbing fibers are the terminals of the axons arriving from inferior olive neurons that form strong synaptic connections to Purkinje cells. In adults only one climbing fiber innervates each Purkinje cell. That input might contain 500 synaptic boutons that tightly invest the large ascending proximal dendrite and its major branches. Immature climbing fibers, on the other hand, form fewer synapses, mostly on the Purkinje cell soma, and many climbing fibers project to each Purkinje cell in the first postnatal week (in rodents). The transition from multiple innervation to single innervation of individual Purkinje cells occurs at the same time there is a change in the number of Purkinje cells innervated by each climbing fiber. This "neural unit" shrinkage is seemingly quite analogous to the reduction in the size of motor units in the peripheral nervous system. Thus one olivocerebellar axon may give rise to branches that innervate more than 100 Purkinje cells during the first postnatal week, but over the next several weeks its projection is trimmed to only about 7 Purkinje cells (Fig. 19.18), albeit these connections are much more powerful.

It has long been appreciated that the loss of climbing fiber inputs depends on the presence of parallel fiber innervation from granule cells of the distal part of the Purkinje cell arbor. Elimination of granule cell inputs to Purkinje cells by X irradiation, viral infection, or in mutants such as *reeler*, *weaver*, and *staggerer* results in a higher incidence of Purkinje cells that are multiply innervated by climbing fibers in adulthood. Some studies suggest that the activity of the parallel fiber input is the important parameter. Perturbation of activity along the parallel fiber–Purkinje cell pathway in mGluR1 and GluRδ2 knockout mice or application of NMDA receptor antagonists all inhibit the elimination of climbing fibers (Hashimoto & Kano, 2005). In addition, disruption of one calcium binding kinase (PKC gamma) appears to selectively prevent climbing fiber elimination (Hashimoto & Kano, 2005). Although the mechanism by which this kinase alters synapse elimination is not known, these animals recently have been shown to have a profound deficit in vestibulo-ocular reflex (VOR) motor learning but not other kinds of cerebellar learning (Kimpo & Raymond, 2007). These results imply that synapse elimination may be important in generating the circuitry for some kinds of adult learning. As we will mention later, however, synapse elimination itself may be a form of learning.

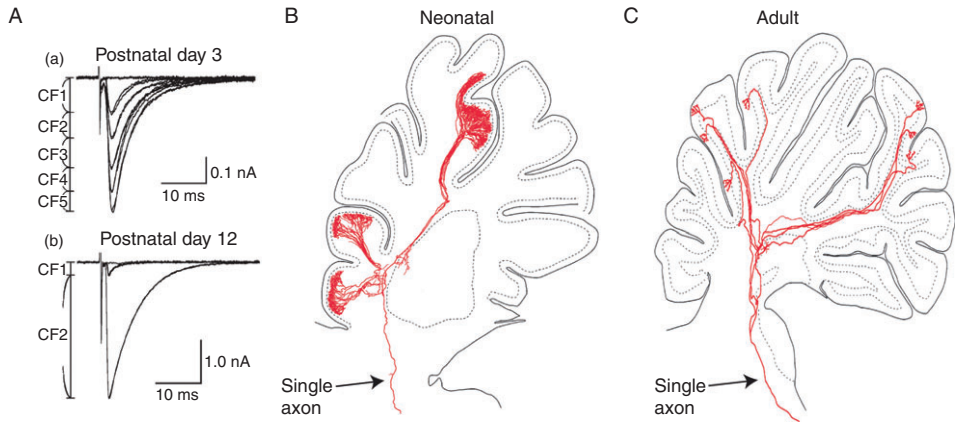

FIGURE 19.18 **Synapse elimination and axonal pruning of climbing fibers in the neonatal period.** (A) Recordings from Purkinje cells while olivocerebellar axons are stimulated in the inferior olive show functional evidence of synapse elimination. At birth, each Purkinje cell is innervated by several different climbing fibers, and as the strength of stimulation is increased, additional inputs are recruited (compare with Figs. 19.1C and 19.15B). The average number of climbing fibers innervating each cerebellar Purkinje cell, in the rat, decreases gradually as the animal matures until most are singly innervated. (B, C) Reconstructions of the trajectory of single neonatal (B) and adult (C) olivocerebellar climbing fiber axons. Both neonatal and adult axons terminate in several separate lobules in the hemisphere. However, neonatal olivocerebellar axons have many more branches than those in adult axons and presumably innervate many more Purkinje cells than those in adult animals. After pruning is complete, each axon gives rise to ~7 climbing fibers that each singly innervates a different Purkinje cell. *(A) Adapted from Hashimoto and Kano (2003). (B, C) Modified from Sugihara (2005).*

Summary

In many parts of the central and peripheral nervous system, the divergence and convergence of synaptic circuits are decreased. A popular hypothesis, albeit still somewhat perplexing, is that neural activity differences between axons underly synapse elimination. This hypothesis has driven researchers to try many kinds of experiments to test electrical activity's role. At present, the precise way in which electrical activity exerts an influence on the synapse elimination process remains a central and unresolved question.

IS SYNAPSE ELIMINATION STRICTLY A DEVELOPMENTAL PHENOMENON?

In this chapter, we presented evidence to demonstrate that synapse elimination is a powerful force that can refine synaptic circuits in young animals, based on interneuronal competition. Is there any reason to think it is more than a strictly developmental phenomenon? The most important form of adult plasticity must certainly be memory. Might synapse elimination have something to do with memory? A number of neurobiologists, including Kandel (1967), Toulouse, Dehaene, and Changeux (1986), and Edeleman (1988), have explicitly made arguments for selection (as opposed to instruction) as potentially playing an important role in learning. The idea is that in the brain synaptic circuitry exists *a priori* for many things that may ultimately be learned, so that learning might occur by the selection of synaptic pathways that already exist rather than construction of new circuits. Although such selection could occur by increasing the strength of one set of synaptic interconnections or weakening of others, it could also occur by completely eliminating some circuits. It is important to emphasize the distinction between plasticity that alters the strengths of existing connections and the more extreme kind of plasticity, analogous to the developmental synaptic processes described here, that causes permanent eradication of an axon's input to particular postsynaptic cells.

Because postsynaptic cells appear to be the intermediary in synaptic competition leading to axonal removal (see earlier), once an axon's synaptic drive to a postsynaptic cell is removed, it can no longer have any influence on the synaptic connections of the other axons that remain connected. Complete loss of influence following synaptic disconnection is thus a plausible explanation for the finite length of critical periods. For example, once all the inputs driven by an eye deprived of vision are eliminated, return of visual experience in that eye can no longer cause a shift in ocular dominance columns if that shift is mediated via activation of postsynaptic cells. The same argument could also be made for memory. Memories have a kind of indelibility that prevents more recent unrelated memories from "overwriting" prior ones. Input elimination is an attractive means of ensuring indelibility because by eliminating competing (i.e., asynchronously firing) inputs, a circuit becomes sheltered from disruption by different activity patterns.

A model of memory based on this kind of synapse elimination, however, would require that axonal inputs continue to be eliminated in the adult brain. That critical periods in the visual system are strictly developmental can be used as an argument against the idea that these kinds of changes may underlie adult memory. On the other hand, critical periods in the visual system tend to be prolonged in proportion to their distance from the retinal

input. For example, critical periods for higher visual processing areas occur later in development than in those areas that are more proximal in the visual pathway. The loss of overlapping connections is known to occur prenatally within thalamic circuitry well before segregation in layer IV primary visual cortex, and higher anatomical levels in the visual cortex that receive input from layer IV segregate out later than layer IV. A possible explanation for this sequential crystallization of brain regions may be that synapse elimination can occur only when a cohort of synchronous inputs work together to drive the elimination of competing inputs. Such a collection of synchronously active neurons requires that the presynaptic input to these cells has itself sorted out. It also is the case that the length of the critical periods for vision are vastly longer in humans than other mammals, as is the rest of our neotenic development. For example, whereas our closest animal relatives finish the critical period for monocular deprivation by 7 months of age, in humans, monocular deprivation can affect visual acuity even in children 6 to 7 years old.

Summary

We would not like to give the impression that naturally occurring synapse elimination at developing systems is the equivalent of learning and memory. But, as neurobiologists who have studied this phenomenon and mulled these ideas over for many years, we have come to the conclusion that permanent loss of axonal input is an attractive mechanism for information storage. Whether our bias is reasonable based on the data or rather due to structural elimination of competing hypotheses from our brains, we do not know.

CHAPTER

20

Dendritic Development

Dendrites play a critical role in information processing in the nervous system as substrates for synapse formation and signal integration. Neurons have highly branched, cell type–specific dendritic arbors (or dendritic trees). The size, shape, branching pattern, and position of dendritic arbors are the main determinants of what inputs they receive and how those inputs are integrated. It is now widely recognized that dendrites develop in constant interaction with other neurons and glia. The signals from these other cells affect dendritic arbor development in different spatial domains and time scales. For instance, synaptic inputs may increase calcium influx rapidly and locally to enhance rates of branch addition and stabilization. This dynamic morphological remodeling allows neurons to modify their structure and synaptic connectivity in response to afferent inputs (Cline, 2001; Ruthazer, Akerman, & Cline, 2003; Sin, Haas, Ruthazer, & Cline, 2002). In contrast, calcium signals with slower temporal dynamics may selectively signal to the nucleus to trigger gene transcription (Dolmetsch, Pajvani, Fife, Spotts, & Greenberg, 2001; Kornhauser et al., 2002; Wu, Deisseroth, & Tsien, 2001). Such activity-induced genes can then have profound effects on dendritic arbor structure and function (Cantallops & Cline, 2008; Leslie & Nedivi, 2011; Nedivi, 1999; Nedivi, Wu, & Cline, 1998). Dendrite arbor structure and plasticity are altered under a variety of neurological disorders, including mental retardation (Bagni & Greenough, 2005; Govek et al., 2004; Na & Monteggia, 2011; Newey, Velamoor, Govek, & Van Aelst, 2005) or seizure (Nishimura, Gu, & Swann, 2011), and can be affected by exposure to drugs, including nicotine (Gonzalez, Gharbawie, Whishaw, & Kolb, 2005) and cocaine (Kolb, Gorny, Li, Samaha, & Robinson, 2003; Morrow, Elsworth, & Roth, 2005). The study of dendritic arbor development can therefore provide important insight into the cellular basis of normal brain development, as well as neurological and psychiatric disorders.

After a brief description of dendritic arbor development, we discuss four principles of dendritic development: (1) Transcriptional programs establish rudimentary dendritic morphology characteristic of distinct neuronal subclasses. (2) Extracellular cues interact with signaling pathways to sculpt dendritic morphology. (3) Coordinate sculpting of axonal and dendritic arbors leads to formation of neural circuits optimized for information processing. (4) Electrical and synaptic activity refine dendritic arbor morphology and synaptic connectivity.

Although these principles are general ones, applicable to most if not all parts of the nervous system, we illustrate each one with reference to a model system that has been useful for studying it. Thus, we highlight *Drosophila* mechanoreceptor neurons for genetic analysis, mammalian cortex for extrinsic signals, vertebrate retina for circuit formation, and *Xenopus retinotectal* system for activity-dependent structural plasticity.

DYNAMICS OF DENDRITIC ARBOR DEVELOPMENT

Dendritic arbor development requires global, arbor-wide architectural modifications (e.g., generalized arbor growth), as well as localized structural changes (e.g., sprouting and retraction of higher order branches). Some changes in dendritic arbor morphology occur rapidly in response to synaptic inputs or growth factors, whereas others occur with some time delay, secondary to new gene transcription and protein turnover.

The advent of *in vivo* time-lapse imaging has allowed the assessment of cellular events underlying the development of dendritic arbors. *In vivo* imaging of dendritic arbor development was pioneered in the 1980s by Purves and colleagues, who discovered that peripheral neurons could be imaged repeatedly in developing mice (Hume & Purves, 1981).

© 2013 Elsevier Inc. All rights reserved.

These studies revealed considerable heterogeneity in the dynamics of dendritic arbor structure and suggested that dendrite structure was affected by differences in afferent inputs to different neurons. More than a decade passed before the methods were developed to reliably label single neurons in the CNS and image their dendrites over time without damage (Wu & Cline, 1998). *In vivo* time-lapse imaging of neurons is now routine in several systems, including fish, amphibian tadpoles, *Drosophila*, and rodents, thanks to technical advances in imaging reagents and widespread use of 2-photon microscopy.

In vivo time-lapse imaging studies of developing optic tectal neurons in *Xenopus* and Zebrafish and peripheral sensory neurons in *Drosophila* demonstrate that the dendritic arbors develop through a gradual process in which branches are added and retracted rapidly (Fig. 20.1). Figure 20.1A illustrates the generalized growth of differentiating optic tectal neurons imaged in the intact *Xenopus* tadpole over three days, and Figure 20.1B shows an optic tectal neuron imaged *in vivo* over about one day, but at shorter intervals. Widespread changes in dendritic architecture are apparent when time-lapse images are collected over daily intervals or longer, while short interval imaging unveils sites of local branch dynamics and growth that contribute to the changes in structure seen at longer intervals. Many more branches are added to the arbor than are ultimately maintained, so that the net elaboration of the dendritic arbor occurs as a result of the stabilization of a tiny fraction of the newly added branches. These branches then become the substrate for further branch additions. In this way the complex arbor develops gradually as a result of concurrent and iterative branch addition, retraction, stabilization, and extension (Cline, 2001; Hua & Smith, 2004). Time-lapse imaging studies in other systems including rodent hippocampus and cortex, and chick auditory system (Dailey & Smith, 1996; Sorensen & Rubel, 2006) indicate that this plan is fundamental to dendrite development.

TRANSCRIPTIONAL CONTROL OF DENDRITE DEVELOPMENT

Studies using *Drosophila* genetics have been instrumental in the identification of core transcriptional programs that control dendrite development. The dendritic arborization (da) neurons, a group of *Drosophila* sensory neurons with a stereotyped dendritic branching pattern, have provided a useful assay system for the genetic dissection of dendrite development (Gao, Brenman, Jan, & Jan, 1999; Grueber, Jan, & Jan, 2002; Jan & Jan, 2010). Each hemisegment of the abdomen of the *Drosophila* embryo or larva has 15 da neurons that can be subdivided into four classes based on their stereotyped location and unique dendritic branching pattern (Fig. 20.2) (Grueber, Jan, & Jan, 2002; Grueber, Ye, Moore, Jan, & Jan, 2003b). Class I and II have relatively simple dendritic branching patterns and small dendritic fields, whereas class III and IV neurons have more complex dendritic branching patterns and large dendritic fields.

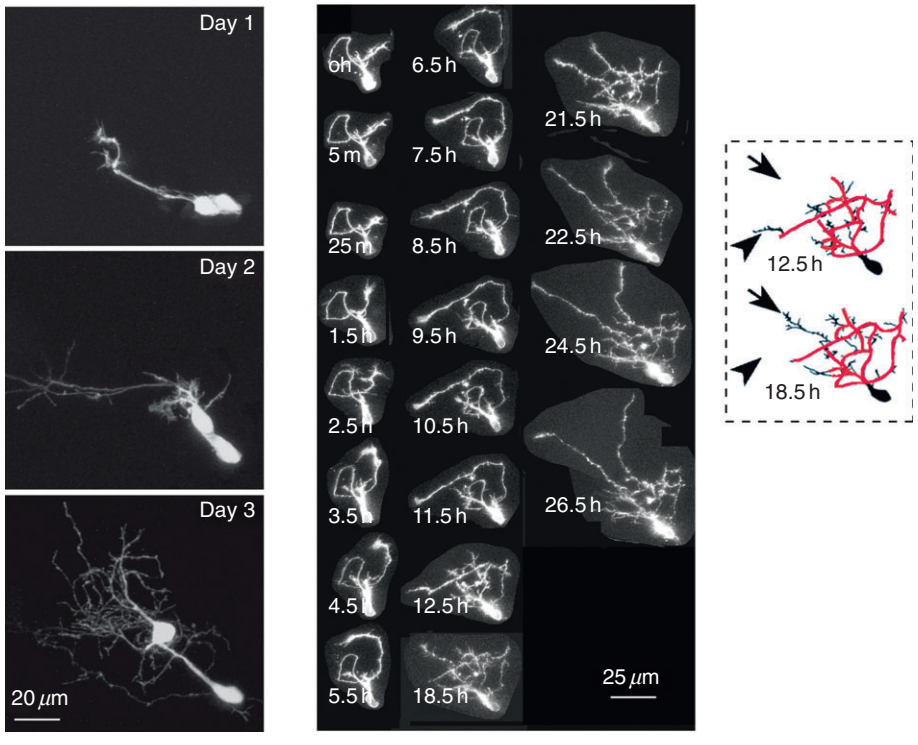

FIGURE 20.1 Time-lapse images of *Xenopus* optic tectal neurons collected *in vivo*. (A) This example shows two neighboring, newly differentiated neurons, close to the proliferative zone, imaged over a period of 3 days. These cells initially present glial-like morphologies (day 1). By the next day, these cells have elaborated complex dendritic arbors (day 2), which continue to grow to the end of imaging period (day 3). (B) Example showing an optic tectal interneuron imaged at short intervals over about 1 day. Dendritic trees develop as neurons differentiate within the tectum. Although portions of the dendritic arbor are stable over time (red outlined skeleton at 12.5 h and 18.5 h), other areas are very dynamic as dendritic branches are both added (arrows) and retracted (arrowheads) over time (in this case between 12.5 h and 18.5 h). *Source: From Bestman, Santos da Silva, and Cline (2008).*

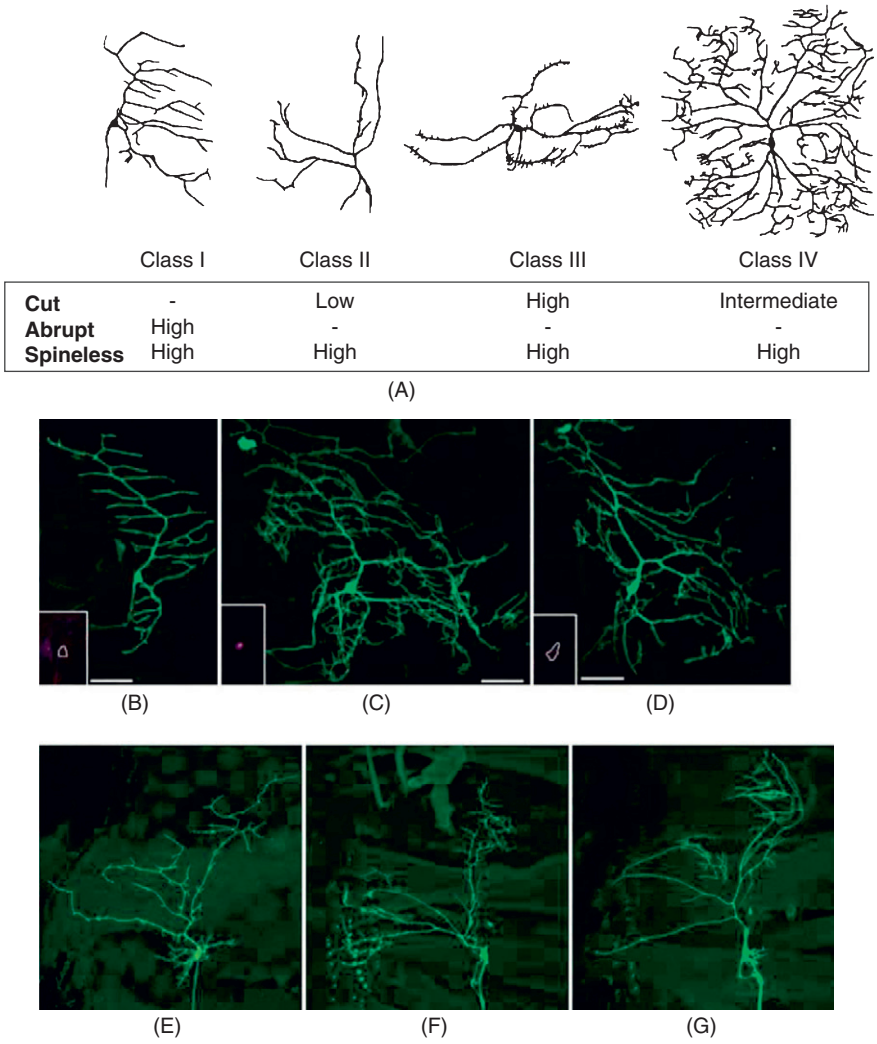

FIGURE 20.2 Transcription factors regulate the diversity and complexity of dendrites. (A) Dendrite morphologies of representative class I, II, III, and IV dendritic arborization (da) sensory neurons in the *Drosophila* PNS and a summary of the relative levels of expression of the transcription factors Cut, Abrupt, and Spineless in these neurons. (B–D). Ectopic expression of *cut* increases the dendritic complexity of class I da neurons. (B) Wild-type dendritic morphology of the ventral class I neuron vpda. Cut is normally not expressed in vpda (*inset*). (C) Ectopic expression of Cut in vpda leads to extensive dendritic outgrowth and branching. (D) Ectopic expression of CCAAT-displacement protein (CDP), a human homolog of *Drosophila cut*, also induces overbranching. (E–G) Loss of *spineless* function leads to a dramatic reduction in the dendritic diversity of different classes of da neurons. In loss-of-function *spineless* mutants, class I (E), class II (F), and class III (G) da neurons begin to resemble one another. *Source: From Parrish et al. (2007b).*

Transcription Factors Regulate Cell Type–Specific Dendritic Morphology

Expression of the gene *cut* in da neurons differs such that neurons with small and simple dendritic arbors either do not express Cut (class I neurons) or express low levels of Cut (class II), whereas neurons with more complex dendritic branching patterns and larger dendritic fields (class III and IV) express higher levels of Cut. Analysis of loss-of-function mutations and class-specific overexpression of Cut demonstrated that the level of Cut expression controls the distinct, class-specific patterns of dendritic branching (Grueber, Jan, & Jan, 2003a). Loss of Cut reduced dendrite growth and class-specific terminal branching and converted class III and IV neurons to class I and II morphologies with simpler dendritic branching patterns and smaller dendritic fields. Conversely, overexpression of Cut in neurons that express lower levels of endogenous Cut transformed branch morphology toward that seen in high-Cut expressing neurons. Furthermore, a human Cut homologue, CDP, can substitute for *Drosophila* Cut in promoting the dendritic morphology of high-Cut neurons (Fig. 20.2). Thus, Cut may function as an evolutionarily conserved regulator of neuronal-type specific dendrite morphologies.

Class III and class IV da neuron dendrites are made distinct by different combinations of Cut and another transcriptions factor Knot/Collier, which is expressed in Class IV but not in other classes of da neurons. In Class IV da neurons, Knot/Collier suppresses the tendency of Cut to induce actin-rich dendrite protrusions known as "dendritic spikes," structures unique to Class III da neurons. In contrast, Class III da neurons express high levels of Cut but not Knot/Collier—a combination that favors the formation of dendritic spikes. Thus, Knot/Collier and Cut provide an example of a combinatorial mechanism for specifying neuronal type–specific dendrite morphology (Jinushi-Nakao et al., 2007).

In contrast to Cut, Spineless (ss), the *Drosophila* homologue of the mammalian dioxin receptor, is expressed at

similar levels in all da neurons. In *ss* mutants, different classes of da neurons elaborate dendrites with similar branch numbers and complexities (Fig. 20.2), suggesting that da neurons might reside in a common "ground state" in the absence of *ss* function. Studies of the epistatic relationship between Cut and Spineless indicate that these transcription factors likely are acting in independent pathways to regulate morphogenesis of da neuron dendrites (Kim, Jan, & Jan, 2006). A comprehensive analysis of transcription factors with RNAi screens has revealed more than 70 transcription factors regulate dendritic arbor development of class I neurons in *Drosophila*. These findings suggest that complicated networks of transcriptional regulators likely regulate neuron-specific dendritic arborization patterns (Parrish, Emoto, Kim, & Jan, 2007b).

The Maintenance of Dendritic Fields

Dendrite development is a dynamic process involving both growth and retraction. Thus, selective stabilization or destabilization of branches might be one important mechanism to shape dendritic arbors. Studies of *Drosophila* class IV da neurons revealed that dendritic fields are actively maintained and there is a genetic program to maintain dendritic fields. The tumor suppressor Warts (Wts), as well as the Polycomb group of genes are required for the maintenance of the class IV da dendrites.

Drosophila has two NDR (nuclear Dbf2-related) families of kinase: Trc and Wts. Wts and its positive regulator Salvador originally were identified as tumor suppressor genes that function to coordinate cell proliferation and cell death. Loss-of-function mutants of either gene cause a progressive defect in the maintenance of the dendritic arbors, resulting in large gaps in the receptive fields (Fig. 20.3). Time-lapse studies suggest that the primary defect is in the maintenance of terminal dendrites, so Wts may normally function to stabilize these dendrites.

How are the establishment and maintenance of dendritic fields coordinated? In *Drosophila* class IV neurons, the Ste-20-related tumor suppressor kinase Hippo (Hpo) can directly phosphorylate and regulate both Trc, which functions in the establishment of dendritic tiling, and Wts, which functions in the maintenance of dendritic tiling (Emoto, Parrish, Jan, & Jan, 2006). Furthermore, *hpo* mutants have defects in both establishment and maintenance of dendritic fields. How Hpo regulates the transition from establishment to maintenance of dendritic fields remains to be determined.

What might be the downstream genes regulated by Wts? In the *Drosophila* retina, Wts regulates cell proliferation and apoptosis by phosphorylating the transcriptional coactivator Yorkie (Huang et al., 2005), but Yorkie does not appear to function in dendrite maintenance. Instead, the Polycomb genes are good candidates as targets for Wts/Sav for dendritic maintenance. The Polycomb genes regulate gene expression by repressing developmentally regulated genes. Polycomb genes can be separated into two multiprotein complexes: Polycomb repressor complex 1 (PRC 1) and PRC2. PRC2 is thought to mark the genes to be silenced by methylating histone H3, and PRC1 then comes in and blocks transcription. Mutants of several members of PRC1 and PRC2 have dendrite maintenance phenotypes very similar to that of Wts. Further, genetic and biochemical experiments suggest a functional link between Hpo/Wts signaling and the Polycomb genes, and that Polycomb genes regulate the dendritic field in part through Ultrabithorax (Ubx), one of the Hox genes in *Drosophila* (Parrish, Emoto, Jan, & Jan, 2007a).

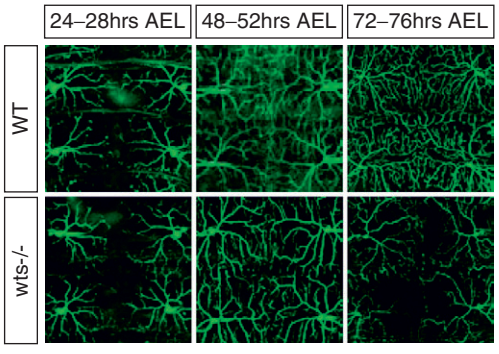

FIGURE 20.3 Dendritic fields are largely unchanged once established during development. Late-onset dendritic loss in *Drosophila warts* mutants (*wts*−/−) in late larval stages. Live images of wild-type (WT) and *wts* mutant (*wts*) dendrites of class IV da neurons at different times after egg laying (AEL). EXTRACELLULAR REGULATION OF DENDRITIC DEVELOPMENT

Regulation of Dendritic Differentiation and Dendrite Orientation

The developing cerebral cortex in mammals has been a valuable system to identify molecular mechanisms of dendritic growth control. Most excitatory cortical neurons are generated from precursors in the germinal zones lining the ventricle (Fig. 20.4). Once the cells become postmitotic, they migrate from the ventricular zone to the cortical plate. Following migration, pyramidal neurons extend an axon toward the ventricle and an apical dendrite toward the pial surface. To test the role of the local cortical environment in regulating the differentiation and guidance of nascent axons and dendrites, Polleux and Ghosh developed an *in vitro* assay in which dissociated neurons from a donor cortex were plated onto cortical slices in organotypic cultures. Neurons plated on cortical slices behave like the endogenous pyramidal neurons and

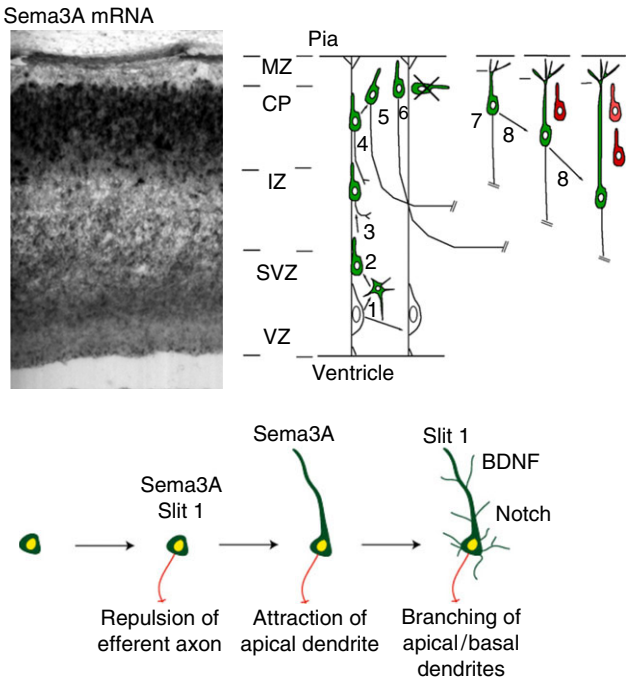

FIGURE 20.4 Upper Panel: Development of the dendritic morphology of cortical pyramidal neurons. Pyramidal neurons are generated from radial glial precursors in the dorsal telencephalon during embryonic development. Upon cell cycle exit from the ventricular zone (VZ), young post-mitotic neurons migrate along the radial glial scaffold and display a polarized morphology with a leading process directed toward the pial surface and sometimes a trailing process directed toward the ventricle. The leading process later becomes the apical dendrite. The trailing process of some neurons (but not all) develops into an axon that grows toward the intermediate zone (IZ; the future white matter) once cells reach the cortical plate (CP). Upon reaching the top of the cortical plate, postmitotic neurons detach from the radial glial processes and have to maintain their apical dendrite orientation toward the pial surface and axon outgrowth orientation toward the ventricle, which appears to be regulated by Sema3A, which acts as a chemoattractant for the apical dendrite and a chemorepellant for the axon. Adapted from Polleux and Ghosh (2008). Lower Panel: A model of how sequential action of extracellular factors might specify cortical neuron morphology. A newly postmitotic neuron arrives at the cortical plate, where it encounters a gradient of Sema3A (Polleux et al., 1998), which directs the growth of the axon towards the white matter. The same gradient of Sema3A attracts the apical dendrite of the neuron toward the pial surface (Polleux et al., 2000). Other factors, such as BDNF and Notch, control the subsequent growth and branching of dendrites. *Source: Adapted from (Polleux & Ghosh, 2008).*

extend an axon toward the ventricular zone and an apical dendrite toward the pial surface. Both the oriented growth of the axon and the apical dendrite are regulated by the chemotropic signal Sema 3A, which is present at high levels near the pial surface, and acts as a chemorepellant for axons and a chemoattractant for dendrites (Polleux, Giger, Ginty, Kolodkin, & Ghosh, 1998; Polleux, Morrow, & Ghosh, 2000).

The basis of the differential response of axons and dendrites to Sema3A appears to be asymmetric targeting of sGC to the emerging dendrite, which regulates cGMP levels (Polleux et al., 2000). Inhibition of cGMP-dependent kinase by pharmacological or genetic perturbation leads to ectopic dendritic orientation (Demyanenko et al., 2005; Polleux et al., 2000). Experiments carried out in *Xenopus* spinal neurons indicate that modulation of cGMP signaling by semaphorins can convert axons into dendrites, suggesting that local control of cGMP may be important in regulation of dendritic differentiation (Nishiyama et al., 2011). In addition to cGMP signaling, the nonreceptor tyrosine kinases Fyn and Cdk5 play important roles in mediating the effects of Sema3A on cortical dendrite orientation (Morita et al., 2006; Sasaki et al., 2002).

The concept of dendritic guidance turns out to be a general one: studies in *Drosophila* show that diffusible proteins (Netrin A and B) secreted by midline cells activate a cell-surface receptor (Frazzled) to pattern dendrites of motor neurons (Furrer, Kim, Wolf, & Chiba, 2003; Huber, Kolodkin, Ginty, & Cloutier, 2003; Yu & Bargmann, 2001).

Regulation of Dendritic Growth and Branching

The growth and branching of dendrites can be influenced by a large number of extracellular signals (see Fig. 20.9). In this section we discuss how specific extracellular factors regulate the development of the dendritic tree.

Neurotrophins

Neurotrophins (NGF, BDNF, NT-3, and NT-4) exert their effects on the growth and branching of dendritic arbors through the Trk family of tyrosine kinase receptors. Experiments in which the effects of neurotrophins on dendritic growth control have been examined in slice cultures from mammalian hippocampus or cortex indicate that, in general, neurotrophins increase dendritic complexity of pyramidal neurons by increasing total dendritic length, the number of branchpoints, and/or the number of primary dendrites (Baker, Dijkhuizen, Van Pelt, & Verhaagen, 1998; McAllister, Lo, & Katz, 1995; Niblock, Brunso-Bechtold, & Riddle, 2000; Yacoubian & Lo, 2000). By contrast, BDNF injection into *Xenopus* optic tectum increases synapse density on tectal neurons without affecting dendritic arbor structure (Sanchez et al., 2006).

The complexity of neuronal dendrites is likely to be influenced by the action of multiple neurotrophic factors. For example, Osteogenic Protein-1 (OP-1), a member of the transforming growth-factor-beta (TGFβ) superfamily, increases dendritic growth and branching in dissociated embryonic cortical neurons (Le Roux, Behar, Higgins, & Charette, 1999). Insulin-like growth factor-1 (IGF-1) affects dendrite growth and branching of postnatal layer 2 cortical neurons (Niblock et al., 2000). Furthermore, insulin receptor signaling is required for visual experience–dependent enhanced dendritic arbor growth in *Xenopus*

tectal neurons (Chiu, Chen, & Cline, 2008), illustrating that neurotrophin signaling mechanisms operate broadly across evolution.

Recent work indicates that Trk receptors and most other tyrosine kinase receptors affect dendrite development through the MAP kinase and PI-3 kinase pathways, which in turn include PTEN (phosphatase and tensin homolog deleted on chromosome Ten), mTOR (mammalian Target of Rapamycin), and local protein synthesis (Chow et al., 2009; Jaworski, Spangler, Seeburg, Hoogenraad, & Sheng, 2005). In addition to control of local protein synthesis, these signaling pathways appear to influence neuronal morphology by regulating the activity of the Rho family GTPases, which mediate actin cytoskeleton dynamics and are known to induce rapid dendritic remodeling (Box 20.1; Fig. 20.5).

Slit/Robo Signaling

The Slits are a well-studied family of multifunctional guidance cues that have been shown to both repel axons and migrating cells, as well as promote elongation and branching of developing sensory axons (reviewed in Huber et al., 2003). Generally, Slits exert their effects through binding to specific members of the Roundabout, or Robo, family of receptors. Slit1, and two of the three Robo receptors, Robo1 and Robo2, are expressed in the developing cortex during the time of initial axon and dendrite differentiation. Slit proteins simultaneously repel pyramidal neuron axons and stimulate dendrite growth and branching and these effects of Slit1 are mediated by the Robo1 and 2 receptors (Whitford et al., 2002). Thus, in contrast to the guidance role that Sema3A plays in orienting apical dendrites, Slit1 acts as a more general dendrite growth and branching signal for cortical neurons.

WNT Signaling

Another illustration of the ability of individual signals to control diverse biological responses including the control of axonal and dendritic development is provided by the WNT family of secreted proteins. The WNTs are a large family of proteins initially identified as potent morphogens involved in patterning organ development in both invertebrates and vertebrates. WNTs also have been shown to regulate cell proliferation, migration, and survival (Ciani, Krylova, Smalley, Dale, & Salinas, 2004; Ciani & Salinas, 2005). WNT proteins can function as axon-guidance molecules and as target-derived signals that regulate axonal remodeling and synapse formation (Budnik & Salinas, 2011; Hall, Lucas, & Salinas, 2000; Krylova et al., 2002). WNT proteins signal through at least three different pathways. The binding of WNT proteins to Frizzled receptors results in the activation of the scaffold protein Dishevelled (Dvl). In the so-called canonical pathway, WNT proteins signal through Dvl to inhibit GSK3-β a serine/threonine kinase. Inhibition of GSK3-β, in turn, activates β-catenin-mediated gene transcription. WNT proteins can also signal through Dvl to regulate Rho GTPases. Finally, WNT proteins can activate a Ca^2-dependent pathway, again through Dvl. WNT proteins induce axonal remodeling through the activation of Dvl and the subsequent inhibition of GSK3-β (Hall et al., 2000). Dvl has been shown to act locally to regulate microtubule stability by inhibiting a pool of GSK3-β through a β-catenin- and transcriptional-independent pathway (Ciani et al., 2004).

WNT proteins control dendritic arborization of hippocampal neurons (Rosso, Sussman, Wynshaw-Boris, & Salinas, 2005). Salinas and colleagues have found that *Wnt7b* is expressed in the mouse hippocampus and induces dendritic arborization of hippocampal neurons during development. This effect is mimicked by the expression of DVL. Importantly, analyses of the *Dvl1* mutant mouse revealed that DVL1 is crucial for dendrite development, as hippocampal neurons developed shorter and less complex dendrites in the mutant than in the wild-type. A dominant-negative β-catenin does not block DVL function in dendrites, suggesting that the WNT canonical pathway is not involved. In this case WNT7B and DVL signal through a noncanonical pathway in which the small GTPase Rac, but not Rho, is involved. First, endogenous DVL associates with Rac but not Rho in hippocampal neurons. Second, WNT7B or expression of DVL activates Rac in hippocampal neurons. Last, expression of a dominant- negative Rac blocks DVL function in dendrites.

Inhibition of the WNT pathway by SFRP1 (a secreted antagonist of WNT proteins) decreases Rac activation by WNT7B and blocks the effect of WNT7B in dendrite development (Rosso et al., 2005). Rosso et al. also report that WNT7B and DVL activate JNK, a downstream effector of Rac. Inhibition of JNK blocks DVL function in dendrites, whereas pharmacological activation of JNK enhances dendrite development. It remains to be determined whether JNK acts downstream of Rac, or whether the WNT–DVL pathway regulates Rac and JNK independently. Although Rho GTPases

FIGURE 20.5 Visual experience regulates dendritic growth through Rho, Rac, and Cdc42. (A) Visual stimulation over a 4-hour period increases the rate of dendrite growth in optic tectal neurons from *Xenopus*. Expression of constitutively active (CA) RhoA, dominant negative (DN) Rac, or DN Cdc42 affects specific aspects of dynamic dendritic arbor growth, as shown in the images of GFP-expressing tectal neurons collected *in vivo*. As summarized in the diagram on the right, visual stimulation, acting through glutamate receptors, triggers enhanced dendrite growth by regulating the Rho GTPases. are well-known modulators of dendrite development and maintenance (see Box 20.1), the mechanisms by which extracellular factors modulate these molecules during dendrite morphogenesis remains poorly understood. The findings reported by Rosso et al. (2005) demonstrate that DVL functions as a link between WNT factors and Rho GTPases in dendrites, and they reveal a novel role for JNK in dendrite development.

Cadherins and Catenins

One of the central challenges in the study of dendritic development is to understand how extracellular cues that regulate dendritic branching are integrated with

BOX 20.1

RHO GTPASES CONTROL THE STRUCTURE OF THE DENDRITIC CYTOSKELETON

All the pathways that regulate dendritic development necessarily converge on the regulation of the cytoskeleton, which is controlled by the Rho GTPases. It is noteworthy that many, if not all, of these pathways also affect gene expression and different aspects of dendritic function, such as synaptic transmission, calcium signaling, and neuronal excitability. Such divergence of signaling from extracellular cues assures that the development of dendritic structure and function are tightly coregulated.

The dendritic cytoskeleton is composed of bundles of microtubules extending within the center of the dendritic shaft, a cortex of actin sandwiched between the microtubular bundles and the plasma membrane, and an actin matrix at the tip of dendritic processes. Fine terminal dendritic branches, or filopodia, have actin filaments as their sole cytoskeletal component (reviewed in Van Aelst and Cline (2004)). Considerable effort has been devoted to understanding the interaction between extracellular signaling events and the cytoskeleton, since these interactions are likely to be essential for the highly stereotyped and yet plastic elaboration of the dendritic arbor structure. A general scenario is emerging in which an extracellular signal interacts with a cell surface receptor that activates a cascade controlling the RhoA GTPases that, in turn, affect both the actin- and microtubule-based cytoskeleton in dendrites (Newey et al., 2005). The significance of these Rho GTPase regulatory molecules for dendritic morphogenesis is perhaps best illustrated by the fact that the abnormal development of dendritic trees, a hallmark of several different types of mental retardation, is at least in part caused by deficient signaling via Rho GTPases (Govek, Newey, & Van Aelst, 2005).

The Rho GTPases regulate the cytoskeleton in all cell types, but the elaborate and plastic structure of neurons poses particularly fascinating regulatory constraints on GTPase signaling (da Silva & Dotti, 2002; Luo, 2000; Van Aelst & Cline, 2004). The Rho GTPases function as bimodal switches, cycling between inactive, GDP-bound and active, GTP-bound conformations. RhoA, Rac1, and cdc42 are arguably the best studied of the small Rho GTPases. These molecules regulate both actin and microtubule dynamics (Gundersen, Gomes, & Wen, 2004; Zheng, 2004), and the manipulation of their individual activities has shown that each plays a particular role in dendritic structure development (reviewed in Newey et al. (2005)). The interplay of these effects on the cytoskeleton is key in shaping the intricacy of dendritic trees.

As more refined methods are used to probe the molecular and cellular basis of structural plasticity, our understanding of the intricate web of control becomes more complete. A striking example is that of the *in vivo* dendritic arbor development of optic tectal neurons in *Xenopus*. These neurons respond to stimulation of the tadpole visual system with an increased dendritic arbor growth rate, which requires glutamate receptor activity (Sin et al., 2002). Expression of dominant negative or constitutively active forms of RhoA, Rac, and Cdc42 demonstrated the participation of the Rho GTPases in the activity-dependent enhanced dendritic arbor growth rate. Expression of dominant negative forms of Rac or Cdc42, or expression of active RhoA blocked dendritic arbor elaboration in response to visual stimulation (Li, Aizenman, & Cline, 2002; Li, Van Aelst, & Cline, 2000; Sin et al., 2002) (Fig. 20.5A). These data suggest that glutamatergic synaptic input regulates the development of dendritic arbor structure by controlling cytoskeletal dynamics and that the Rho GTPases are an interface between glutamate receptor activity and the cytoskeleton. Furthermore, these data and reports from other systems support a model in which Rac and Cdc42 activity regulate rates of terminal branch dynamics, whereas RhoA regulates extension of branches in response to activity (Ahnert-Hilger et al., 2004; Hayashi, Ohshima, & Mikoshiba, 2002; Lee, Winter, Martícke, Lee, & Luo, 2000; Li et al., 2000, 2002; Nakayama, Harms, & Luo, 2000; Ng et al., 2002; Pilpel & Segal, 2004; Ruchhoeft, Ohnuma, McNeill, Holt, & Harris, 1999; Scott, Reuter, & Luo, 2003; Sin et al., 2002; Wong, Faulkner-Jones, Sanes, & Wong, 2000).

Branch formation requires the regulation of local cortical actin dynamics to create protrusive forces that allow filopodial sprouting (Luo, 2000). Time-lapse imaging indicates that filopodia are extremely dynamic, consistent with the

BOX 20.1 (*cont'd*)

rapid assembly and disassembly of actin filaments (Hossain, Hewapathirane, & Haas, 2011). The stabilization of filopodia and their extension as branches likely depend on their invasion by microtubules. Although the invasion of filopodia by microtubules is a key regulatory event in dendritic arbor development, the mechanisms regulating this process are unknown. Microtubules generate the mechanical forces necessary for branch elongation and can serve as tracks for the delivery of new membrane as branches extend (Horton & Ehlers, 2003, 2004), as well as transport of ribonucleoprotein (RNP) granules that regulate local protein synthesis (Bagni & Greenough, 2005). A close interplay between actin and microtubules is fundamental for the cellular events leading to changes in dendritic architecture. Importantly, in nonneuronal cells, the activity of Rho GTPases not only induces changes in both actin and microtubules but is also itself modified by alterations in the dynamics of the two cytoskeletons, thus serving as the regulator for the interplay between actin and microtubules (Etienne-Manneville, 2004; Fukata, Nakagawa, & Kaibuchi, 2003; Wittmann & Waterman-Storer, 2001; Zheng, 2004).

The role of RhoA in regulating the extension of branches in response to activity relies on its capacity to control microtubule stabilization (e.g., via mDia; Palazzo, Cook, Alberts, & Gundersen, 2001) and favor polymerization of cortical actin (Da Silva et al., 2003; Nobes & Hall, 1995), whereas Rac and cdc42 act on branch dynamics by regulating actin (e.g., supporting filopodial formation; Luo, 2002) and by favoring microtubular dynamics (e.g., by regulating catastrophe rates; Daub, Gevaert, Vandekerckhove, Sobel, & Hall, 2001; Kuntziger, Gavet, Manceau, Sobel, & Bornens, 2001). The description of the function of other Rho GTPases, such as that of Rnd2 in regulating branching via its effector Rapostlin (Negishi & Katoh, 2005), will help in the detailed understanding of how Rho GTPases regulate dendritic arbor development.

Rho GTPases are distributed ubiquitously throughout the neuronal cytoplasm (Govek et al., 2005), and, consequently, the activity of these proteins must be restrained in dendrites by resident upstream regulators. The link between incoming signals, for instance by activation of neurotransmitter receptors, and GTPase activity is mediated by GTPase regulatory proteins, which are particularly interesting because they are capable of integrating extracellular signaling with other signaling events relevant to neuronal structure. These include the guanine exchange factors (GEFs), which activate GTPases by favoring the substitution of GDP for GTP, and GTPase activating proteins (GAPs), which inactivate GTPases by inducing GTP hydrolysis (Bernards & Settleman, 2004; Schmidt & Hall, 2002). A rush of recent papers has examined the potential participation of several GEFs and GAPs in activity-dependent dendritic structural plasticity. GAPs can regulate dendritic development, as is exemplified by the observation that p190 RhoGAP is necessary for the dendritic remodeling that allows the shift from pyramidal to nonpyramidal morphologies in cortical cultures (Threadgill, Bobb, & Ghosh, 1997). Importantly, p190 RhoGAP is likely to exert its effect in an activity-dependent manner as indicated by its importance in fear memory formation in the lateral amygdala (Lamprecht, Farb, & LeDoux, 2002).

GEFs also play important roles in regulating dendrite arbor structure. For instance, Tiam1, a Rac-GEF, is located in dendrites and in particular in spines in cortical and hippocampal neurons. Tiam is noteworthy because it associates with the NMDA receptor, is phosphorylated in a calcium- and NMDA receptor–dependent manner, and is required for dendritic arbor development (Tolias et al., 2005). This is particularly interesting if one considers that the closely related member of the Dbl family of GEFs (Rossman & Sondek, 2005), Trio, regulates the development of axons in a potentially calcium-dependent manner (Debant et al., 1996), indicating the subcellular localization within different neuronal compartments is key to the specificity of GEF function. Kalirin, another example of a RhoGEF, in this case a dual RhoA- and Rac1-GEF, has been shown to regulate the development and maintenance of dendritic arbors by modulation of RhoA and Rac activities (Penzes et al., 2001). Recruitment of this Rho GTPase regulator in dendrites depends on the ephrin-EphB transynaptic signaling pathway, another cell surface signaling system linked to the actin cytoskeleton regulatory machinery. EphrinB-EphB receptor signaling may coordinate pre- and postsynaptic structural and functional development (Palmer & Klein, 2003). Its activation results in the translocation of Kalirin to synaptic sites and the activation of a signaling pathway involving Rac1 and the specific downstream effector PAK (Penzes et al., 2003). One intriguing possibility is that the Ephrin-EphR signaling could be coordinated with regulation of NMDA receptor distribution and calcium-permeability in postsynaptic sites (Dalva et al., 2000; Takasu, Dalva, Zigmond, & Greenberg, 2002). This kind of crosstalk between proteins involved in cell–cell contact and neurotransmitter receptors provides evidence for coregulation of development of dendritic arbor structure and synaptic communication.

Ca^2 activity-dependent signals. A potential clue comes from recent results exploring the role of β-catenin and cadherins in dendritic branching (Yu & Malenka, 2003). Overexpression of β-catenin (and other members of the cadherin/catenin complex) enhances dendritic arborization, whereas sequestering endogenous β-catenin causes a decrease in dendritic branching. Importantly, the authors show that blocking β-catenin prevents the enhancement of dendritic morphogenesis caused by neuronal depolarization. Furthermore, the release of secreted WNT, which occurs during normal neuronal development, is enhanced by manipulations that mimic increased activity, and WNTs contribute to the effects of neural activity on dendritic arborization. These results indicate that β-catenin is an important mediator of dendritic morphogenesis and that WNT β-catenin signaling is likely to be important during critical stages of dendritic development (Yu & Malenka, 2003).

These observations are reinforced by the recent demonstration that another class of cadherins (*Celsr1–3*) regulates dendritic branching of cortical pyramidal neurons (Shima, Kengaku, Hirano, Takeichi, & Uemura, 2004). This class of cadherins has been identified in vertebrates as orthologs of *flamingo*, a gene previously implicated in the control of dendritic development in *Drosophila* (Gao, Kohwi, Brenman, Jan, & Jan, 2000). Shima et al. (2004) combined loss-of-function techniques including RNAi-mediated gene silencing in single neurons using biolistic-delivery in P8 organotypic slice cultures to demonstrate that knocking-down *Celsr2* expression in both layer 5 pyramidal neurons and Purkinje cerebellar neurons significantly reduces dendritic branching (Shima et al., 2004). Furthermore, using the same technique, Shima et al. performed a structure-function analysis demonstrating that these effects of *Celsr2* on dendritic branching require the integrity of a site on the extracellular portion outside the cadherin-domain as well as a portion of the intracellular domain called the EGF-HRM region. These results indicate that cadherins play an important role in the control of dendritic complexity.

DENDRITIC DEVELOPMENT AND CIRCUIT FORMATION IN MAMMALIAN RETINA

Why are dendrites so elaborately patterned? A main reason is that their form underlies their function, and their function can be quite complex. The size, shape, branching pattern, and position of dendritic arbors are main determinants of what inputs they receive and how those inputs are integrated. These relationships have been demonstrated in many regions of the nervous system of both vertebrates and invertebrates. Here, to exemplify the relationship between dendritic development and circuit function, we focus on the vertebrate retina.

Retinal circuitry is described in Chapter 26, and summarized in Figure 26.2. Briefly, light excites photoreceptors, which form synapses on dendrites of bipolar cells; the axons of these cells form synapses on retinal ganglion cells (RGCs), whose axons send information to the brain. Horizontal cells and amacrine cells mediate lateral interactions. Complexity in this seemingly simple circuit arises from the existence of multiple subtypes of each main cell type—at least 12, 30, and 20 subtypes of bipolar, amacrine cells, and retinal ganglion cells, respectively, in mammals, along with several photoreceptor subtypes (red, blue, and green cones plus rods in humans) and 2–4 horizontal cell types in most species (but only one in mice). The synapses these cells make and receive are highly specific and the circuits they form are complex. As development proceeds, the dendrites of RGCs and amacrine cells and axons of bipolar cells extend to form the inner plexiform layer through a sequence of intercellular interactions (Godinho et al., 2005; Mumm et al., 2006). We will describe two main features of dendritic development, termed laminar and lateral specificity, that help explain how intrinsic and extrinsic factors regulate the development of retinal neuronal dendrites into circuits. We also mention studies from *Drosophila* da neurons, introduced above, in which similar phenomena have been studied in greater molecular depth.

LAMINAR SPECIFICITY IN THE INNER PLEXIFORM LAYER

The inner plexiform layer (IPL) is divided into a series of at least 10 narrow, parallel sublaminae, with arbors of individual RGCs confined to just one (monostratified) or two (bistratified) of the sublaminae. Distinct RGC subtypes display distinct sublaminar patterns. Likewise, axons of bipolar cells and processes of amacrine cells (amacrine cell processes both make and receive synapses but are generally called dendrites) are also confined to few sublaminae in subtype-specific patterns. Thus, the laminar restriction of dendrites and axons in the IPL is a main determinant of synaptic connectivity, and therefore the visual features to which subsets of RGC respond. For example, dendrites of RGCs that respond to decreases and increases in light intensity (so-called OFF and ON cells) are restricted to the outer and inner halves of the IPL, respectively, where they receive synapses from the specific subsets of interneurons that endow them with these response properties (Famiglietti & Kolb, 1976; Roska & Werblin, 2001).

How does laminar specificity arise? Most IPL synapses form prior to visual experience, though they may be modified by electrical activity (see below). An appealingly

simple idea is that expression of a homophilic adhesion molecule by pre- and postsynaptic partners, perhaps as a consequence of their cell autonomous differentiation programs, could match them to each other. In chick embryos, four closely related transmembrance recognition molecules of the immununoglobulin superfamily—Dscam, DscamL, Sidekick-1, and Sidekick-2—appear to play such roles. They are expressed by nonoverlapping subsets of bipolar, amacrine, and retinal ganglion cells that form synapses in distinct IPL sublaminae (Figure 20.6). Each of the four proteins is concentrated within the appropriate sublaminae and each mediates homophilic adhesion. Ectopic expression of any one of them in small groups of cells redirects their dendritic processes to the sublamina in which that immununoglobulin superfamily is most prominent. Conversely, when expression of any of the four is decreased, with interfering RNAs, the processes wander beyond their appropriate sublaminae (Yamagata & Sanes, 2008; 2010; Yamagata, Weiner, & Sanes, 2002). Together, these results suggest the existence of an "Ig superfamily code" for laminar specificity in retina. Genetic studies indicate that Dscams and Sidekicks also mediate laminar specificity in mouse retina (Fuerst, Harris, Johnson, & Burgess, 2010; Yamagata & Sanes, 2011), although the situation is complicated by the fact that Dscams (but not Sidekicks) also act as repellents implicated in dendritic patterning in the orthogonal plane (Fuerst, Koizumi, Masland, & Burgess, 2008; Fuerst et al., 2009; see below).

Recent studies have implicated the semaphorins in determining how particular connections come to occupy specific positions. The semaphorins are a diverse set of transmembrane and secreted ligands that signal through receptors of the plexin and neuropilin families. As noted above, the semaphorins had already been implicated in sculpting dendritic arbors of cortical neurons. Retinas from mice lacking various combinations of receptors and/or ligands have mistargetted arbors (Matsuoka et al., 2011a, 2011b). Clearly the codes have yet to be fully broken, but Dscams, Sidekicks, and Semaphorins account for only a fraction of the laminar choices that retinal axons make. However, an attractive model is that cues such as Semaphorins and Plexins help place arbors in appropriate laminar regions, where recognition molecules such as Sidekicks and Dscams further refine sublaminar patterns and promote specific connectivity among arbors that coexist within sublaminae.

Lateral Specificity in the Inner Plexiform Layer: Dendro–Dendritic Interactions Regulate the Shape and Organization of Dendritic Fields

Dendrites are highly organized within the "x-y plane" of the retina. This type of organization is very important for the function of the retinal circuit. For example, the size and shape of an RGC's arbor are prime determinants of its receptive field; the even spacing of neuronal dendrites and the degree of dendritic arbor overlap ensure uniform coverage of each part of the visual field by a full set of processing elements. Dendro–dendritic interactions have a profound influence on the size and shape of the dendritic field, as well as the spatial relationship between dendritic fields. In many areas of the nervous system, dendrites of different types of neurons are intermingled and packed into a tight space. This arrangement is not random but well organized. At least four mechanisms contribute to the orderly organization of dendritic fields: tiling, mosaicism, self-fasciculation, and self-avoidance (Fig. 20.7).

Tiling

Tiling, first discovered in mammalian retina (Wassle, Peichl, & Boycott, 1981), refers to an arrangement in which arbors of individual neurons of a single subtype overlap minimally. A leading model is that dendrites of a given neuronal class grow until they are stopped by repulsive signals from the dendrites of their neighbors, leading to an arrangement in which arbors efficiently fill a field while avoiding overlap (Grueber & Sagasti, 2010). The degree of tiling is quantified by a "coverage factor," which corresponds to the number of arbors of a given subtype a pin

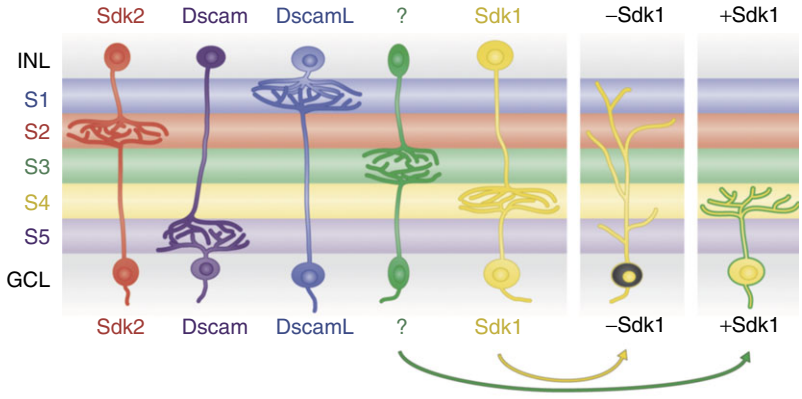

FIGURE 20.6 Expression of Sidekick 1, Sidekick 2, Dscam, and DscamL by nonoverlapping subsets of neurons in chick retina. Processes of most neurons that express each gene arborize in the same inner plexiform sublaminae, and altered expression of the gene (illustrated for Sidekick 1 in RGCs) leads to redistribution of their dendrites. *Source: From Sanes and Zipursky (2010).*

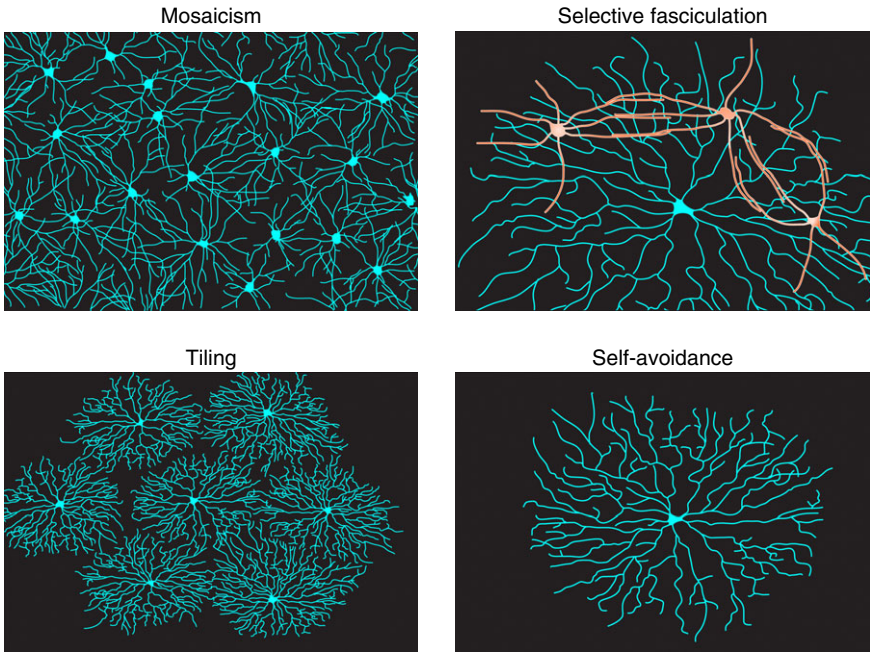

FIGURE 20.7 Four cellular processes that lead to regular arrangement of dendrites in the tangential plane of the retina's inner plexiform layer.

piercing the retina vertically would encounter. Thus, for perfect tiling, the coverage factor is 1.0. Dendrites of a few RGC subsets form tiled arrays in this sense (Dacey, 1993), as do the axonal arbors of many classes of bipolar cells (Wassle, Puller, Muller, & Haverkamp, 2009), but in fact dendrites of most RGC and amacrine subtypes do not tile: their coverage factors are significantly >1 and range up to >30 (Devries & Baylor, 1997; Peichl & Wassle, 1979). Thus, for these cells, regulation of dendritic size and control of dendritic overlap must arise from other mechanisms. One such mechanism is mosaicism (discussed below).

Tiling requires some cell surface recognition molecules to mediate the homotypic repulsion between neurons of the same type. Although the signal(s) that mediate vertebrate tiling behavior remain to be identified, studies in *Drosophila* and *C. elegans* have shown that the evolutionarily conserved protein kinase Tricornered (Trc) and the putative adaptor protein Furry (Fry), are important components of the intracellular signaling cascade involved in tiling (Emoto et al., 2004; Gallegos & Bargmann, 2004). In *trc* or *fry* mutants, dendrites no longer show their characteristic turning or retracting response when they encounter dendrites of the same type of neuron. In the mutants, unlike in the wild-type, there is extensive overlap of dendrites between adjacent neurons of the same kind. As a result, the mutant neurons have enlarged dendritic fields (Emoto et al., 2004).

Mosaicism

Neurons of most retinal subtypes are spaced more evenly than would be expected by chance alone. This regularity can be measured as the reduced probability of finding two cells of a single type near each other; the presence of an "exclusion zone" defines and characterizes the so-called "mosaic" arrangement (Eglen, 2006; Novelli, Resta, & Galli-Resta, 2005; Wassle & Riemann, 1978). Even in the absence of tiling, mosaics can help distribute each cell type evenly across the retina, thus optimizing dendritic coverage. Remarkably, mosaics are independent of each other; while a neuron of one subtype is unlikely to be adjacent to another of the same subtype, there is no restriction on its spatial relationship to neighboring neurons of other subtypes (Rockhill, Euler, & Masland, 2000), suggesting that molecular cues expressed by specific subtypes pattern mosaics by mediating homotypic (within-subtype) short-range repulsive interactions. Recently, a transmembrane protein called MEGF10 was found to mediate homotypic repulsive interactions critical for mosaic spacing of two interneuronal subtypes that occupy distinct cellular strata: horizontal cells and starburst amacrine cells (Kay & Sanes, 2011).

Selective Fasciculation

In some cases, dendrites of a particular neuronal subtype not only overlap, but they fasciculate. These associations presumably augment the specificity of the synapses that pass information laterally through the retina—for example, the electrical synapses that interconnect horizontal cells and the chemical synapses that interconnect starburst amacrine cells. Numerous cell adhesion molecules have been identified that promote fasciculation in other systems, and several are expressed by subsets of retinal neurons, but none has so far been shown to function in the IPL. On the other hand, the Dscams, mentioned above

as mediators of laminar specificity, appear to have a separate role as modulaters of fasciculation in mouse retina. Intriguingly, their role is a negative one; in their absence, neurites hyperfasciculate, leading to loss of selectivity and formation of large bundles that disrupt tiling and mosaicism (Fuerst et al., 2008, 2009). Thus, the selectivity of lateral interactions appears to require a proper balance between attractive and repellent interactions.

Self-Avoidance

Self-avoidance is a phenomenon in which neurites of a cell can recognize and avoid other neurites emanating from the same cell, while interacting freely with neurites emanating from other, similar neurons (Grueber & Sagasti, 2010). Self-avoidance thus leads to maximal and uniform coverage of receptive or projective fields by an individual neuron, while allowing multiple neurons to share the same field. The remarkable feature of self-avoidance is that it requires endowing neurons with individual molecular identities so they can discriminate between self and nonself neurites within a subtype (Zipursky & Sanes, 2010). For example, strict self-avoidance among retinal starburst amacrine cell dendrites is what endows them with the radial shape for which they are named, yet the dendrites bundle with dendrites of other starbursts and even form numerous synapses with them (Lefebvre & Sanes, 2011). Some RGC subtypes also show dendritic self-avoidance (Montague & Friedlander, 1991).

In *Drosophila*, da neuronal dendrites show self-avoidance that is attributable to the expression of Dscam1, a member of the immunoglobulin superfamily, originally identified as an axon guidance receptor. Alternative splicing of DSCAM1 in flies can potentially generate over 38,000 isoforms (Schmucker et al., 2000). A neuron typically expresses only a couple dozen of those isoforms (Neves, Zucker, Daly, & Chess, 2004). Dscam appears to be involved in self-avoidance through isoform-specific homophilic binding (Hummel et al., 2003; Wang, Zugates, Liang, Lee, & Lee, 2002; Zhu et al., 2006) in which neurites expressing the same set of Dscam isoforms repel one another (Wojtowicz et al., 2004). Mutant da neurons devoid of Dscam exhibit dendrite bundling and a crossing-over phenotype. This self-avoidance phenotype can be rescued by expressing a randomly selected single DSCAM isoform in the neuron, suggesting that Dscam is necessary in the da neuron for their dendritic self-avoidance, but the particular isoform is not important (Hughes et al., 2007; Matthews et al., 2007; Soba et al., 2007). In mice, Dscams may also play a role in self-avoidance, but they do not have numerous isoforms, so their roles are generic; they limit interactions of neurites both within an arbor and between arbors (isoneuronally and heteroneuronally). On the other hand, a gene cluster encoding a set of >50 protocadherins does exhibit isoform diversity, homophilic specificity, and combinatorial expression, suggesting that they could act in vertebrates as Dscam1 does in flies (Zipursky & Sanes, 2010). Indeed, deletion of the 22 genes of the protocadherin gamma subcluster markedly degrades self-avoidance among dendrites of mouse starburst amacrines (Lefebvre & Sanes, 2011).

ACTIVITY-DEPENDENT DENDRITIC DEVELOPMENT

Synaptic inputs play a significant role in controlling dendritic arbor development. Synaptic communication allows pre- and postsynaptic neurons to assess potential partners within a developing circuit, to establish and strengthen optimal connections, and to prune back or eliminate suboptimal contacts. Experience-dependent effects on brain development are readily demonstrated in sensory projections where afferent input can be manipulated from the periphery. *In vivo* imaging experiments in the visual system of *Xenopus* tadpoles showed that a relatively brief 4 hour period of simulated motion stimulus results in significant increased dendritic arbor growth rate, that requires glutamatergic synaptic transmission and Rho GTPase activity (Sin et al., 2002) (Fig. 20.5). Electrophysiological recordings from tectal neurons in animals with short-term visual enhancement (STVE) indicate that the visual experience increases synaptogenesis and synapse maturation (Aizenman & Cline, 2007), promotes maturation of tectal circuitry (Pratt, Dong, & Aizenman, 2008), and increases signal to noise in visual stimulus detection (Aizenman, Akerman, Jensen, & Cline, 2003). Recently experience-dependent increases in gene transcription were shown to regulate dendritic development and visual system function (Schwartz, Schohl, & Ruthazer, 2009, 2011). Together these studies indicate that sensory inputs activate a divergent range of cellular events that cooperate to orchestrate the development of functional circuits.

THE SYNAPTOTROPHIC MODEL OF DENDRITE DEVELOPMENT

How does activity regulate dendrite development? We will address this complex question by starting at the proximal site of activity-dependent regulation: the synapse. Considerable evidence supports the Synaptotrophic model of arbor development, presented by Vaughn (Cline & Haas, 2008; Vaughn, 1989; Vaughn, Barber, & Sims, 1988), which postulates that the formation and stabilization of synaptic contacts control the elaboration of dendritic (and axonal) arbors by regulating the stabilization or retraction of dynamic branches in the arbor (Fig. 20.8).

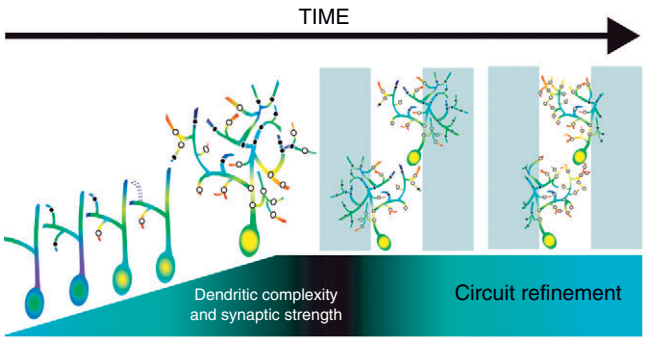

FIGURE 20.8 Schematic diagram of the effect of synaptic input on dendrite development. During dendritic development, newly generated glutamatergic synapses are mediated primarily by NMDA type glutamate receptors (black dots). With the addition of AMPA type glutamate receptors (white dots), synapses can be active at resting membrane conditions and overall synaptic strength is increased leading to dendritic branch stabilization. Dendrites with relatively weak synapses lacking AMPA receptors are retracted (dotted line). The resulting local increases in calcium influx through AMPA/NMDA containing synapses (indicated with "hot" colors) may enhance rates of branch addition and further stabilization. Newly stabilized branches become the substrate for further branch additions. It is the interplay between the dendrites and their synaptic partners that leads to selective stabilization and elaboration of branches toward appropriate target areas (gray and white bars) that is essential for circuit refinement. These processes are not just important during development, but underlie changes in circuit refinement in the mature nervous system. *Source: From Bestman et al. (2008).*

Although the greatest numerical increase in synapse density in mammalian cortex occurs after lamination has occurred and many pyramidal cells have extended dendrites (Rakic, Bourgeois, Eckenhoff, Zecevic, & Goldman-Rakic, 1986), a key observation from Vaughn's EM studies was that synapses form on arbors as the arbors elaborate (Vaughn, 1989; Vaughn et al., 1988). Indeed, whole cell recordings from newly differentiated optic tectal neurons in *Xenopus* or cortical neurons in turtle demonstrate that they have glutamatergic and GABA ergic synaptic inputs as soon as they extend their first dendrites (Blanton & Kriegstein, 1991; Wu, Malinow, & Cline, 1996).

Glutamatergic synapse formation is a multistep process in which an initial adhesion event is rapidly followed by synaptic transmission mediated by NMDA receptors. NMDA receptor activity promotes the trafficking of AMPA receptors into nascent synapses, which renders the synapses functional of resting potential (Cline, Wu, & Malinow, 1997). The Synaptotrophic hypothesis predicts that manipulations of synapse formation or synapse stabilization would affect dendritic arbor development. Adhesive events mediated by neurexin-neuroligin were recently shown to be required for tectal cell dendritic development (Chen, Tari, She, & Haas, 2010), consistent with Vaughn's idea. Time-lapse *in vivo* imaging experiments showed that blockade of NMDA or AMPA receptors or interference with their trafficking perturbs tectal cell dendritic arbor development by interfering with addition or stabilization of dendritic branches (Haas, Li, & Cline, 2006; Rajan & Cline, 1998). Genetically decreasing NMDA receptor subunit expression also disrupted dendritic arbor development in the rodent somatosensory system (Lee, Lo, & Erzurumlu, 2005). Time-lapse imaging demonstrated that blocking trafficking of AMPA receptors into developing synapses increased the rates of branch retractions in the developing dendritic arbor and increased the proportion of transient dendritic branches (Cline & Haas, 2008; Haas et al., 2006), exactly as predicted by the Synaptotrophic hypothesis, that strengthening synapses formed onto newly established dendritic branches would stabilize the branches. Similarly in the hippocampus and cortex, perturbing AMPA receptor activation or trafficking affects synapse maturation and dendrite arborization on pyramidal neurons (De Marco Garcia, Karayannis, & Fishell, 2011; Shi, Cheng, Jan, & Jan, 2004a; Shi, Cox, Wang, Jan, & Jan, 2004b), again supporting the general principle that afferent inputs control dendritic arbor development *in vivo*.

During early stages of neuronal development, GABAergic synaptic activity depolarizes neurons from their resting potential because the reversal potential for chloride is relatively positive due to the delayed expression of the KCC2 chloride transporter. In *Xenopus* neurons, premature expression of KCC2 blocked the maturation of glutamatergic synaptic inputs and indicated that depolarizing GABAergic inputs cooperate with NMDA receptors to promote AMPA receptor trafficking into developing synapses (Akerman & Cline, 2006). Premature expression of KCC2 in cortical neurons impaired dendritic arbor development (Cancedda, Fiumelli, Chen, & Poo, 2007), suggesting that depolarizing GABAergic input might affect dendritic arbor development indirectly through an effect on development of excitatory synaptic inputs. It is interesting to note that once dendritic arbors are elaborated, glutamatergic synaptic input activity and CaMKII stabilize dendritic arbor structure (Wu & Cline, 1998), suggesting that signaling cascades downstream of these events proximal to the synapse change as the neuron and circuit develop.

Recent studies provided the first evidence that inhibitory GABAergic inputs regulate dendritic arbor development. Shen, Da Silva, He, and Cline (2009) expressed a peptide in optic tectal neurons, called ICL, which interfered with the residence of $GABA_A$ receptors at synaptic sites. ICL expression selectively decreased inhibitory GABAergic, but not glutamatergic, synaptic inputs onto tectal neurons, shown by electrophysiological criteria. *In vivo* imaging experiments showed that ICL expression severely disrupted dendritic arbor development and experience-dependent structural plasticity, in striking similarity to the effect of interfering with glutamatergic

synaptic maturation (Haas et al., 2006). Further studies showed that ICL-expression in tectal neurons significantly disrupted visual information processing and visually guided behavior (Shen, McKeown, Demas, & Cline, 2011). These studies demonstrate that both excitatory and inhibitory synaptic inputs regulate dendritic arbor development, but whether similar or unique mechanisms operate under these circumstances is not yet known.

BRANCH RETRACTION AND SYNAPSE ELIMINATION

Although dendrite arbor elaboration clearly requires net branch addition and extension, both branch and synapse elimination are integral parts of dendritic arbor development. The final structure of cortical pyramidal dendrites is heavily influenced by pruning major portions of the arbor. For instance, a recent study in ferret visual cortex showed that layer 4 neurons initially form an apical dendrite, which is subsequently retracted to produce the classical stellate morphology. Furthermore, visual input is required for the pruning of the apical process (Callaway & Borrell, 2011). Another clear example of this phenomenon comes from study of the retina, where developing retinal ganglion cells transiently respond to both light on and light off events and their dendritic arbors terminate in both On and Off neuropil laminae. With normal visual experience, the bistratified dendritic arbors are pruned to On and Off laminae. Dark-rearing blocks the normal pruning of dendritic branches in retinal ganglion cells so that retinal ganglion cells remain responsive to On and Off visual stimuli (Tian & Copenhagen, 2003). In contrast to the relatively large-scale dendrite pruning mentioned above, a recent study, which combined in time-lapse imaging and subsequent serial section electron microscopic reconstruction of the imaged neuron, showed that synapse elimination is a prominent activity-dependent component of microcircuit assembly (Li, Erisir, & Cline, 2011). In this study, time-lapse *in vivo* imaging over periods of hours or days allowed identification of newly added or relatively stable dendritic branches, while the serial section EM allowed ultrastructural comparison of synaptic contacts on identified dynamic and stable branches. Although one might anticipate that new dendritic branches might have few synapses and that synapse density might increase with branch stabilization, this study showed otherwise. Surprising, newly emerged dendritic branches had a significantly higher synapse density compared to more stable branches. As dendritic branches stabilize, most synapses are eliminated and one input remains and becomes morphologically mature (Li & Cline, 2010). Furthermore, visual experience and NMDA receptor activity were required for both synapse elimination and synapse maturation. These data provide quantitative ultrastructural understanding of the activity-regulated cellular mechanisms contributing to dendritic arbor development.

CALCIUM-DEPENDENT MECHANISMS THAT MEDIATE DENDRITIC GROWTH

The effects of neuronal activity on dendritic arbor development are mediated by calcium signaling. Calcium levels in neurons are regulated by influx through voltage-sensitive calcium channels (VSCC), NMDA receptors, and calcium-permeable AMPA receptors, as well as by release of calcium from intracellular stores (Fig. 20.9). Release from internal stores principally involves calcium-induced calcium release (CICR) or activation by ligands that lead to the production of IP_3, which acts on internal stores. Two major signaling targets of elevated intracellular calcium are calcium/calmodulin dependent protein kinases (CaMKs) and mitogen-activated kinase (MAPK), which have multiple effects on dendrite development that reflect rapid and local consequences of kinase activity, as well as regulation of gene transcription through calcium-responsive transcription factors, such as CREB and CREST.

Of the CaMKs, CaMKII has been most extensively studied in relation to a role in dendritic development and function because both CaMKII isoforms, αCaMKII and βCaMKII, are present at high levels in dendrites. Most functional heteromers of CAMKII in cells include both α and β isoforms, and the α to β ratio in the heteromer regulates its association with the actin cytoskeleton and therefore its microdistribution in cells (Lisman, Schulman, & Cline, 2002). CaMKII strengthens synapses and stabilizes or restricts dendritic growth of frog tectal neurons *in vivo* and mammalian cortical neurons *in vitro* (Redmond, Oh, Hicks, Weinmaster, & Ghosh, 2000; Wu & Cline, 1998). CaMKIV is predominately localized in the nucleus, where it can respond to cytosolic calcium transients that enter the nucleus and regulate dendritic morphology through transcription events (Mauceri, Freitag, Oliveira, Bengtson, & Bading, 2011). The best-characterized target of CaMKIV is the transcription factor CREB. A noteworthy effector of CREB is CPG15, candidate plasticity gene 15 (Nedivi, 1999; Nedivi, Fieldust, Theill, & Hevron, 1996; Nedivi, Hevroni, Naot, Israeli, & Citri, 1993). CPG15 is a highly conserved neurotrophic molecule, which can promote neural survival and differentiation in mammalian systems (Putz, Harwell, & Nedivi, 2005). CPG15 enhances dendritic and axon arbor elaboration, and increases synaptogenesis and synaptic strength when expressed in *Xenopus* optic tectal cells *in vivo* (Cantallops, Haas, & Cline, 2000; Nedivi et al., 1998). Furthermore, the trafficking of GPI-linked CPG15 to the surface of axons is activity-regulated (Cantallops & Cline, 2008), suggesting that

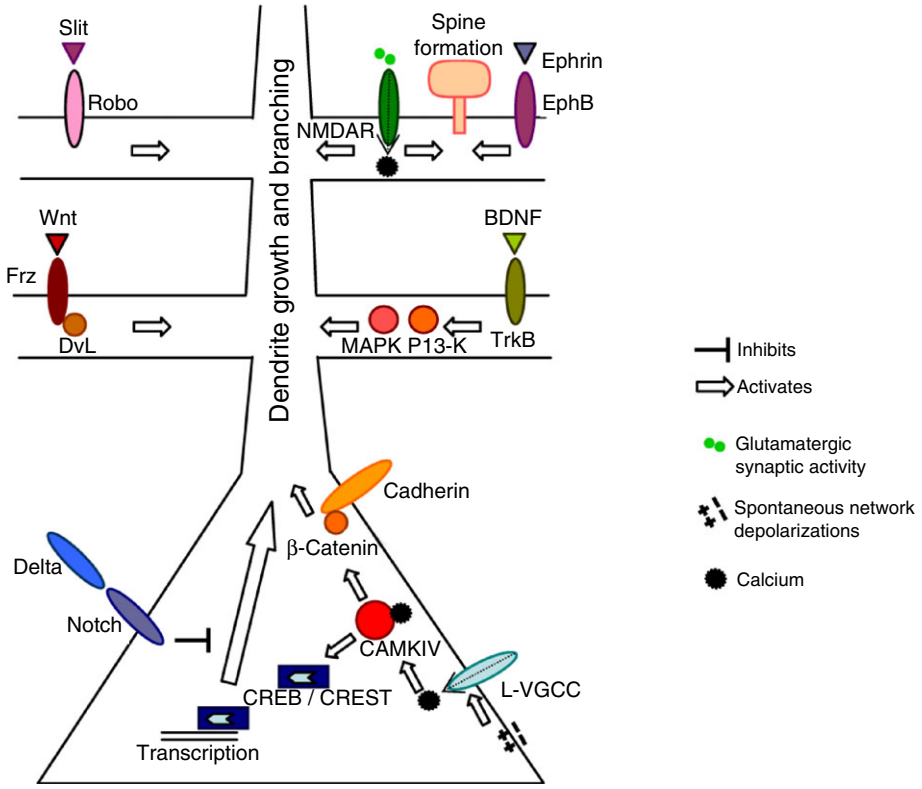

FIGURE 20.9 A summary of signaling pathways by which neuronal activity influences dendritic development. The effects of neuronal activity on dendritic development are mediated by calcium influx via voltage-gated calcium channels (VGCCs) and NMDA receptors, as well as release from internal stores. Local calcium signals act via Rho family proteins to regulate dendritic branch dynamics and stability, whereas global calcium signals recruit transcriptional mechanisms to regulate dendritic growth.

sensory activity regulates both the transcription and cellular localization of CPG15, which in turn promotes and coordinates multiple aspects of circuit development.

PROTEIN SYNTHESIS DEPENDENT REGULATION OF DENDRITE DEVELOPMENT

Protein synthesis can be regulated locally within dendrites by mRNA binding proteins, such as the fragile X mental retardation protein, FMRP, cytoplasmic polyadenylation element binding protein (CPEB), staufen, and pumilio. In general, these proteins bind specific mRNA cargo and hold them translationally silent until they are signaled to release the cargo for translational processing. The possibility that local protein synthesis in dendrites might affect neuronal morphology was first suggested from studies on material from patients with Fragile X Syndrome (Purpura, 1974), in which the spines on pyramidal cell dendrites were unusually long and thin. Work in a variety of systems has begun to elucidate the role of mRNA binding proteins in dendrite development. For instance, in *Xenopus*, *in vivo* imaging of neurons expressing dominant negative forms of CPEB showed that CPEB RNA binding and microtubule-based transport into dendrites was required for normal dendritic arbor development and visual experience–dependent structural plasticity. Furthermore, electrophysiological recordings show that cells that are deficient in CPEB function fail to integrate into the retinotectal circuit and do not respond to visual inputs (Bestman & Cline, 2008). Work in rodent visual cortex indicated that CaMKII translation was regulated by CPEB1 downstream of visual experience and NMDA receptor activity (Wells et al., 2001). Many candidate mRNA cargoes of CPEB have been identified bioinformatically. Given that CaMKII, which is just one protein that is translationally regulated by CPEB, is itself pleiotropic with respect to control of dendrite arbor development, it is clear that we must embrace the complexity of activity-dependent regulatory mechanisms controlling dendritic arbor development and circuit connectivity.

CONVERGENCE AND DIVERGENCE

A wide variety of signaling pathways participate in dendritic arbor development by regulating different downstream events such as cytoskeletal rearrangements, Ca homeostasis, and membrane cycling (Fig. 20.10). In addition, many signaling cascades diverge, for example to regulate somatic gene expression, local protein synthesis as well as the Rho GTPases. These diverging pathways ultimately result in modifications of dendritic plasticity. One example

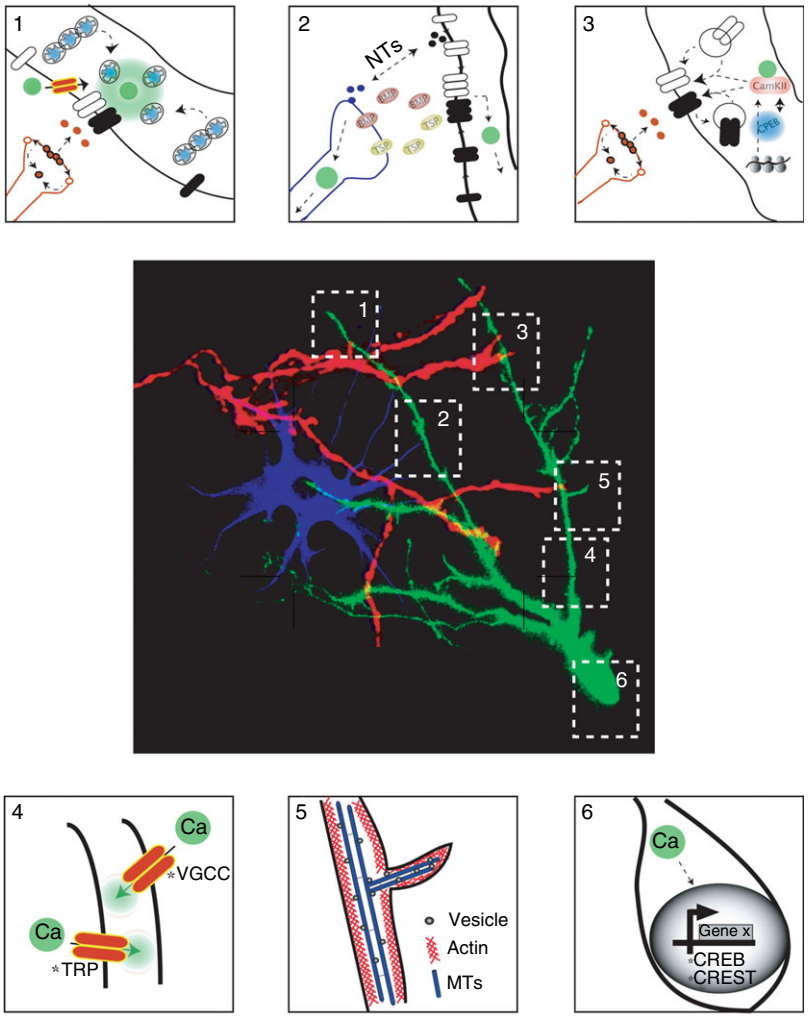

FIGURE 20.10 Summary of multiple mechanisms that influence dendritic growth and remodeling. Dendritic arbors develop within a complex environment in which they contact and receive signals from afferent axons, glial cells, and other dendrites. Several changes occur at sites of contact between axons and dendrites, marked by 1 and 3 in the image, including local changes in enzyme activity, such as CaM kinase and phosphatases, receptor trafficking, and local protein synthesis. Interactions between glia and neurons, marked by #2, include release of trophic substances that regulate synapse formation and maintenance. Process outgrowth, represented by #4 and #5, is mediated by cytoskeletal rearrangements. Finally activity-induced gene transcription, #6, can change the constellation of protein components in neurons in response to growth factors or synaptic inputs.

of divergence comes from the activation of the Ras superfamily GTPases that regulate membrane cycling downstream of neurotransmitter receptor activity. Synaptic NMDA receptors activate the Rab GTPase Rab5 (Pfeffer & Aivazian, 2004) that in turn regulates the internalization and dephosphorylation of AMPA receptors (Brown, Tran, Backos, & Esteban, 2005), an event associated with changes in dendritic structure (Ikegaya et al., 2001) and synaptic strength. Similarly, decreasing or increasing the activity of the Ras GTPase Rap1 decreases or increases, respectively, dendritic arbor elaboration *in vitro* (Chen, Wang, & Ghosh, 2005). One way Rap1 works is by regulating how calcium influx affects CREB-dependent transcription (Chen et al., 2005). Rap1 also mediates the internalization of AMPA type glutamate receptors from local synaptic sites in response to NMDA receptor signaling (Zhu, Qin, Zhao, Van Aelst, & Malinow, 2002). Since blocking glutamate receptor activity also decreases dendritic arbor development (Rajan & Cline, 1998), it is possible that Rap1 may act principally to control cell surface levels of glutamate receptors and this, in turn, affects dendritic arbor elaboration, as shown by interfering with AMPA receptor trafficking (Haas et al., 2006; Shi et al., 2004b). As with the Rho GTPases, Rap1 and the other GTPases regulating membrane cycling are at nodal points in the cascades controlling cell surface distribution of membrane proteins. For instance, Rap1 is downstream of other receptors, such as the neurotrophin receptors, plus GTPase-dependent membrane cycling regulates the cell surface distribution of signaling molecules, other than glutamate receptors. As illustrated in Figure 20.10, the pathways regulating dendritic arbor development are nonlinear and neither their regulation nor their targets are independent. Consequently, it is essential to investigate the function of these complex molecules in their normal *in vivo* context in order to dissect their endogenous functions.

CONCLUSION

Studies such as those summarized here, aided by computational approaches to map biochemical events in space and time, will ultimately lead to a complete appreciation

of the signaling pathways that regulate dendritic structural and functional plasticity. Elucidation of these pathways will reveal mechanisms by which activity can rapidly affect dendritic structure, and over more-prolonged time frames, exert profound changes in the so-called intrinsic states of the dendritic tree by modifying gene expression (Goldberg, 2004). Knowledge of these events, together with an understanding of the integrative capacity of dendrites, is essential to grasp the function of neuronal circuits and the brain.

CHAPTER

21

Early Experience and Sensitive Periods

The nervous system has evolved to cope with an environment that is in many ways largely predictable. Therefore, much of the architecture and functional properties of the brain can be specified by genetic determinants that reflect the common experience of previous generations. Most of this circuitry is established prenatally, guided by genetically determined molecular mechanisms and shaped by patterns of spontaneous impulse activity that propagate through the central nervous system (CNS) in unborn animals, as discussed in Chapters 16, 18, and 19.

Not all aspects of an animal's world are certain, however. Details of an animal's physical characteristics vary, as do habitats and social conditions. To deal with such uncertainties, the CNS maintains the capacity to modify its connections based on the interactions of an animal with its environment. Through adaptive adjustments based on use or quality of performance, the developing nervous system customizes its functional properties to the needs and environment of the individual animal with a precision that does not need to be, and sometimes cannot be, encoded in the genome.

Although the nervous system is capable of making adaptive adjustments throughout the lifetime of an animal, many neural circuits pass through a period during their development when the capacity for adjustment in response to experience is substantially greater than it is after the circuit has matured. This period is referred to as a *sensitive period* (Knudsen, 2004). During a sensitive period, information derived from experience selects particular functional properties from a range of possible properties that a circuit could adopt. If appropriate experience is not gained during a sensitive period, many circuits never attain the ability to process information in a typical fashion, and, as a result, perception or behavior may be impaired permanently.

This chapter introduces four examples of circuits that have been relatively well studied with respect to their dependence on instruction by early experience for normal development. These examples are the circuits involved in (1) song memorization in songbirds, (2) sound localization in owls, (3) binocular processing in the mammalian visual cortex, and (4) temperament in rats. Sensitive periods for language learning in humans and filial imprinting in birds are also discussed. These examples are used to illustrate the principles that govern sensitive periods, discussed at the end of the chapter.

The terms *sensitive period* and *critical period* both appear in the scientific literature to denote a period of dramatically increased plasticity during development. *Sensitive period* is the more general term. The term *critical period* was borrowed (Hubel & Wiesel, 1970) from the behavioral literature, where it emphasizes that a particular kind of experience is essential (critical) for the development of a specific capacity or behavior, such as the capacity for stereoscopic vision or for language (Box 21.1). For many neural circuits, however, experience during this especially plastic period may not be essential for the circuit to develop the capacity to function adaptively. The latter example would be a sensitive but not a critical period. Thus, while all critical periods are sensitive periods, not all sensitive periods are critical.

As you read about each of these examples, you will notice a number of recurring themes. First, as circuits that are shaped by experience during a sensitive period develop, they reach a stage when they rely on ("expect") specific spatial and temporal patterns of input in order to select a particular pattern of interconnections. These learned patterns of interconnections adjust the properties of the circuit to the sensory conditions of the individual animal. Second, the changes in the pattern of interconnections that result last for the lifetime of the animal. Third, sensitive period learning begins when the circuit is capable of processing the relevant information. This capacity requires that both excitatory and inhibitory circuitry

BOX 21.1

SENSITIVE PERIODS IN HUMANS

Many human capabilities depend critically on experience gained during early life. These capabilities range from fundamental capacities, such as stereoscopic vision, visual acuity, and binocular coordination, to high-level capacities, such as social behavior, language, and the ability to perceive forms and faces. Because in each case, specific kinds of experience during a restricted period in early life is essential for the normal development of the capacity, these periods are sometimes referred to as critical periods.

The best known and most thoroughly studied sensitive period in humans is for language (see Chapter 48). A clear relationship exists between the age of exposure to a language and the level of proficiency achieved in that language (Newport, Bavelier, & Neville, 2001). This relationship holds for the learning of both first and second languages. Acquisition of a first language has been assessed in children who have been raised in the absence of any language (feral or abused children) or, more frequently, in congenitally deaf children who have been raised without the aid of sign language. Much more data are available for people who began learning a second language at different ages. For both first and second languages, a thorough command of the language is attained by those who learn the language before 7 years of age. The degree of language proficiency that is eventually achieved decreases progressively with age of exposure and reaches adult levels by the end of adolescence.

Only certain aspects of language are affected by learning during sensitive periods (Kuhl, 2000; Newport et al., 2001). Full proficiency with grammar (the classes of words, their functions, and relations in a sentence), syntax (the way in which words are put together in a sentence), and the production and comprehension of phonetics (the speech sounds of a language) are each dependent on early exposure to language. In contrast, semantics (word meaning) and size of vocabulary are not affected by the age of exposure. Thus, sensitive periods seem to affect the formal and subtle aspects of language, whereas the capacity to learn new words and their meanings continues unabated throughout life.

Physiological measures reveal an age dependence in the way in which language is processed and represented in the brain (Dehaena et al., 1997; Weber-Fox & Neville, 1996). Various techniques have been used to assess brain activity while human subjects make perceptual judgments in language tasks. These techniques include functional magnetic resonance imaging, positron emission tomography, and event-related potentials. In normal adults, language is processed in specific areas, primarily in the left or "dominant" hemisphere. In people who have learned a second language prior to the age of 7 years, the brain areas that are involved in processing the first and second languages overlap extensively. In contrast, in people who have learned a second language later in life, the areas of the brain that are activated by the second language do not overlap, or they overlap little, with those that are activated by the first language. The brain areas activated by the second language are less lateralized to the left hemisphere and are more variable across subjects. The effect of age at the time of learning on the brain areas activated by language is far more conspicuous for tasks requiring grammatical and phonic judgments than for tasks requiring semantic judgments. Thus, consistent with the behavioral observations of the age dependence for learning grammar and phonetics, the regions of the brain that contribute to the processing of grammar and phonetics are shaped in a unique way during sensitive periods.

Detailed knowledge of the mechanisms that control sensitive periods and of the plasticity that occurs during sensitive periods will provide a basis for formulating optimal therapeutic procedures to help minimize long-term harmful effects of early abnormal experience—associated with neonatal and childhood disabilities, for example—and maximize the acquisition of normal function once normal conditions are restored. Such knowledge may also lead to improved methods of rearing and teaching normal children that take advantage of the full capacity of the central nervous system to learn from experience.

operate effectively and that the molecular mechanisms necessary to support synaptic remodeling are active. Fourth, sensitive period learning ends once an animal has received adequate experience and the neural circuit has become committed to a particular pattern of interconnections. Finally, the timing of sensitive periods can be altered by environmental conditions that deprive the animal of the necessary input or that arouse the animal in the context of the relevant experience or by manipulation of the cellular or molecular machinery that governs the plasticity. These examples of sensitive period learning highlight the dynamic interplay between genetic instruction and the profound influence of early experience in shaping the functional capacities of the mature brain.

BIRDSONG: LEARNED BY EXPERIENCE

The song of most songbirds depends on learning that occurs early in life during a sensitive period (Doupe & Kuhl, 1999; Konishi, 1985). Birdsong is a special form of vocal communication used by certain species of birds to identify neighbors, defend territories, and attract mates. Songs are distinguished from other communication sounds by their length, spectral complexity, and periodic structure—properties that give birdsong its melodic quality. The songs sung by birds are characteristic of the species (conspecific song); dialects of the species' song often reflect the geographical area in which the bird was raised (Fig. 21.1A).

Songs are passed on from one generation to the next by a combination of genetic instruction and learning. In a few species of songbirds, the influence of genetic instruction is strong, and learning plays a relatively minor role. In most, however, the role of learning is paramount. Some of these species learn new songs each year (seasonal learners), whereas others learn their songs only once early in life. In the latter case, the birds memorize their songs as juveniles, during a sensitive period.

White-crowned sparrows and zebra finches are species that memorize their songs during a sensitive period (Immelmann, 1972; Konishi, 1985). The extent of the sensitive period in each species has been determined by raising birds in acoustic isolation and then exposing them to conspecific song for brief periods in development. The effect of this experience on song learning is assessed by observing the song that the male eventually sings (in these species, only the male sings). Birds raised in acoustic isolation throughout the sensitive period sing an "isolate" song (Fig. 21.1B) that lacks the spectral and temporal complexity typical of normal song. When juvenile birds are allowed to hear conspecific song even for a few days during the sensitive period, however, they memorize that particular song and reproduce it accurately when they later learn to sing.

Song memorization in these species illustrates an important principle that pertains to most sensitive period learning: The nervous system is genetically predisposed to accept only a limited range of potential stimuli as appropriate for learning (Doupe & Kuhl, 1999). For example, juvenile birds that are allowed to hear only alien songs that differ substantially from their conspecific song develop isolate song, indicating that they reject these distinctly alien songs as models for learning. Even within the range of songs that a bird will learn, it strongly prefers a conspecific song when given a choice of several similar song types. Moreover, juveniles memorize conspecific songs rapidly, whereas they memorize slightly different alien songs only after much longer periods of experience. Thus, the circuits responsible for song memorization contain genetically determined filters that require certain spectral and temporal features before the stimulus is accepted as

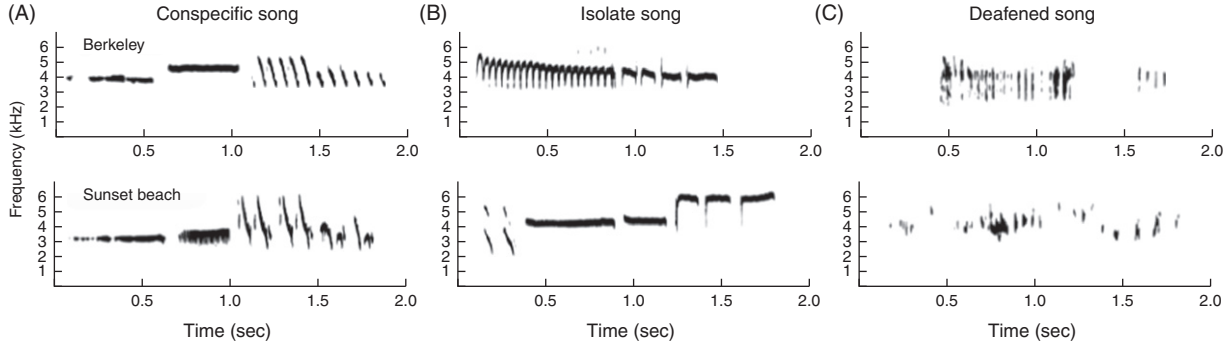

FIGURE 21.1 Songs of white-crowned sparrows. These are sonograms (time-frequency sound spectrograms) of songs from birds with different kinds of early experience. Sound energy in each frequency band is indicated by the darkness of the trace. (A) Song dialects. Birds raised in different areas sing slightly different songs. These dialects are stable for many years and are transmitted by learning. (B) Isolate songs. These simpler songs develop in birds raised in acoustic isolation or in birds that fail to copy a tutor song. (C) Songs of deafened birds. These kinds of songs develop in birds that are deafened after the sensitive period for song memorization but before the period of vocal learning. The birds need to hear their own voice to develop normal song. *From Konishi (1985).*

appropriate, and within the range of stimuli that is deemed acceptable, some song patterns are preferred over others.

Song learning involves two components: song memorization and vocal learning. In white-crowned sparrows, these components are separated by many months (Fig. 21.2A), whereas in zebra finches, which develop much more rapidly, they overlap. During the sensitive period for song memorization, according to a current hypothesis, high-order sensory neurons become tuned to respond selectively to the acoustic patterns of the songs that the bird memorizes. During the period of vocal learning, these high-order neurons act as templates for evaluating the bird's own song, guiding the development of song so that it eventually matches the previously memorized song pattern.

A Sensitive Period for Song Memorization

The sensitive period for song memorization begins at about 2 weeks of age and lasts for about 8 weeks in both zebra finches and white-crowned sparrows (Doupe & Kuhl, 1999; Immelmann, 1972). Baby birds that are exposed to a conspecific song before the sensitive period opens do not learn the song, even though they can hear at this early age. This suggests that the neuronal substrate for song memorization is not yet ready to be shaped by experience. In addition, juvenile birds that do not hear a normal song until after 3 to 4 months of age do not learn to sing a normal song. Apparently, by this age, the influence of experience on the neuronal substrate for song memorization has become reduced greatly.

The time at which learning occurs during the sensitive period for song memorization is determined by the individual's own experience. Once the sensitive period has opened, exposure of a juvenile bird to normal song for 1 week is sufficient for the bird to memorize the song, although subsequent exposure to other songs can still modify the song that the bird comes to sing. If a juvenile bird is kept in acoustic isolation (or hears only songs that are suboptimal as models for learning) for many weeks past the opening of the sensitive period and then hears normal song, it learns the normal song. Thus, during the sensitive period, the nervous system waits in a receptive state for appropriate experience-dependent instruction. Once this instruction is received, a particular pattern of connectivity becomes established and the sensitive period closes (Knudsen, 2004).

When a juvenile is deprived continuously of appropriate auditory experience, its capacity to memorize song eventually diminishes with age. Under these conditions, the sensitive period closes gradually because of additional, age-dependent factors (discussed later) that reduce the plasticity of the relevant circuits. As a bird approaches this age, experience with appropriate stimuli must be richer in order to have an effect. For example, white-crowned sparrows raised in acoustic isolation until 50 days of age no longer memorize songs presented from loudspeakers, but do memorize songs presented by live tutors. Thus, the enriched sensory experience provided by social interactions with the tutor overcomes the decline in the facility of the pathway for song memorization, essentially extending the sensitive period.

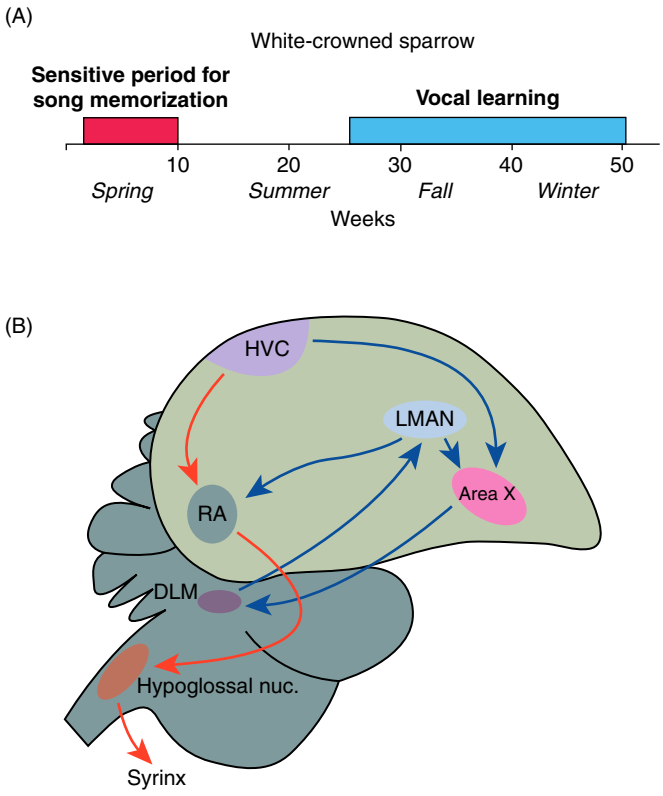

FIGURE 21.2 The sensitive period for song memorization and the set of nuclei that comprise the song system in songbirds. (A) Time-line for song learning for the white-crowned sparrow. For this species, the sensitive period for song memorization does not overlap with the period when the bird learns to sing. (B) A schematic diagram of a side view of the brain of a songbird. The vocal motor pathway, shown in red, consists of the HVC, the robust nucleus of the archopallium (RA), and the hypoglossal nucleus. The anterior basal ganglia pathway, shown in blue, consists of Area X, the medial portion of the dorsolateral nucleus of the thalamus (DLM), and the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN).

Vocal Learning

Learning to sing requires a combination of vocal practice and auditory feedback. A young bird that is deafened after song memorization but before the onset of vocal learning, and is thereby prevented from hearing its own voice, will not develop a normal song (Fig. 21.1C). Clearly, auditory feedback is essential for shaping the patterns of connectivity in the vocal motor pathway while the bird is learning to sing. Auditory feedback is necessary for the

bird both to learn how internally generated motor commands correspond with the sounds they produce and to compare the sounds they produce with the memorized song template.

A Neural Pathway for Song Learning

The neural mechanisms that underlie song memorization are being explored in many laboratories but, as yet, we know little about this aspect of song learning. In contrast, a great deal is known about the neural mechanisms that underlie song production (Mooney, 2009). The pathway for song production was identified by its sexual dimorphism in species in which only males sing. In these species, a distinct set of nuclei, referred to as the song system, is conspicuously hypertrophied in males (Fig. 21.2B). The song system consists of two distinct groups of nuclei: one group in the posterior forebrain that is responsible for song production and another in the anterior forebrain that is critical for song learning and maintenance.

The posterior, vocal motor pathway consists of three serially connected nuclei: the HVC and the robust nucleus of the archopallium (RA) in the forebrain and the hypoglossal nucleus in the brainstem (Fig. 21.2B). As a bird prepares to sing, a wave of neural activity spreads from the HVC to the RA, and finally to the hypoglossal nucleus, which contains the motor neurons that control the vocal musculature. Bilateral lesions of the HVC or the RA leave birds permanently incapable of producing song, although they still can make other kinds of unlearned vocalizations.

The anterior, basal ganglia pathway (Fig. 21.2B) consists of Area X, a thalamic nucleus (DLM), and the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN), and is essential for experience-dependent adjustments of song (Brainard & Doupe, 2000; Sober & Brainard, 2009). Lesions made in the LMAN of a young bird that is just learning to sing cause a dramatic cessation of song development, freezing the bird's song in an immature state. This freezing of song resembles song crystallization. In adult birds, LMAN lesions result in birds that sing normal songs, but can no longer adjust the quality of their songs based on experience.

In young birds, the anterior pathway provides information to the vocal motor pathway for the purpose of vocal learning. According to one hypothesis, the anterior pathway compares auditory feedback about the song that a bird produces with a stored template of the memorized song. The result of this comparison is then used to instruct the development and maintenance of connections in the vocal motor pathway. Consistent with this hypothesis, Area X and the LMAN in the anterior pathway contain neurons that respond maximally to the sound of the bird's own song. During development, axons from the LMAN are the first to innervate the RA in the vocal motor pathway. Information transmitted by the LMAN-RA pathway is mediated predominantly by NMDA receptors, a class of glutamate receptors that, when activated, is known in other systems to induce synaptic plasticity. As birds begin learning to sing, a second set of axons enters the RA from the HVC in the vocal motor pathway and begins making glutamatergic synapses. These later connections may be guided by the activity of the preexisting, LMAN-RA synapses.

Hormonal Regulation of Learning

A bird's song becomes stable ("crystallizes") by the time it reaches adulthood. Indeed, exposure of a juvenile bird to high levels of testosterone causes its song to crystallize prematurely in an abnormal state (Konishi, 1985). Conversely, juvenile birds that are castrated before they learn to sing produce inconsistent song patterns throughout life. In adult birds, consistent song is maintained by the action of the anterior pathway, which detects and corrects deviations of the song that the bird is singing from the memorized song (Sober & Brainard, 2009).

Seasonal song learners, such as canaries, appear to recapitulate the process of song memorization and vocal learning each year. This relearning is linked with, and could result from, the waxing and waning of steroid hormone levels. This raises the intriguing possibility that these sensitive periods can be opened and closed by hormonal or environmental factors.

Summary

Song learning in birds shares many characteristics with language learning in humans (Box 21.1). Song is a learned form of vocal communication used by certain species of birds to attract mates, defend their territories, and identify their neighbors. Songs are learned in two phases. The first is song memorization, which for many species takes place during a sensitive period. The second is vocal learning, during which vocal practice and auditory feedback shape the bird's song to match the memorized song. The neural pathway for song production is sexually dimorphic in many species in which only males sing. A separate pathway, in the anterior forebrain, plays a special role in vocal learning, guiding adjustments in sound production as the bird learns to sing and actively maintaining the quality of adult song over time.

SOUND LOCALIZATION: CALIBRATED BY EARLY EXPERIENCE IN THE OWL

A pathway that is highly modifiable during a sensitive period is the auditory pathway that creates a map of space in the midbrain of the barn owl (Fig. 21.3). This pathway

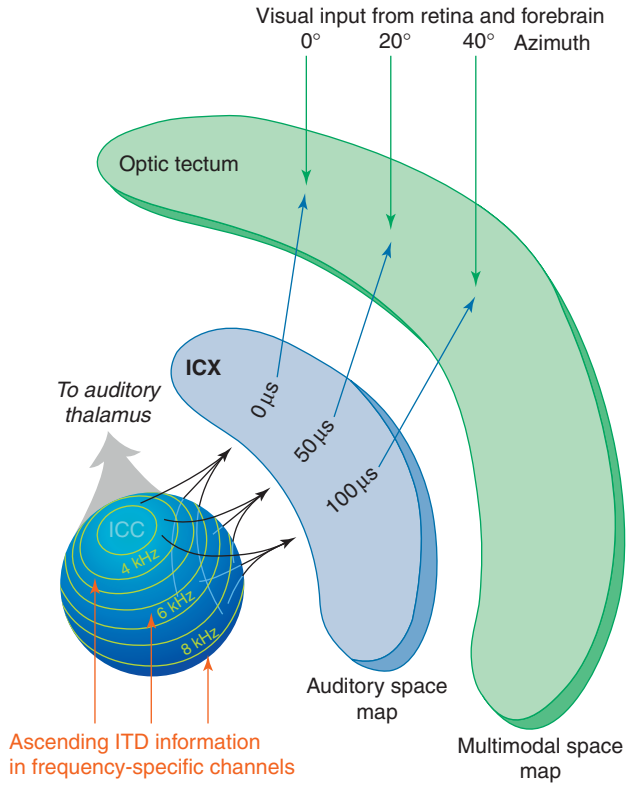

FIGURE 21.3 The ascending auditory pathway to the optic tectum in the barn owl. Auditory inputs enter the optic tectum from the brainstem (bottom arrows); these inputs already encode frequency-specific information about interaural time difference (ITD). These inputs project into the central nucleus of the inferior colliculus (ICC), where they are organized topographically by frequency. Bands in the ICC represent these frequencies (e.g., 4, 6, 8 kHz). Neurons in the ICC convey information both to the auditory thalamus (the primary pathway) and to the external nucleus of the inferior colliculus (ICX). In the ICX, ITD information is combined across frequency channels to synthesize a map of auditory space. For example, an ITD of 0 µs is generated by sound stimuli directly in front of the animal, such that sound reaches the two ears at exactly the same time. At the position marked 0 µs in the ICX are neurons that respond maximally to sounds with an ITD value of 0 µs and thus respond selectively to sounds originating in front of the animal. Sounds originating, for example, from positions that are further to the left-hand side will reach the ears with progressively greater left ear-leading ITDs and thus stimulate neurons with progressively larger best ITDs. From the ICX, the auditory map of space is conveyed via a topographic projection to the optic tectum. Here the auditory map is aligned and merged with a visual map of space (top arrows, representing inputs from the retina and the forebrain) to produce a multimodal space map.

transforms a representation of auditory spatial cues that exists in the central nucleus of the inferior colliculus (ICC; see Chapter 24) into a topographic representation of space in the external nucleus of the inferior colliculus (ICX). The auditory map of space is then sent on to the optic tectum, the avian analog of the mammalian superior colliculus, where it aligns with and is integrated with a visual map of space. The function of this pathway is to determine the locations of auditory stimuli, information that can be used to direct the animal's attention and orienting movements toward interesting auditory stimuli (see Chapter 31).

The pathway derives the location of a sound source by evaluating spatial cues that are present in the auditory signals at the two ears. The most reliable cues for sound localization are interaural timing differences (ITDs) and interaural level differences (ILDs). ITDs arise from the difference in the path length that sound must travel to reach the near versus the far ear. Because the ears are on the sides of the head, ITD varies systematically with the horizontal (azimuthal) location of a sound source (Fig. 21.4A; contour lines). ILDs result from the fact that each ear is most sensitive to sound coming from certain directions. Consequently, a sound from a particular direction will usually produce a higher sound level in one ear than the other. ILDs vary both with the azimuthal and with the elevational location of a sound source in spatial patterns that depend on sound frequency.

In creating the map of auditory space, the nervous system can only roughly anticipate the relationship between encoded values of ITD and ILD and the locations of sound sources that produce them. The correspondence of ITDs and ILDs with locations in space changes with the size and shape of the head and ears, features that vary across individuals, as well as for a given individual during growth. Moreover, the encoded values of sound timing and level that are transmitted to the CNS depend on the sensitivity and transduction properties of each ear, and these properties can change over time. Therefore, to establish and maintain an accurate map of space in the optic tectum, this midbrain pathway must learn the exact relationship between the encoded cue values and the locations of sound sources that produce them.

The influence of early experience on the owl's auditory space map has been demonstrated using a variety of techniques that change the relationship between cue values and locations in space: For example, the external ears have been altered drastically or the auditory canal of one ear has been plugged chronically (Knudsen, 1999). The midbrain pathway responds adaptively to such manipulations by adjusting the tuning of neurons in the ICX and optic tectum to ITDs and ILDs that restore an accurate map of space. In young animals, this plasticity enables the recovery of a substantially normal auditory map even after severe disruptions of hearing. In adult animals, plasticity is far more limited in extent.

An instructive signal that adjusts the tuning of ICX and tectal neurons is provided by the visual system. The instructive role of vision in guiding the tuning of ICX and tectal neurons has been demonstrated in experiments in which owls wear optical displacing prisms that chronically shift the visual field (Knudsen, 2002). The effect of experience with displacing prisms on auditory spatial tuning is most apparent in the optic tectum, where the visual receptive field of each neuron indicates the location

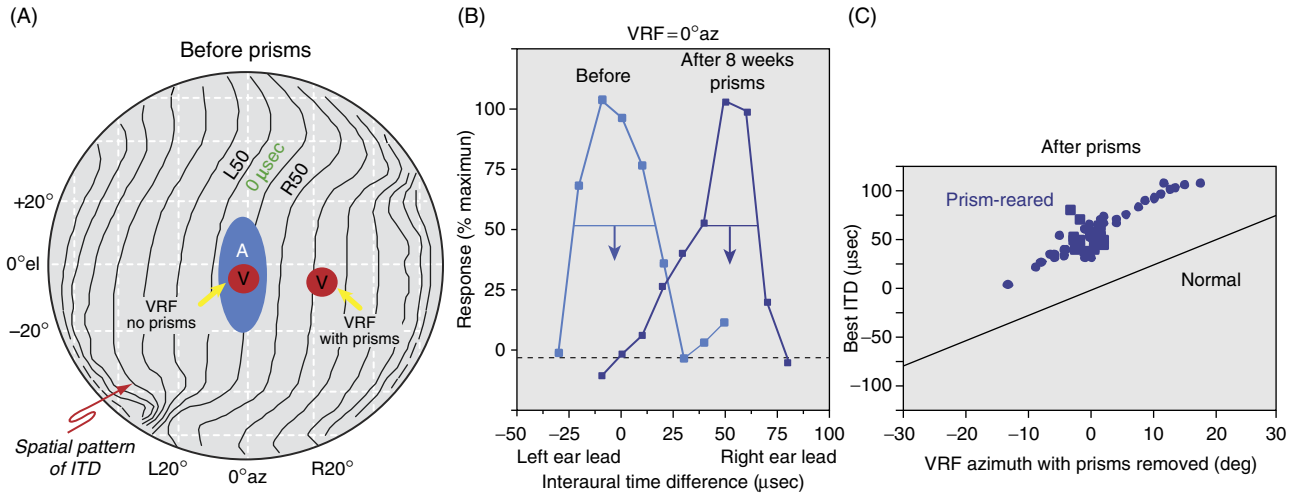

FIGURE 21.4 Rearing owls with laterally displacing, optical prisms causes an adaptive shift in the tuning of neurons in the optic tectum for ITD. (A) This map represents the space in front of the owl, showing both the elevation and the azimuth of a stimulus in space. Contour lines indicate the correspondence of ITD values (in microseconds) with particular locations in space. The point at which the 0° axes intersect represents the point in space directly in front of the owl's head. The auditory (A) and visual (V) receptive fields of one tectal neuron are shown in the center of the map. This neuron responds optimally when the stimulus is directly in front of the animal. Normally, the auditory and visual receptive fields are aligned. Optical prisms induce a horizontal displacement of the neuron's visual receptive field (VRF), resulting in a misalignment between A and V. (B) Tuning for ITD is shifted by prism experience. These ITD tuning curves were recorded from similar sites in the optic tectum before (blue) and after (purple) 8 weeks of prism experience. Both sites had a VRF at 0° azimuth. After 8 weeks of experience, the neuron is tuned for the ITD produced by an acoustic stimulus at the location of the optically displaced VRF, as shown in A. Arrows indicate the best ITD for each site; the best ITD is defined as the center of the range of ITDs to which the neuron responded with more than 50% of its maximum response. (C) The relationship between best ITD and VRF azimuth is shifted systematically from normal in prism-reared owls. The black line indicates the regression of best ITD on VRF azimuth that is observed in normal owls. Dots represent individual sites in a prism-reared owl. The map of ITD is shifted systematically relative to the visual map of space.

in auditory space to which that neuron should normally be tuned. When prisms that displace the visual field horizontally are placed in front of the eyes, the visual receptive fields of tectal neurons are shifted horizontally and out of alignment with the auditory receptive fields of these neurons (Fig. 21.4A). In juvenile birds, continuous experience with such prisms over a period of 6 to 8 weeks causes the auditory receptive fields of tectal neurons to realign with their visual receptive fields: The tuning of tectal neurons to ITDs and ILDs changes so that they respond to auditory cue values representing the locations of their optically displaced visual receptive fields (Figs. 22.4B, C). As a result, the auditory map of space shifts to match the optically shifted visual map. This adjustment is adaptive because, by making it, the animal alters its orientation toward sounds so that it sees the source of the sound through the prisms.

A Sensitive Period for Neuronal Adjustments

This adaptive auditory plasticity is regulated developmentally. The magnitude of the shift in neuronal ITD tuning that is induced under standard conditions of prism experience depends greatly on the age of the animal (Fig. 21.5). Large shifts in ITD tuning, of up to 70 μs, occur in juvenile owls (even larger shifts can be induced by ear

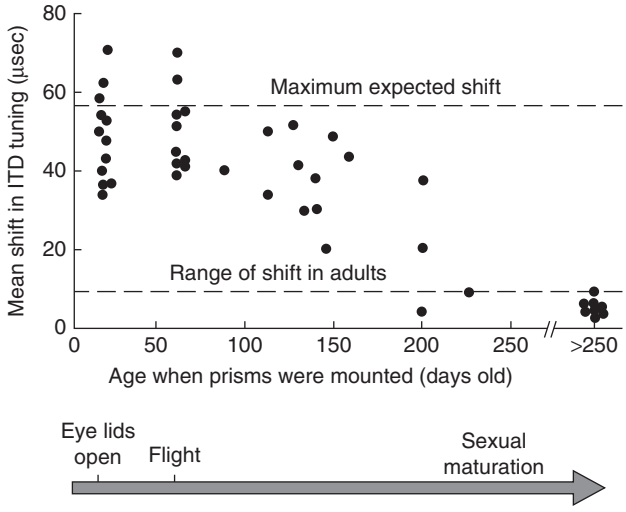

FIGURE 21.5 The sensitive period for visual calibration of neuronal ITD tuning in the optic tectum. Each dot represents data from a single owl. The large arrow below is a timeline, indicating important developmental stages in an owl's life. Each owl experienced a 23° displacement of the visual field for at least 60 days. ITD tuning was then measured at 15 to 23 sites in the superficial layers of the optic tectum. The difference between the best ITD measured and the best ITD expected normally, based on the location of the site's VRF (see Fig. 21.4C), was taken as the "shift in ITD tuning." The mean shift in ITD tuning for the population of sampled sites as a function of the age of the owl when prisms were first mounted is plotted.

plugging). In adult owls, equivalent conditions rarely shift ITD tuning by more than 10 μs, even after many months of prism experience. The period during which prism experience induces large changes in ITD tuning, the sensitive period, ends as the owls approach sexual maturity, at about 200 to 250 days old.

Although an experience-dependent shift in ITD tuning is observed most easily in the optic tectum (due to the physiological reference provided by the visual receptive field of the neuron), the site in the pathway where the plasticity actually takes place is in the ICX: The maps of ITD in the ICX and in the optic tectum are shifted by equivalent amounts in prism-reared owls, whereas the representation of ITD in the ICC remains unaltered.

Mechanisms of Plasticity

A shift of the auditory space map that occurs during the sensitive period is associated with a change in the architecture of the neurons that project from the ICC to the ICX (DeBello, Feldman, & Knudsen, 2001). A topographic projection from the ICC to the ICX brings ITD information to the appropriate site in the ICX, where the information is integrated across frequency channels to create spatial receptive fields (Fig. 21.3). A topographic projection is established early in development, before prism experience exerts its effects (Fig. 21.6A). Prism experience causes neurons in the portion of the ICC that represents the shifted values of ITD to project axons to neurons in novel regions of the ICX (Fig. 21.6B; red lines) that then become tuned to those abnormal values of ITD. Thus, experience induces the elaboration of axons at sites in the ICX where they support appropriate responses. In owls that have acquired shifted space maps, the learned anatomical circuit coexists with the normal circuit.

The newly learned responses that result from prism experience are mediated differentially by special classes of excitatory and inhibitory neurotransmitter receptors. Drugs that specifically block the *n*-methyl-d-aspartate (NMDA) glutamate receptor, such as AP5, eliminate or severely reduce the responses of ICX neurons to newly learned values of ITD, while having substantially less effect on their responses to the normal value. At the same time, responses to the now inappropriate, normal values of ITD are actively suppressed by powerful inhibition mediated by $GABA_A$ receptors. The actions of NMDA and $GABA_A$ receptors play critical roles in many other examples of experience-dependent plasticity as well.

As mentioned earlier, large shifts in ITD tuning in response to visual field displacement occur only in juvenile owls during a sensitive period. In contrast, removal of prisms from adult owls that have been raised from the day of eye opening wearing prisms results in a shift of the map of ITD back to normal. The genetically programmed, normal circuitry persists into adulthood even without validation by experience. In owls that have been raised with prisms, the adult circuit is able to switch back and forth, over a period of weeks, from an abnormal representation of ITD to a normal representation of ITD and vice versa, depending on the visual world the animal experiences. In this case, acquired alterations in circuit architecture resulting from experience during the sensitive period, together with the genetically programmed circuit architecture, influence the range of connectional states that the circuit can assume later in adult life.

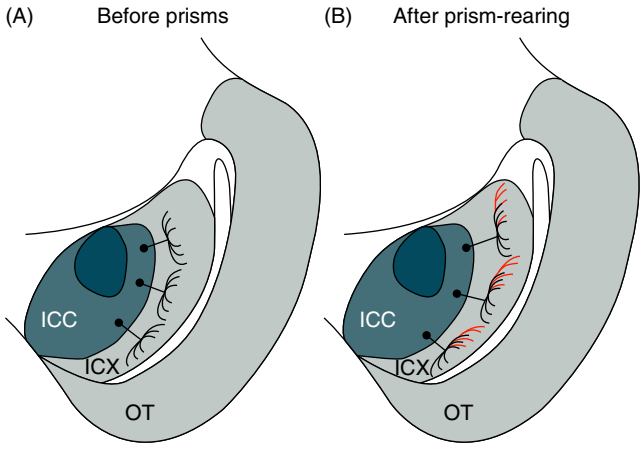

FIGURE 21.6 Schematic model of the change in the pattern of axonal projections from the ICC to the ICX that accompanies the shift in the map of ITD in the ICX. Based on DeBello et al. (2001). (A) The initial state of the projection before prism experience. (B) After prism experience, axonal projections from the ICC to the ICX are shifted systematically as indicated by the red arbors.

Plasticity after the Sensitive Period

Although plasticity is greatest during this sensitive period, the capacity for substantial plasticity persists into adulthood. The difference is that, in adult owls, more sophisticated conditions are necessary in order to induce plasticity. For example, relatively large cumulative changes in the functional properties of neurons can be instructed in small steps over time, as long as each incremental step is within the more limited adjustment range of the adult pathway. Also, plasticity can be increased dramatically in adults when the owls are highly attentive to the information that instructs change, such as when they hunt live prey that they can both see and hear. These special conditions are not necessary to induce large-scale plasticity during the sensitive period. Nevertheless, these conditions engage mechanisms of plasticity that drive adaptive adjustments in the adult nervous system, and they could be optimized to maximize adaptive changes in adult animals after sensitive periods have closed.

Summary

The brain derives the location of a sound source by evaluating spatial cues that are present in the auditory signals at the two ears. Interaural timing differences and interaural level differences are used to determine the position of a sound in space. In owls, this information is used to create a map of auditory space, which is aligned closely with a visual map of space in the optic tectum. Establishing and maintaining the alignment of the auditory space map with the visual space map in the optic tectum is an active process, guided by information provided by experience. The capacity of this pathway to change adaptively in response to experience is particularly great during a sensitive period. Plasticity during the sensitive period involves changes in circuit architecture and depends on the action of specific subtypes of glutamate and GABA receptors.

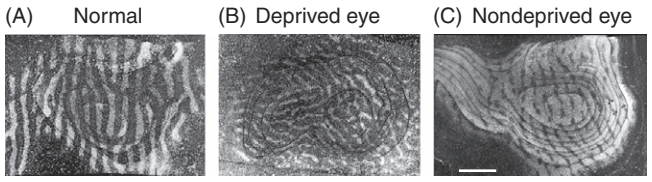

FIGURE 21.7 Critical period plasticity of the anatomical projections representing the left and right eyes in the visual cortex of monkeys. These are dark field autoradiographs of tangential sections through layer 4 of the primary visual cortex, showing the pattern of trans-synaptic labeling (bright areas) from the thalamic lateral geniculate nucleus (LGN) that resulted from an injection of a radioactive tracer into one eye; the intervening dark areas represent LGN input from the opposite (non-injected) eye. Scale bar indicates 2.5 mm. (A) The pattern of LGN input to the visual cortex in a normal monkey. (B) Severely reduced LGN input from the deprived eye of a monkey that experienced monocular deprivation from 3 weeks until 7 months old. (C) Greatly expanded LGN input from the nondeprived eye of a monkey that experienced monocular deprivation from 2 weeks until 18 months old. *From Hubel et al. (1977).*

BINOCULAR PROCESSING IN THE MAMMALIAN VISUAL CORTEX DEPENDS ON EARLY EXPERIENCE

In the mammalian nervous system, visual information from the two eyes first comes together at the level of the primary visual cortex. As described in detail in Chapter 18, visual experience during a limited period early in life has an enormous impact on how much of the visual cortex is devoted to processing input from each eye and the degree to which binocular inputs are combined (Hubel & Wiesel, 1970; Hubel, Wiesel, LeVay, 1977). Early in development (before birth in many species), afferents that provide inputs from the left and right eyes, respectively, begin to cluster in separate, interleaved areas in layer 4 of the primary visual cortex (Fig. 21.7A). This early clustering of eye-specific inputs from the lateral geniculate nucleus (LGN) is driven by a combination of molecular mechanisms and patterns of spontaneous neuronal activity.

Soon after birth, a period, referred to as a "critical period" by Hubel and Wiesel (1970), opens during which visual experience influences the competition among LGN afferents for territory in layer 4. As long as the eyes are coordinated and used equally, the typical final state, consisting of equally wide ocular dominance columns, is achieved (Fig. 21.7A). If, however, vision is impaired in one eye, due to monocular eyelid closure in an experimental animal or to a cataract in a human, for example, the balance between LGN afferents in their competition for territory in layer 4 is disrupted: LGN afferents that convey input from the impaired eye lose the ability to drive layer 4 neurons in an abnormally large region of the cortex (Fig. 21.7B), whereas LGN afferents that convey input from the nondeprived eye gain the ability to drive layer 4 neurons in an abnormally large portion of the cortex (Fig. 21.7C). As a consequence, activity throughout most of the visual cortex becomes driven by LGN afferents from the nondeprived eye.

A Critical Period for Binocular Processing in the Visual Cortex

The critical period for binocular processing in the visual cortex has been studied particularly carefully in cats and primates by measuring the age dependence of the effects of monocular eyelid closure. The onset of the critical period is rapid, beginning at about 3 weeks in cats. By 4 to 6 weeks of age, the cortex is maximally sensitive to monocular deprivation: A few days of monocular deprivation cause a complete shift in ocular dominance, leaving the cortex almost entirely driven by input from the nondeprived eye (Fig. 21.8). Beyond 6 weeks of age, the critical period gradually closes: Over the next 10 months, the rate at which ocular dominance can be shifted by monocular deprivation and the degree to which it can be shifted both decrease (Fig. 21.9). Once a cat is about 1 year old, monocular deprivation even for months no longer affects ocular dominance in the cortex (Fig. 21.8C). Similar critical periods, but extending later in life, exist for the visual cortex in monkeys and humans.

The critical period for binocular processing in the visual cortex is unusual in one respect: There is no predisposition to establish a normal pattern of connectivity based on normal experience. Even after baby cats or monkeys have experienced normal binocular vision for several weeks, monocular deprivation still causes the responses in the cortex to become dominated by the nondeprived eye. Moreover, once the responses in the cortex become

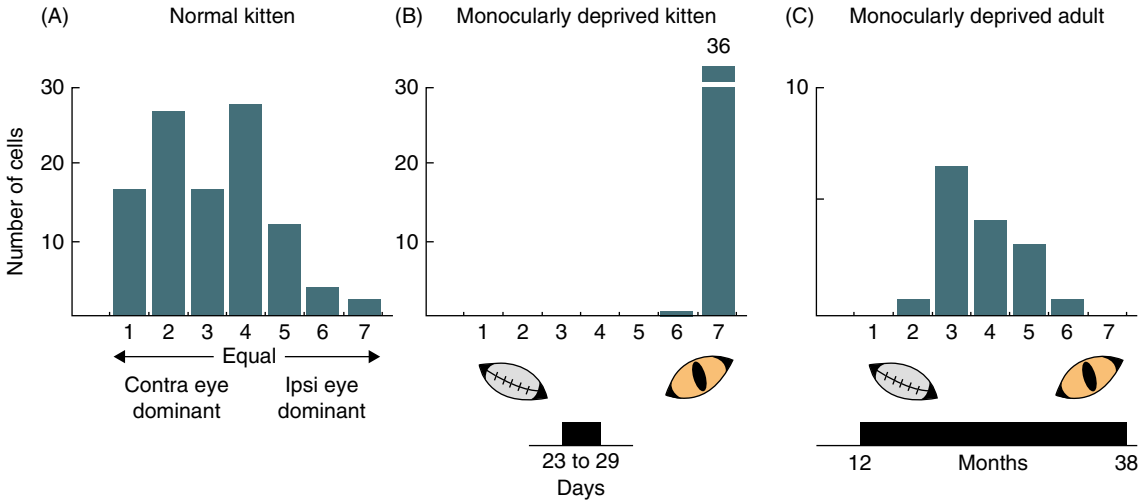

FIGURE 21.8 Effect of chronic closure of one eye on the responsiveness of visual cortical neurons to input from each eye. (A) Ocular dominance distribution in the primary visual cortex of two normal kittens, 3 to 4 weeks old. Cells in group 1 were driven only by the contralateral eye; for group 2, the contralateral eye was markedly dominant; for group 3, the contralateral eye was slightly dominant; for group 4, there was no apparent difference in the drive from the two eyes; for group 5, the ipsilateral eye dominated slightly; for group 6, it dominated markedly; and for group 7, cells were driven only by the ipsilateral eye. (B) Ocular dominance distribution was altered dramatically in a kitten exposed to contralateral eye closure for 1 week (from 23 to 29 days of age). (C) Ocular dominance distribution was essentially normal in an adult cat exposed to contralateral eye closure for 26 months. *From Hubel and Wiesel (1970).*

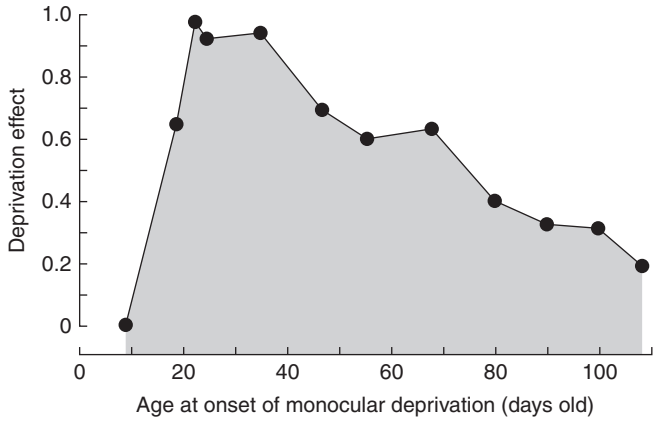

FIGURE 21.9 The critical period for binocular processing in the primary visual cortex of the cat. The degree of functional disconnection of cortical neurons from the deprived eye is quantified and plotted as a function of the kitten's age at the time of monocular closure. Chronic monocular closure lasted 10 to 12 days. Each point represents data from a single animal. Functional disconnection was based on the ocular dominance distribution (see Fig. 21.8) and indicated the degree to which the influence of the closed eye was weakened or lost. The index was defined such that the mean value for normal cats was 0, whereas total disconnection resulted in a value of 1. *From Olson and Freeman (1980).*

dominated by one eye, reinstating normal visual input to the previously deprived eye does not readily restore normal binocular responses in the cortex. Instead, the nondeprived eye continues to dominate the responses of cortical neurons for as long as animals have been studied (up to 5 years after restoration of binocular input). Thus, unlike song memorization in songbirds, where just a brief exposure to conspecific song establishes a robust and permanent memory of the song, the neural circuitry that supports normal binocular processing is not stabilized rapidly by exposure to normal binocular input. Instead, normal binocular vision must persist throughout the entire critical period to prevent the cortex from becoming dominated by monocular responses. An adaptive advantage of this characteristic of the binocular pathway has yet to be recognized.

Research on ocular dominance plasticity has shifted recently to rodents, particularly to mice, in which targeted genetic manipulations have led to major discoveries regarding molecular mechanisms that govern the plasticity (Tropea, Van Wart, Sur, 2009). However, the critical period is far less critical in rodents than it is in cats or primates (Hofer, Mrsic-Flogel, Bonjoeffer, & Hubener, 2006): Monocular deprivation causes significant shifts in ocular dominance in the cortex of adult mice, and restoration of binocular vision after monocular deprivation during the critical period results in the recovery of binocular responses. Thus, as with song memorization in songbirds, the degree to which binocular processing in the visual cortex depends on experience during a restricted developmental period varies across species.

Mechanisms of Plasticity

The dramatic change in the responsiveness of neurons in the visual cortex to input from the two eyes that is caused by early monocular deprivation is accompanied by an equally dramatic change in the axonal architecture

of the LGN neurons that project to layer 4: axonal arbors conveying input from the normal eye expand while those conveying input from the impaired eye shrink. The anatomical remodeling of LGN axons depends on the availability of neurotrophins—BDNF and NT-4—as well as on the expression of their cognate receptor, TrkB (Lein & Shatz, 2001). The adjustments of synaptic drive by the left and right eyes result from long-term potentiation and long-term depression of synapses in the cortex, and require the activation of NMDA receptors.

A variety of mechanisms that contribute to synapse formation or stabilization have been shown to modulate ocular dominance plasticity. Ocular dominance plasticity is enhanced by genetic overexpression of BDNF in mice or by application of neuromodulators, such as acetylcholine or norepinephrine, in cats. Plasticity can be enhanced in both young and adult mice by genetic mutations of developmentally regulated molecules that normally restrict plasticity, such as a classically immune system molecule and its receptor (PirB) or Nogo and its receptor, which inhibits axonal outgrowth, or by enzymatic degradation or genetic manipulation of the extracellular matrix, which restricts synaptic remodeling (Miyata, Komatsu, Yoshimura, Taya, & Kitagawa, 2012). Most of these interventions have been shown to prolong plasticity in developing animals or to "reopen" ocular dominance plasticity in adults.

The spatial and temporal patterns of activity that drive cortical plasticity depend on a precise balance of excitatory and inhibitory influences. The critical period for binocular processing does not open until inhibitory connections, which develop after excitatory connections, become effective (Hensch, 2005). The critical period opens prematurely in mice in which inhibition has been enhanced pharmacologically. Conversely, the critical period is delayed indefinitely in mice in which a class of GABA receptors has been genetically deleted and, in these same mice, ocular dominance plasticity is reinstated by pharmacological enhancement of GABA-mediated transmission.

Large, rapid shifts in ocular dominance in response to monocular deprivation occur only during a critical period. However, in adult mice, in which a shift in ocular dominance has been induced by monocular deprivation during the critical period and is followed by recovery of binocular responses by reopening the eye, closure of the same eye for a second time (but not of the nondeprived eye) causes a rapid shift in ocular dominance in the same direction (Hofer et al., 2006). Thus, analogous to the case described for barn owl sound localization, changes in circuit architecture that result from experience during the critical period have a permanent effect on the range of connectional states that the visual cortex can assume later in adult life.

Dark-Rearing Prolongs the Critical Period

An environmental manipulation that prolongs the critical period is raising animals in complete darkness. At the beginning of the critical period, most cortical neurons respond to inputs from either eye, but the responses tend to be weak. In cats that are raised in the dark until well past the end of the critical period (as defined by monocular deprivation), cortical neurons continue to be driven binocularly and their responses remain weak. When these animals are finally allowed visual experience, the responses of these neurons gradually increase in strength and the relative representations of the left and right eyes are shaped by the animal's experience: In monocularly deprived cats, nondeprived eye inputs become predominant in the cortex, and in cats that experience binocular vision, normal ocular dominance columns develop. Thus, without strong experience-driven input, the mechanisms that control ocular representation in the cortex remain in an uncommitted state, waiting for instruction for a prolonged, if not indefinite, period of time.

Summary

The processing of input from the two eyes in the primary visual cortex is shaped by binocular experience during a sensitive period. Because the effects of disruptions of binocular vision are apparently irreversible when they occur during this limited period in early life, this period has been referred to as a *critical period*. During prenatal development and before the onset of vision, thalamic inputs representing the left and right eyes segregate from each other to form ocular dominance columns of roughly equal width in the visual cortex. Soon after birth, a period opens during which the visual experience of the animal shapes the representations of the two eyes in the cortex. Normal binocular vision consolidates and refines the established patterns of ocular representation. Impaired vision in one eye, however, causes the LGN axons in layer 4 carrying information from the impaired eye to shrink and their synapses to loose efficacy, whereas axons carrying information from the nonimpaired eye expand and their synapses increase in efficacy. In contrast, equivalent, monocular deprivation in adult animals has no apparent effect, at least in cats and primates. The critical period for binocular processing in the visual cortex can be prolonged substantially by rearing animals in complete darkness.

A SENSITIVE PERIOD FOR SHAPING THE TEMPERAMENT OF RATS

The way in which a rat pup is cared for by its mother during a sensitive period has an enormous impact on a rat's temperament as an adult (Weaver et al., 2004).

In this example, the primary influence of early experience is to set the expression level of a gene, the gene for the glucocorticoid receptor (GR), in a particular circuit in the hippocampus. The protein product of this gene strongly influences a rat's emotional responses to stressful conditions. The effect of mothering on the expression level of this gene occurs only during the first week of a rat's life, and the behavioral consequences of this experience last throughout adulthood.

Different rats respond differently to threatening situations. For example, when introduced into a new environment, some rats are calm and adventurous, whereas others are anxious and fearful. This fundamental difference in emotional responses to stressors reflects, in part, a rat's interactions with its mother during the first week after birth (Fig. 21.10). Rats raised by a mother who groomed them extensively (high-grooming) and nursed them in a way that facilitated their access to milk (arched-back nursing) are less fearful and less reactive to stressors as adults than are rats raised by a mother who did not treat them in this way.

Cross-fostering experiments demonstrate that the transmission of these traits is dominated by experience and not by genetics. Rats born to low-grooming mothers (nonattentive and no arched-back nursing) but raised by high-grooming mothers become themselves calm, adventurous, high-grooming mothers. Conversely, rats born to high-grooming mothers but raised by low-grooming mothers become anxious, low-grooming mothers. Thus, the transmission of these traits depends on mother–infant interactions during the first week of a rat's life. The experiments demonstrate that, although genetics constrains the ranges of these traits, early experience can modify them dramatically.

FIGURE 21.10 A rat mother grooms her pups during the first week after their birth. This interaction permanently affects the temperament of these rat pups.

The emotional responses of a rat to stressors reflect the reactivity of the hypothalamic-pituitary-adrenal (HPA) system. Activation of the HPA system leads to the release of a special class of stress hormones, glucocorticoid hormones, from the adrenal glands. Animals with high circulating levels of glucocorticoid hormones are anxious and fearful, those with low circulating levels of this hormone are calm.

The hippocampus exerts a powerful negative feedback on the release of glucocorticoid hormones from the adrenal glands. High levels of GRs in the hippocampus result in low basal levels of glucocorticoids and tight regulation of glucocorticoid release when an animal is stressed. Low levels of GRs in the hippocampus have the opposite effects.

Mechanisms of Plasticity

The expression level of GRs in the hippocampus is adjusted by interactions of a rat pup with its mother. Rats raised by high-grooming mothers express high levels of GRs in the hippocampus, whereas rats raised by low-grooming mothers express low levels of GRs. The same effect is observed in experiments in which mothering behavior is manipulated. For example, removing rat pups from a mother for 15 minutes and then returning them to the mother, causes the mother to increase her grooming of those pups. Rats that experience this increase in grooming express increased levels of GRs in the hippocampus compared with control animals; correspondingly, they are less reactive to stressors, less fearful, and more adventurous. This manipulation has these effects only when applied during the first two weeks after birth.

One mechanism that mediates the effect of mothering on GR levels in the hippocampus, and therefore on an animal's reactivity to stressors, is the methylation of the GR gene. Methylation silences the GR gene by blocking access of transcription factors to a promoter region of the gene. Gene promoter methylation is adjusted during development and is stable thereafter. Experience during the first week after birth with a high-grooming mother (Fig. 21.10) causes the GR gene promoter to become demethylated, resulting in high levels of GR gene expression and high levels of GRs in the hippocampus. Conversely, experience with low-grooming mothers causes the GR gene promoter to become methylated, leading to low GR levels in the hippocampus. The sensitive period for the effect of mothering on the temperament of rats is accounted for by the narrow window in development when the methylation state of the GR gene is adjusted by experience. The persistence of the effects of this experience is due to the subsequent stability of the gene's methylation state.

A second mechanism that contributes to the effect of mothering on GR levels in the hippocampus is the

acetylation of histones. Acetylation of histones in the chromatin of a gene increases the access of transcription factors to promoters. Histones within the nucleosome core that includes the GR gene are more acetylated in rats reared by high-grooming mothers than in rats reared by low-grooming mothers, an effect that increases the transcription of the GR gene and raises GR levels in the hippocampus. The difference in histone acetylation is thought to be driven by the difference in the methylation state of the GR gene, discussed earlier.

The contribution of histone acetylation to controlling GR levels in the hippocampus has been tested by administering an inhibitor of histone deacetylation to adult rats that had been reared by low-grooming mothers. The inhibitor increased acetylation of the histones surrounding the GR gene, increasing access of demethylating enzymes to the gene. The inhibitor thereby caused a decrease in the methylation state of the gene, which increased GRs in the hippocampus and changed the temperament of the adult rats into the calm, adventurous temperament typical of rats raised by high-grooming mothers.

Summary

Interactions of a rat with its mother during the first week of life shape the way in which a rat responds to stressful situations as an adult. The primary mechanism for this effect is an experience-dependent adjustment of the expression level of the GR gene in the hippocampus. High levels of maternal care during the first postnatal week causes a demethylation of a GR gene promoter, resulting in a stable increase in GR gene expression in the hippocampus and a consequent decrease in basal levels of glucocorticoid hormones and a tighter regulation of glucocorticoid hormone release in response to stressors. As a result, the animal is calm, adventurous, and reacts in a measured fashion to stressors. Maternal behavior has these effects only during a sensitive period in a rat's development when the methylation state of the GR gene can be altered. Thereafter, the methylation state of the GR gene remains stable throughout adulthood.

PRINCIPLES OF SENSITIVE PERIOD LEARNING

During the maturation of many neural circuits, patterns of neuronal activity, driven by stimuli or the animal's behavior, shape the circuit's functional properties, architecture, and/or biochemistry. This shaping process selects circuit properties that are appropriate for the individual's experience.

Circuit changes that occur during sensitive periods differ from those that occur in adulthood in terms of their magnitude and persistence and the behavioral conditions under which the changes can occur. As illustrated by the preceding examples in this chapter, sensitive period experience can cause changes in the nervous system that are beyond the range of changes that occur in adults, and the changes that result typically persist for the lifetime of the animal.

Changes in circuit properties are more readily induced during sensitive periods than in mature circuits. During sensitive periods, circuits may be altered simply by exposing animals to unusual conditions such as monocular deprivation or abnormal patterns of auditory spatial cues, for example. In mature circuits, equivalent conditions either have no effect or require the attention of the animal to the conditions in order for plasticity to occur.

Sensitive period learning is influenced heavily by genetic predispositions. Only a limited range of stimuli is allowed to operate as an instructive influence for a particular circuit. Within this acceptable range, some stimuli are preferred over others. This property is well illustrated by song memorization in songbirds and by imprinting (Box 21.2). The predisposition of the nervous system to be instructed by "normal" experience probably originates in the selectivity of the response properties, genetically determined as well as shaped by experience, of the neurons that provide input to the sites in the pathway where the learning takes place. As learning progresses, the selectivity of the pathway for acceptable input increases.

Whether a particular pathway passes through a sensitive period can vary across species. For example, some songbirds, such as canaries and mockingbirds, learn new songs seasonally throughout life, whereas others, such as white-crowned sparrows and zebra finches, learn their songs only during a sensitive period. Such species differences may provide a useful tool for uncovering the mechanisms that are responsible for sensitive periods.

The magnitude of changes that may result from experience-driven adjustments varies greatly across circuits and across species. The magnitude of changes depends on the degree of genetic specification of the inputs to the site of change. When the selection of appropriate inputs is from a large potential range of inputs, the effect of experience can have a profound influence on a circuit. Conversely, when the range of potential inputs is highly restricted by genetic specification, the effect of experience is correspondingly small.

The duration of different sensitive periods also varies greatly. At one end of the spectrum are the sensitive periods for imprinting, which may open and close within hours (Box 21.2). At the other end are sensitive periods for acquiring complex cognitive capabilities, such as language (described in Chapter 48), which involve sensitive periods that last for many years.

BOX 21.2

FILIAL IMPRINTING: BABIES LEARN TO RECOGNIZE THEIR PARENTS

For many species of birds and mammals, including ducks, geese, mice, and monkeys, parental care is essential for the survival of the young. The young of these species learn rapidly to distinguish their parents from all other individuals and form a unique and close relationship with their parents from that point on—a process referred to as filial imprinting (Hess, 1973; Horn, 2004). Filial imprinting can involve the learning of visual, auditory, olfactory, and gustatory cues that identify a parent. The learning of these cues takes place during short, well-defined sensitive periods early in postnatal life.

The visual component of the learning process usually is preceded by auditory, olfactory, and/or gustatory components. In many species, the babies learn to recognize the vocalizations of the mother based on experience that begins before or soon after the animal is born. In addition, babies may learn the odor and/or taste of the mother from the odors and tastes experienced immediately after birth. The recognition of the parent based on acoustic and/or chemical cues helps the young select the correct individual for visual imprinting, once the eyes and nervous system are capable of adequate form vision.

Sensitive periods for filial imprinting are relatively discrete and can be as short as a few hours in some species (Ramsay & Hess, 1954). For example, the sensitive period for filial imprinting in ducklings occurs during the first day of life. When a duckling is exposed once, for 10 minutes, to a model of a male duck on the first day after hatching, the duckling imprints on this particular model. When the duckling is tested 5 to 70 hours later, by being offered a choice between the previously presented model and a model of a female duck, the duckling prefers to follow the model of the male duck over that of the female duck, even when the female model is much closer to the duckling and makes louder calls. Measured by the "following response," imprinting in ducks is most effective between 10 and 20 hours after hatching.

As in other examples of learning during sensitive periods, young animals exhibit an innate preference to imprint on normal stimuli. When given a choice, babies in the process of imprinting attend preferentially to images that more closely resemble members of their own species. Thus, when baby ducks are given the choice of imprinting on geese or on people, they imprint on the (duck-like) geese. This predisposition is based on genetically programmed preferences for simple, conspicuous features—referred to as sign stimuli by ethologists—that tend to distinguish the species from all others. This implies that the neural circuitry involved in filial imprinting, like that involved in song learning in songbirds, contains genetically determined neuronal filters that help identify stimuli that are appropriate models for learning. As imprinting proceeds, learning causes these filters to become more selective until ultimately the young are capable of discriminating one individual from all others.

Imprinting results in rapid functional and structural changes in a specific part of the forebrain of birds (Horn, 2004). In chicks that have been imprinted on an artificial object, neurons in the intermediate and medial mesopallium (IMM) of the forebrain become responsive to the imprinted stimulus, and some become highly selective for the stimulus. Associated with the acquisition of selective neuronal responses in the IMM are local increases in the number of NMDA receptors, increases in the size of certain synapses, and a temporary surge in inhibitory activity. The increased inhibitory activity, which begins soon after exposure to the imprinting stimulus and lasts for many hours, is thought to contribute critically to the shaping of the specificity of IMM neurons for the imprinted stimulus.

The Opening of Sensitive Periods Depends on Pathway Maturation

Sensitive periods cannot open until the brain has matured to the point where three conditions are met. First, the information provided to the circuit from lower level circuits must be sufficiently reliable and precise to allow the circuit to carry out its function. Second, the circuit's connectivity must have matured adequately for it to process the information. For example, the critical period in the visual cortex does not open until and unless inhibitory as well as excitatory connections are effective. Third, the mechanisms that enable plasticity must be active.

Because complex behaviors depend on information that is processed through hierarchies of circuits, the first condition implies that sensitive periods for circuits at

higher levels in these hierarchies cannot open until the information from circuits at lower levels has become reliable. Sensitive periods for low-level circuits, such as the LGN, occur earlier than sensitive periods for higher level circuits, such as those in the visual cortex. The same principle holds for circuits at different levels in the owl's sound localization pathway. Thus, pathways that support complex behaviors, such as human language (Box 21.1) or object recognition, may rely on circuits that pass through sensitive periods that end at very different stages in an animal's life.

Experience cannot shape a circuit until the mechanisms that enable plasticity are active. Experience-driven changes in functional properties can involve a remodeling of axons and dendrites, an elaboration of new synapses, an adjustment of synaptic efficacies, and/or a regulation of gene expression. Anatomical remodeling and the establishment of new synapses may well be guided by the same mechanisms that control synaptogenesis during circuit development (Chapter 16). Neurotrophins (described in Chapter 17)—particularly BDNF, for example—are essential for anatomical remodeling during the critical period in the visual cortex (Lein & Shatz, 2001). Mechanisms that regulate synaptic efficacy during a sensitive period include those that underlie synaptic plasticity in the adult nervous system (Chapter 47). Long-term potentiation (LTP) and long-term depression (LTD), for example, have been shown to operate in many models of sensitive period learning. Moreover, the ubiquitous presence of NMDA receptors at sites of change in the various models of developmental learning indicates that this class of glutamate receptor plays a key role in adjusting patterns of connectivity during sensitive periods.

The Closing of Sensitive Periods Can Involve Many Mechanisms

Sensitive periods end once an animal has received adequate experience and the relevant circuit is irreversibly committed to a pattern of connectivity. The factors that render the commitment irreversible are not known. Many factors may play a role, and the factors that are most important may differ across different pathways.

One factor that may contribute to the closing of sensitive periods is the age- or experience-dependent alteration of molecular mechanisms that support changes in synaptic efficacy such as LTP and LTD, described in Chapter 46. In addition, for those circuits in which axonal elaboration is required for experience-dependent changes in connectivity, the closing of the sensitive period can result from the down-regulation of mechanisms that support, or the upregulation of mechanisms that restrict, axonal growth. In the visual cortex of cats, for example, levels of the growth-associated protein GAP-43, which is thought to be necessary for axonal growth, decrease precipitously during the critical period. A host of other molecular mechanisms could contribute to a decline in plasticity, including the loss of responsiveness of presynaptic axonal arbors to neurotrophins secreted by postsynaptic neurons, the stabilization of synapses by the extracellular matrix or by proteoglycans, the myelination of axons (preventing them from growing or retracting), the expression of molecules that restrict growth, and the downregulation of molecules that promote growth.

Another major factor that decreases the plasticity of circuits is the experience-driven sharpening of functional tuning. Initially in development, neuronal responses are relatively weak and broadly tuned. Experience causes selective changes in anatomical connections and synaptic efficacy that refine the patterns of both excitatory and inhibitory connections. These changes are self-reinforcing due to the action of self-organizational mechanisms that operate by Hebbian principles (Chapter 46). As a result, once a circuit has been shaped to process information in a certain way, it becomes far more difficult for altered experience to induce new patterns of connectivity.

Deprivation Prolongs Sensitive Periods

Sensitive periods typically close once an animal receives adequate experience. Therefore, when an animal is deprived of appropriate experience, the sensitive period is prolonged. For example, raising songbirds in acoustic isolation prolongs the sensitive period for song memorization, and raising cats or mice in complete darkness prolongs the critical period for binocular processing in the visual cortex. This characteristic of sensitive periods indicates that the event that triggers sensitive period adjustments is the powerful and repeated activation of neurons at the site where changes take place. Without the vigorous activation of these neurons, which requires that both inhibitory as well as excitatory circuitry is effective and balanced, the pathway remains in an uncommitted state and capable of adjusting in response to experience when it becomes available. This characteristic suggests that for young animals (including humans) suffering from a peripheral or central abnormality, a total absence of relevant input is far better than abnormal input. This implies that the optimal therapeutic strategy for such individuals is to deprive them of relevant sensory input until the abnormality is corrected. Otherwise, abnormal sensory experience may close the sensitive period, resulting in a commitment to an abnormal pattern of connectivity that cannot later be reversed.

Reopening Sensitive Periods

The possibility of reopening sensitive periods later in life is of particular importance for therapeutic reasons. For example, by reopening the critical period for binocular

processing in the visual cortex, effective binocular processing and stereoscopic vision might be provided to people who did not develop these capacities due to visual impairment or abnormal eye alignment during the visual critical period. To reinstate sensitive period plasticity completely, the factors (listed in the previous sections) that impose the functional constraints on the relevant circuit must, once again, enable modification by experience. In some circuits, the necessary plasticity may be enabled by the manipulation of only one or a few mechanisms. In the visual cortex, ocular dominance plasticity has been at least partially reinstated in adult animals by, for example, injecting fetal astrocytes or inhibitory interneurons into the cortex, local enzymatic degradation of the extracellular matrix, providing molecules that promote synaptogenesis, blocking the action of molecules that prevent synaptic remodeling, or chronic light deprivation. Interventions like these, when combined with appropriate experience, may have the potential to instate normal function to the affected circuit. With increased understanding of the specific neural circuits and computations that depend on sensitive period learning and the mechanisms that govern their plasticity, acquisition of typical behavior in adult animals that have experienced deprived conditions during sensitive periods may be possible.

Summary

Early experience shapes the functional properties, architecture, and biochemistry of many circuits so that the properties of these circuits are appropriate for the needs and the environment of the individual animal. The changes in circuit properties that occur during a sensitive period differ quantitatively, if not qualitatively, from those that occur in mature circuits. First, they occur readily only during a restricted period in the lifetime of the animal. Second, they involve the selection of particular circuit properties from a wide range of possible properties. Third, the changes in circuit properties that occur during sensitive periods typically do not require the attention of the animal. Fourth, the changes persist throughout life.

Sensitive periods vary in timing and duration across pathways and across species; some last only a few hours, whereas others last until the individual reaches sexual maturity. Sensitive periods open once the information conveyed to a circuit is sufficiently precise and the circuit is competent to process the information and to undergo plastic change. The signal that induces change is probably the repeated, vigorous activation of postsynaptic neurons by presynaptic activity representing the occurrence of an appropriate stimulus or the execution of adaptive behavior. The range of stimuli that are effective in driving plastic change is specified by genetic preprogramming, with most pathways biased heavily to prefer normal patterns of stimulation.

After a sensitive period closes, equivalent conditions have much less effect on the architecture, biochemistry, and functional properties of a circuit. The closure of a sensitive period may be triggered by experience itself or as a consequence of circuit maturation. The mechanisms that close a sensitive period probably vary for different circuits. When experience-induced changes require anatomical remodeling, the end of the sensitive period may be controlled by factors that regulate neurite growth and retraction; when the induced changes require adjustments in synaptic efficacy, the sensitive period will be controlled by factors that influence the capacity of synapses to modify their efficacy; and when the induced changes involve adjustments in the levels of specific receptors, the sensitive period will be controlled by mechanisms that regulate the expression of receptors.

SECTION IV

SENSORY SYSTEMS

CHAPTER

22

Fundamentals of Sensory Systems

In bringing information about the world to an individual, sensory systems perform a series of common functions. At its most basic, each system responds with some specificity to a stimulus, and each employs specialized cells—the peripheral receptors—to translate the stimulus into a signal that all neurons can use. Because of their physical or chemical specialization, the many types of receptors transduce the energy in light, heat, mechanical, and chemical stimulation into a change in membrane potential. That initial electrical event begins the process by which the central nervous system (CNS) constructs an orderly representation of the body and of things visible, audible, or chemical. To bridge the distance between peripheral transduction and central representation, messages are carried along lines dedicated to telling the CNS what has taken place in the external world and where it has happened. Such precision requires that labor be divided among neurons so that not only different stimulus energies (light vs. mechanical deformation) but also different stimulus qualities (steady indentation vs. high-frequency vibration of the skin) are analyzed by separate groups of neurons.

In addition to their organization along labeled lines, sensory systems perform common types of operations. Foremost among these is the ability of each system to compare events that occur simultaneously at different receptors, a process that serves to bring out the greatest response where the difference in stimulus strength (contrast) is greatest. At late stages in sensory processing, systems make comparisons with past events and with sensations received by other sensory systems. These comparisons are the fundamental bases of perception, recognition, and comprehension.

This chapter gives an overview of the functional attributes and patterns of organization displayed by the auditory, olfactory, somatosensory, gustatory and visual systems; and it outlines the physiological and anatomical principles common to all sensory systems. When variations on a common theme exist, they are discussed with the goal of bringing the general pattern into sharper focus.

SENSATION AND PERCEPTION

The Function of Each Sensory System Is to Provide the CNS with a Representation of the External World

Because of the changes that occur around an individual, each sensory system has the task of providing a constantly updated representation of the external world. Accomplishing this task is no simple feat because it requires a close interaction between ascending or stimulus-driven mechanisms and descending or goal-directed mechanisms. Together these two mechanisms evoke sensations, give rise to perceptions, and activate stored memories to form the basis of conscious experience. Ascending mechanisms begin with the activity of peripheral receptors, which together form an initial neural representation of the external world. Descending mechanisms work to sort out from the large amount of sensory input those events that require immediate attention. In doing so, the descending mechanisms alter ascending inputs in ways that optimize perception.

Perception of a sensory experience can change even though the input remains the same. A classic example is seen in the image of a vase that can also be perceived as two faces, pointed nose to nose (Fig. 22.1). In this case, the image remains the same—the sensory input remains constant—but the perception of what is being viewed changes as the goal of the viewer changes or as his or her attention wanders. Using this example, it is apparent that detection of a stimulus and recognition that an event

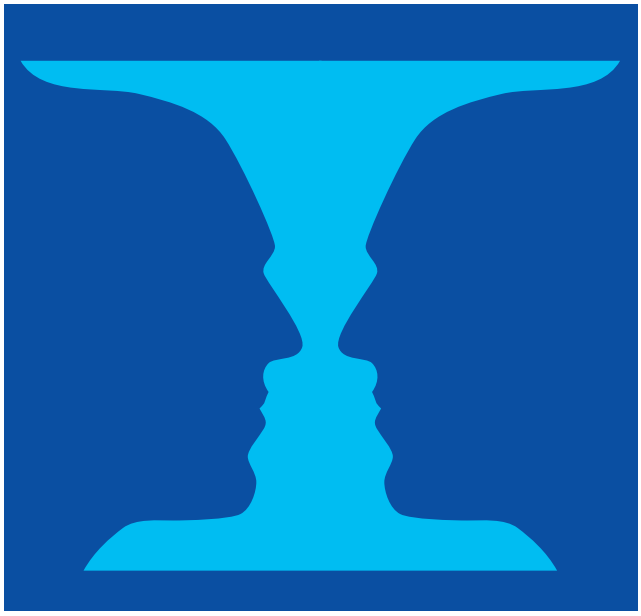

FIGURE 22.1 An example of a figure that can elicit different perceptions (faces or vase) even though stimulus and sensation remain constant. The mind can "see" purple figures against a blue background or a blue figure against a purple background.

has occurred are usually called sensation; interpretation and appreciation of that event constitute perception.

Psychophysics Is the Quantitative Study of Sensory Performance

A psychophysical experiment determines the quantitative relationship between a stimulus and a sensation in order to establish the limits of sensory performance (Stevens, 1957). Such an experiment relies on reports from a subject who is asked to judge quantitatively the presence or magnitude of a stimulus as careful adjustments in the physical attributes are made. One example of threshold detection is the *two-point limen*, in which two blunt probes, separated by a distance that is progressively enlarged or reduced over a series of trials, are applied to the skin surface. The minimum separation distance at which a subject reports two stimuli half the time and one stimulus the other half is taken as the detection threshold. That distance can be measured accurately and is found to vary markedly across the body surface; the two-point limen is smallest for the fingertips and largest for the skin of the back. Other studies, such as those exploring the detection of relative magnitudes of stimuli, can include assessments of object heaviness, loudness of sound, or brightness of light. Studies of this sort have been combined with neurophysiological experiments to compare reports from subjects (sensory behavior) with the responses of single cells (neuronal physiology). Through this procedure the neural mechanisms underlying sensory perception can be examined.

Some general principles hold for all sensation measured in psychophysical experiments. As just pointed out, one principle is that of threshold for detecting a difference between stimuli. Studies look to determine a difference threshold by asking what just noticeable difference (JND) between two stimuli (two lights of different brightness) an observer can detect. E. Weber was the first to formally recognize that small differences between two minimal stimuli are easier to detect than small differences between two robust stimuli. One example is the ability of a subject to detect a difference between two light objects that weigh 0.1 and 0.2 kilograms versus a difference between two heavy objects that weight 10.1 and 10.2 kilograms. The former is much easier than the latter. Weber's law states that the difference threshold for a stimulus is a constant fraction of intensity (the Weber fraction). The formula, $\Delta I/I = k$ describes that law, where I is the intensity of a baseline stimulus, ΔI is the JND between baseline and a second stimulus, and k is the Weber fraction. It is important to recognize that k may be a constant of a particular value for one feature, such as the frequency of sound, but the value changes markedly for another feature of the same sense (sound pressure level). The Weber fraction for sound frequency is exceedingly low (roughly .003), whereas that for sound pressure level is relatively high (0.15). For purposes of comparison, the Weber fraction for luminance is 0.02 and that for concentration of an odorant molecule is 0.10.

G. Fechner proposed that every JND between one stimulus and the next is an equal increment in the magnitude of sensation. That would mean a JND is proportional to a physical variable. His law is formalized in the equation $S = k/\log I$, where S is the sensory experience in terms of magnitude, I is the physically measured intensity of a stimulus, and k is a constant. There is strong intuitive value to this equation because it states the magnitude of a sensory experience is logarithmically related to the physical intensity. Lifting 1 kg and 2 kg produces very different sensory experiences, but lifting 10 kg and 11 kg produces almost the same experience, even though the added weight was equal in the two cases. S. Stevens recognized a century later that rather than a logarithmic relation, perceived sensation and physical intensity were related by a power function, described by the equation $S = kI^P$. Yet the exponent of I could be infinite, depending on the relationship of neural response to stimulus intensity. V. Mountcastle and his colleagues proposed that for mechanosensation the relationship between the physical properties of a stimulus and the response of individual neurons is linear. And most recently, K. Johnson and his colleagues (Johnson et al., 2002) have shown that for the complex percept of roughness perception, a linear relationship exists between subjective experience and neural activity. Thus, a basic law of psychophysics emerges: how an observer perceives a stimulus is a linear function of the intensity of that stimulus.

RECEPTORS

Receptors Are Specific for a Narrow Range of Input

Neurons of the brain and spinal cord do not respond when they are touched or when they are exposed to sound or light or odors. Each form of energy must be transduced by a population of specialized cells, which converts the stimulus into a signal that all neurons understand. In every sensory system, cells that perform this transduction step are called *receptors* (Fig. 22.2). For each of the fundamental types of stimuli (mechanical, chemical, or thermal energy or light), there is a separate population of receptors selective for the particular form of energy. Even within a single sensory system, there are classes of receptors that are particularly sensitive to one stimulus (e.g., heat or cold) and not another (muscle stretch). This specificity in the receptor response is a direct function of differences in receptor structure and chemistry.

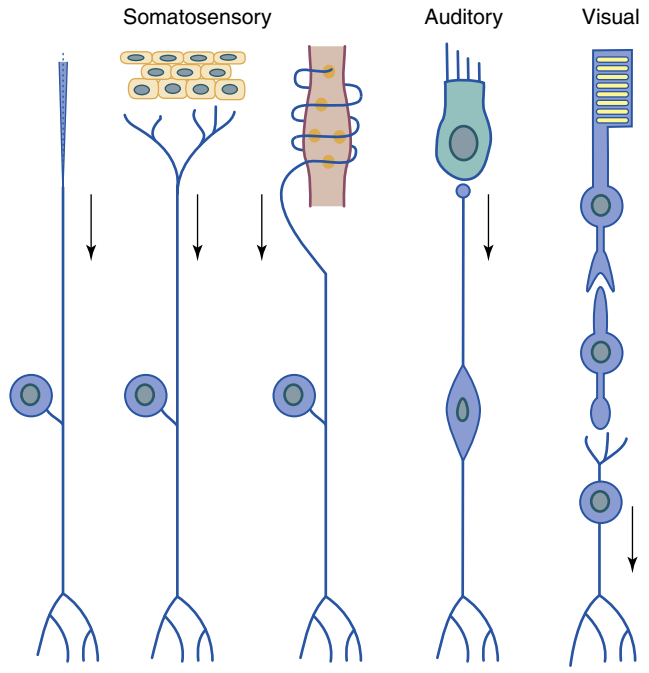

FIGURE 22.2 Receptor morphology and relationship to ganglion cells in the somatosensory, auditory, and visual systems. Receptors are specialized structures that adopt different shapes depending on their function. In the somatosensory system the receptor is a specialized peripheral element that is associated with the peripheral process of a sensory neuron. In the auditory and visual systems, a distinct type of receptor cell is present. In the auditory system, the receptor (hair cell) synapses directly on the ganglion cell, whereas in the visual system, an interneuron receives synapses from the photoreceptor and in turn synapses on the retinal ganglion cell. *Adapted from Bodian (1967).*

Receptor Types Vary across Sensory Systems

Systems differ in the number of distinct receptor types they incorporate, and a correlation exists between the number of receptor types displayed by a system and the types of stimuli that system is able to detect. In the somatosensory system, a large number of receptor types exist to detect many types of stimuli. Separate receptors exist to transduce a variety of mechanical stimuli, including steady indentation of hairless skin, deformation of hair, vibration, increased or decreased skin temperature, tissue destruction, and stretch of muscles or tendons (Fig. 22.2). In the auditory system, two classes of receptor—the inner and outer hair cells of the cochlea—transduce mechanical energy of the basilar membrane, which is set in motion by sound waves (Dallos, 1996). Here, the motility of outer hair cells provides an additional amplification of the basilar membrane motion to increase sensitivity and allow sharp tuning to sound frequency. The inner hair cells respond to the amplified vibrations and excite the large population of neurons upon which they synapse. Thus the two types of receptors act in concert to transduce a single type of stimulus. In the visual system, transduction is performed by two broad classes of receptor in the retina: rods and cones. The number of cone types varies from one in some species to two in many species to three in a few species, but cones in general are tuned to ranges of wavelengths of light. Rods are much more sensitive to light—their intracellular amplification of a single photon's capture generates a much larger current than is achieved in cones—and so they enable vision when light is dim. Olfactory receptors also vary in number from a few hundred types in primates to more than a thousand in rodents. Here the difference between one olfactory sensory neuron (OSN) and the next is a subtle variation on a common theme, since each OSN differs from its neighbor in the primary sequence of a single receptor protein. As that protein varies, so does the OSN's sensitivity to odorant molecules.

Receptors Perform a Common Function in Unique Fashion

All receptors transduce the energy to which they are sensitive into a change in membrane voltage. The task of the receptor is to transmit that voltage change by one route or another to a class of neurons—usually referred to as ganglion cells—that send their axons into the brain or spinal cord (Fig. 22.2). Systems vary in the mechanism whereby receptors and ganglion cells interact. Most receptors in the somatosensory system are part of multicellular organs, the neural components of which are the terminal specializations of dorsal root ganglion cell axons. An appropriate stimulus applied to a somatosensory receptor produces a generator potential—a graded change in membrane voltage—that, when large enough, leads to action potentials

that can be carried over a considerable distance into the central nervous system (CNS). The same approach is used by the olfactory system, since OSNs not only transduce the stimulus of an odorant molecule into a change in membrane potential but also conduct those action potentials into the CNS. We refer to these types of neurons, ones that combine the functions of transduction in the periphery with conduction into the CNS, as long-axon receptors.

Receptor cells of the auditory, vestibular, visual, and gustatory systems are separate, specialized cells that transduce a stimulus and then transmit the resulting signal to the nearby process of a neuron. Because the distances between receptor and target neuron are small, none of these short receptors generate action potentials; they signal their response by a passive flow of current that changes the release of neurotransmitter from either an axon or the base of the cell. These systems differ, however, in the path between receptor and ganglion cell. In the inner ear and in the tongue, sensory receptor cells are modified epithelial cells and not neurons. Nevertheless, they form chemical synapses with the processes of ganglion cells so that these ganglion cells take on the response properties of the receptor cells that innervate them. For these systems, the synapse between a receptor cell and a ganglion cell is little more than the conversion of an analog signal (graded changes in membrane potential) into a digital signal (action potentials). That is not the case in the retina, where photoreceptors relay their response through populations of interneurons interposed between them and retinal ganglion cells (Fig. 22.2). Because of this additional synapse and the opportunity it affords for summation and comparison of receptor signals, the retinal ganglion cell response differs appreciably from that of photoreceptors.

The mechanisms whereby receptor cells transduce and transmit signals are known in greater or lesser detail for each system. Visual transduction is a well-understood, rapid process in which a weak signal (a single photon) can be amplified greatly through a biochemical cascade, leading to the closure of thousands of Na^+ channels and a hyperpolarizing response (Yau & Baylor, 1989). For auditory and vestibular hair cells and somatosensory mechanoreceptors, mechanical deformation of a part of the cell gets transduced into a change in membrane voltage by mechanically gated ion channels, the molecular identity of which is still not known. The response of somatosensory mechanoreceptors is of a single sign because mechanically gated ion channels open and allow depolarizing current to enter (Katz, 1950). This requirement for depolarization may result from the demands placed on the somatosensory ganglion cell to generate action potentials and transmit information over long distances. In contrast, hair cell receptors of the auditory and vestibular systems generate a biphasic response. When protruding villi of a hair cell, called stereocilia, are deflected in one direction, transducer channels open and the cell is depolarized. Yet with deflection of stereocilia in the opposite direction, the same channels close and the cell is hyperpolarized (Hudspeth, 1985). Because sound usually produces a back-and-forth deflection of stereocilia, the result is a back-and-forth movement of the receptor potential—at least for low and moderate frequencies of sound. Thus, the receptor output contains temporal information about the waveform of an acoustic stimulus.

Receptors Have Characteristic Patterns of Position and Density

Receptors are not scattered randomly across the sensory surface. An orderly arrangement of receptors exists along the skin, inner ear, retina, olfactory epithelium, and the lining of the tongue and throat. In the human retina, for example, photoreceptors adopt a hexagonal packing array (Wassle & Boycott, 1991) in the region of highest density, called the fovea. Moreover, only cones are found in the fovea, and for that of humans and other Old World primates, only Red (long wavelength) and Green (middle wavelength) cones are found in the center of the fovea. Hair cells of the vestibular system are even more tightly sequestered, since they occupy very small regions in the semicircular canals and the otolith organs. In the skin, the arrangement of receptors is not nearly so orderly but the density of cutaneous receptors varies markedly across the skin surface. By far the greatest density of receptor terminals is found at the fingertips and the mouth, whereas receptors along the surface of the back are at least an order of magnitude less frequent. In each system, the differences in peripheral innervation density are tightly correlated with spatial acuity. Regions of highest receptor density are also the regions of highest acuity in vision (fovea) and somatic sensation (fingertip).

A perfect test case for innervation density and acuity is seen in the auditory system of microbats. Because these animals use echolocation to navigate and find prey, the auditory system greatly overrepresents the frequencies of sound a bat emits as a probing signal and the surrounding frequencies of Doppler-shifted sounds that echo from objects. Throughout most of the cochlea, the physical properties of the basilar membrane change in a steady fashion so that cochlear hair cells display a progressive shift in the frequency that excites them best. But at the frequencies represented in the Doppler-shifted echo, both the amount of basilar membrane dedicated to those frequencies and the density of inner hair cells along that region increase markedly. The result is a much greater acuity for these information-rich frequencies than for all other frequencies.

Receptors Are the Sites of Convergence and Divergence

The relationship between receptor and ganglion cell is seldom exclusive. Most commonly, a single ganglion

cell receives input from several receptors, and, in many cases, a single receptor sends information to two or more ganglion cells. *Convergence* and *divergence* go hand in hand for the somatosensory system, since a single spot on the skin is often innervated by axons of several ganglion cells, while at the same time the axon of a single ganglion cell can branch to end across a swath of skin. In the somatosensory system, however, the amount of divergence and convergence varies with the class of receptor involved (e.g., thermal receptor vs. mechanoreceptor) and the location of the receptor on the body surface (e.g., shoulder vs. fingertip). Similar features are seen in the mammalian visual system, since divergence and convergence dominate different parts of the retina populated by different receptor types. In the cone-rich central retina, each cone provides as many as five ganglion cells with their main visual drive, whereas in the rod-rich periphery, a few dozen rods supply each ganglion cell with its visual input. In its precision and in its implications for sensory processing, nothing approaches the divergence seen in the cochlea, where a single inner hair cell can be the source of all input received by at least 20 ganglion cells (humans) or as many as 35 ganglion cells (gerbils). Thus, what emerges from a comparison across systems is that convergence and divergence from receptor to ganglion cell vary directly with the demands placed on the system at the specific location. When spatial resolution is a requirement, the convergence of receptor inputs onto individual ganglion cells is low. When detection of weak signals is necessary, convergence is high. When receptor input is used for a complex function or for multiple functions, divergence of input from a single receptor onto many ganglion cells occurs.

Receptors Vary in Their Embryonic Origin

For auditory, vestibular, somatosensory, and olfactory systems, the various classes of receptors and ganglion cells are part of the peripheral nervous system, generated as progeny of neuroblasts located in neural crests and sensory placodes. That is not the case for photoreceptors and retinal ganglion cells. The retina is generated as a protrusion of the embryonic diencephalon and thus all its neurons and supporting cells are CNS derivatives of neural tube origin. As a result of their origin, receptors and ganglion cells of the auditory, vestibular, and somatosensory systems and the OSNs of the nasal epithelium are supported by classes of non-neuronal cells that include modified epithelial supporting cells and Schwann cells. Photoreceptors and retinal ganglion cells, by contrast, are supported by CNS neuroglial cells. Most dramatic of all the consequences resulting from this difference in origin is the ability of axons in somatosensory peripheral nerves to regenerate and reinnervate targets after they are damaged, as opposed to the complete and permanent loss of visual function when optic nerves are cut or crushed.

For all systems except the olfactory, the receptor neurons you were born with are the ones you will live with. Nothing new is added. OSNs, however, have short lives, since they die off and are replaced every 60 days or so. What is seen for all systems, however, is the progressive decline in the number of receptors and in sensory acuity with normal aging. Somatosensory mechanoreceptors in humans are reduced by more than half from the age of 25 years to 65 years. Degeneration of photoreceptors is common as is a progressive reduction in hair cells of both the cochlea and the vestibular organs. Even the OSNs fail to keep up with the ravages of age, since the rate of generation does not match the rate of degeneration. The result in every case is a marked reduction in acuity that can lessen the hedonic value of foods and flowering plants, render a person deaf or blind, and leave him unsteady while standing or walking.

PERIPHERAL ORGANIZATION AND PROCESSING

Sensory Information Is Transmitted along Labeled Lines

A long-appreciated principle that unites structure and function in a sensory system is the doctrine of specific energy, or the *labeled line* principle. This principle states that when a particular population of neurons is active, the conscious perception is of a specific stimulus (Fig. 22.3). For example, activity in one particular population of somatosensory neurons (colored orange in Figure 22.3), leads the CNS to interpret it as a painful stimulus, no matter whether the stimulus is natural (a sharp instrument jabbed into the skin) or artificial (electrical stimulation of the appropriate axons). An entirely separate population of neurons (colored blue in Figure 22.3) would signal light pressure. Why this is so can be seen from the fact that receptors are selective not only in what drives them, but also in the postsynaptic targets with which they communicate. Each ganglion cell transmits its activity into a well-defined region of the CNS, after which a strictly organized series of synaptic connections relays information in a sequence that eventually leads to the thalamus and then to the cerebral cortex (Darian-Smith et al., 1996). It is this orderly relay from receptor to ganglion cell to central neurons at each of several stations that makes up a labeled line. All sensory information arising from a single class of receptors is referred to as a *modality* (e.g., the sensations of pain and light pressure involve distinct modalities). Thus, the existence of labeled lines means that neurons in sensory systems carry specific modalities.

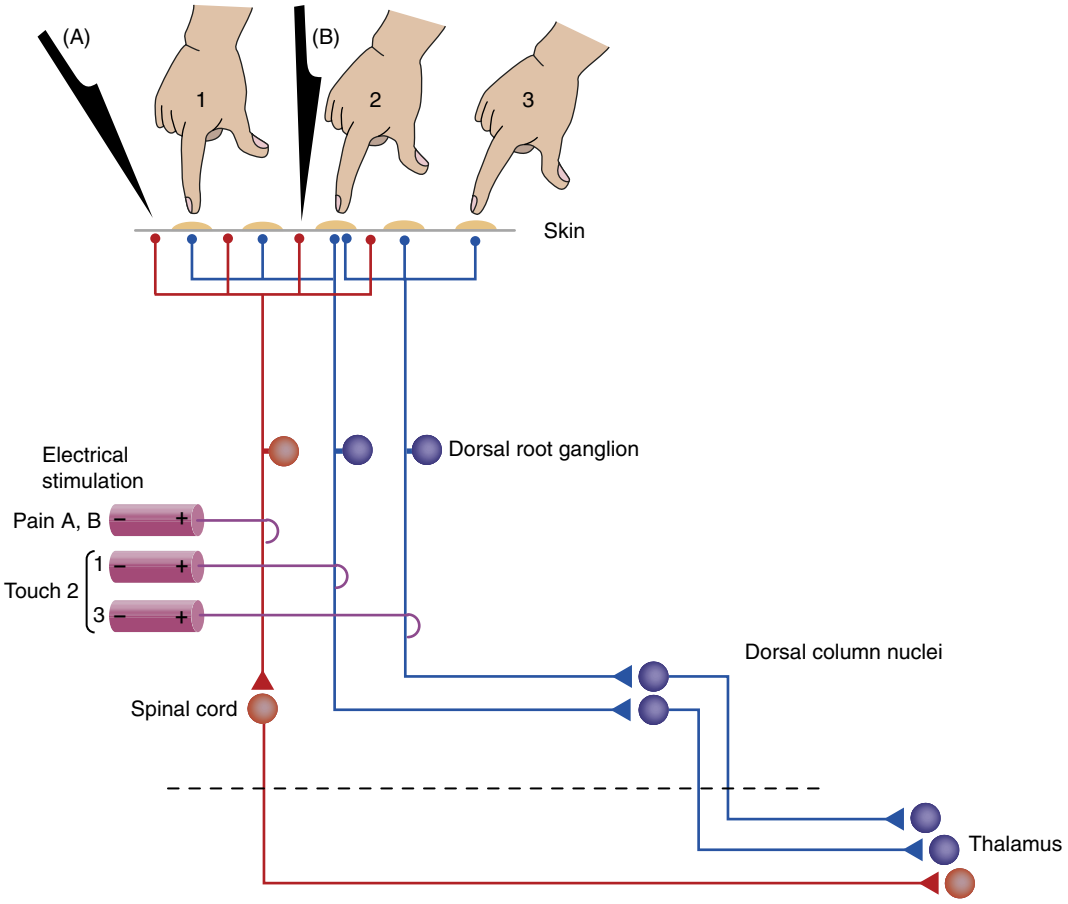

FIGURE 22.3 Example of labeled lines in the somatosensory system. Two dorsal root ganglion (DRG) cells (blue) send peripheral axons to be part of a touch receptor, whereas a third cell (red) is a pain receptor. By activating the neurons of touch receptors, direct touching of the skin or electrical stimulation of an appropriate axon produces the sensation of light touch at a defined location. The small receptive fields of touch receptors in body areas such as the fingertips permit distinguishing the point at which the body is touched (e.g., position 1 vs. position 2). In addition, convergence of two DRG axons onto a single touch receptor on the skin permits touch stimulus 2 to be localized precisely. Electrical stimulation of both axons produces the same sensation, although localized to somewhat different places in the skin. Sharp stimuli (A, B) applied to nearby skin regions selectively activate the third ganglion cell, eliciting the sensation of pain. Electrical stimulation of that ganglion cell or of any cell along that pathway also produces a sensation of pain along that region of skin. Stimuli A and B, however, cannot be localized separately with the pain receptor circuit that is drawn. As the labeled lines project centrally, they cross the midline (decussate) and project to separate centers in the thalamus.

Topographic Projections Dominate the Anatomy and Physiology of Sensory Systems

Receptors in the retina and body surface are organized as two-dimensional sheets, and those of the cochlea form a one-dimensional line along the basilar membrane. Receptors in these organs communicate with ganglion cells and those ganglion cells with central neurons in a strictly ordered fashion, such that relationships with neighbors are maintained throughout. This type of pattern, in which neurons positioned side by side in one region communicate with neurons positioned side-by-side in the next region, is called a *topographic pattern*. As an example, the two touch-sensitive neurons in Figure 22.3 innervate somewhat different positions in the skin. Thus, light touch at position 3 will activate the rightmost ganglion cell in the dorsal root ganglion, whereas touch at position 1 will activate the neighboring ganglion cell. The central projections of these cells are kept separate and activate different targets in the thalamus and above. The end result is a map of the sensory surface of the skin. A different topography is seen in the olfactory system. OSNs divide the nasal epithelium into zones in which sensitivity to a particular range of odorants is maximally represented. A large-scale map has the OSNs in neighboring zones of the epithelium communicate with neighboring regions in the olfactory bulb. Yet the small-scale map from epithelium to bulb displays a fundamental rearrangement in which all OSNs expressing a particular receptor protein send convergent inputs to a single synaptic region (a glomerulus) in the bulb. In general, topographies are a place code for sensory information in which the location of a particular neuron tells you what that neuron responds to, both in place along the sensory surface and in modality.

Neural Signaling Is by a Combination of Rate and Temporal Codes

A great deal of research has been aimed at determining the codes by which neurons signal the presence and the intensity of a stimulus. In addition to place codes, neurons can signal information in the rate at which they respond and in the temporal pattern of their response. For a given receptor, the firing rate or frequency of action potentials signals the strength of the sensory input. The perceived intensity arises from an interaction between this firing rates and the number of neurons activated by a stimulus. Together the number of neurons active with any sensory stimulus and the level of their activity give rise to an intensity code. This is the kind of code used by retinal ganglion cells to signal the intensity (luminance) of light and by spiral ganglion cells to signal the intensity (sound pressure level) of sound. Temporal codes are also used in some systems. For instance, the phase-locking ability of auditory neurons extends to sound frequencies up to a couple thousand cycles per second (kHz), and this code is used for the perception of the pitch of sounds. In addition, all sensory systems must deal with the fact that stimuli can move, as with vibratory stimuli on the skin. This temporal information in a stimulus is carried by the time-varying pattern of activity in small groups of receptors and central neurons.

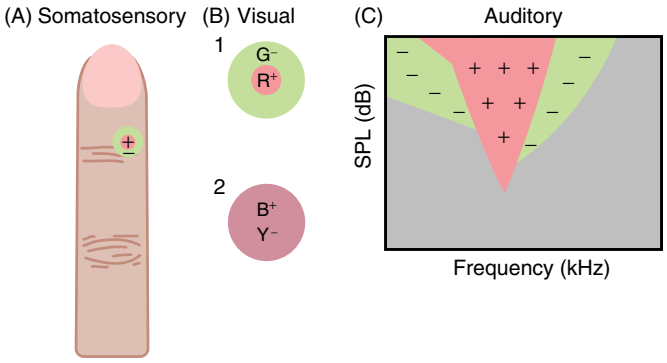

FIGURE 22.4 Center/surround organization of receptive fields is common in sensory systems. In this organization, a stimulus in the center of the receptive field produces one effect, usually excitation, whereas a stimulus in the surround area has the opposite effect, usually inhibition. (A) In the somatosensory system, receptive fields display antagonistic centers and surrounds because of skin mechanics. (B) In the retina and visual thalamus, a common type of receptive field is antagonistic for location and for wavelength. Receptive field 1 is excited by turning on red light (R) at its center and is inhibited by turning on green light (G) in its surround. Receptive field 2 is less common and is antagonistic for wavelength (blue vs. yellow) without being antagonistic for the location of the stimuli. Both are generated by neural processing in the retina. (C) In the auditory system, primary neurons are excited by single tones. The outline of this excitatory area is known as the tuning curve. When the neuron is excited by a tone in this area, the introduction of a second tone in flanking areas usually diminishes the response. This "two-tone suppression" is also generated mechanically, as is seen in motion of the basilar membrane of the cochlea. All of these center/surround organizations serve to sharpen responses over that which would be achieved by excitation alone.

Lateral Mechanisms Enhance Sensitivity to Contrast

A hallmark of all sensory systems is the ability of neurons at even the earliest stages of central processing to integrate the activity of more than one receptor. The most common and easily understood of these mechanisms is *lateral* (or surround) *inhibition* (Fig. 22.4). By this mechanism, a sensory neuron displays a receptive field with an excitatory center and an inhibitory surround (Kuffler, 1953). Such a mechanism serves to enhance contrast: each neuron responds optimally to a stimulus that occupies most of its center but little of its surround. In some cases the comparisons involve receptors of different types so that the center and surround differ not only in sign (excitation vs. inhibition, ON vs. OFF), but also in the stimulus quality to which they respond.

One such example occurs in visual neurons that possess centers and surrounds responsive to stimulation of different types of cones. These cells display a combination of spatial contrast (the difference in the location of cones that produce center and surround) and chromatic contrast (the difference in the visible wavelengths to which these cones respond best). Similar types of responses are evident in the somatosensory system, where the difference between center and surround is the location on the skin from which each is activated. In this case, skin mechanics produce receptive fields with a central hot spot of activity and a surrounding inactive zone. In the auditory system, lateral suppressive areas (Fig. 22.4) are also produced by mechanics, in this case the mechanics of the basilar membrane of the cochlea. These two-tone suppression areas are demonstrated by exciting the auditory nerve fiber with a tone in the central excitatory area and observing the response decrease caused by a second tone in flanking areas (Sachs & Kiang, 1968). In all these sensory systems, center/surround organization serves to sharpen the selectivity of a neuron either for the position of the stimulus or for its exact quality by subtracting responses to stimuli of a general or diffuse nature.

CENTRAL PATHWAYS AND PROCESSING

Axons in Each System Cross the Midline on Their Way to the Thalamus

Axons of ganglion cells entering the CNS form the initial stage in a pathway through the thalamus to the cerebral cortex (Fig. 22.5). Axons in visual, somatosensory, and auditory systems cross the midline—they *decussate*—prior

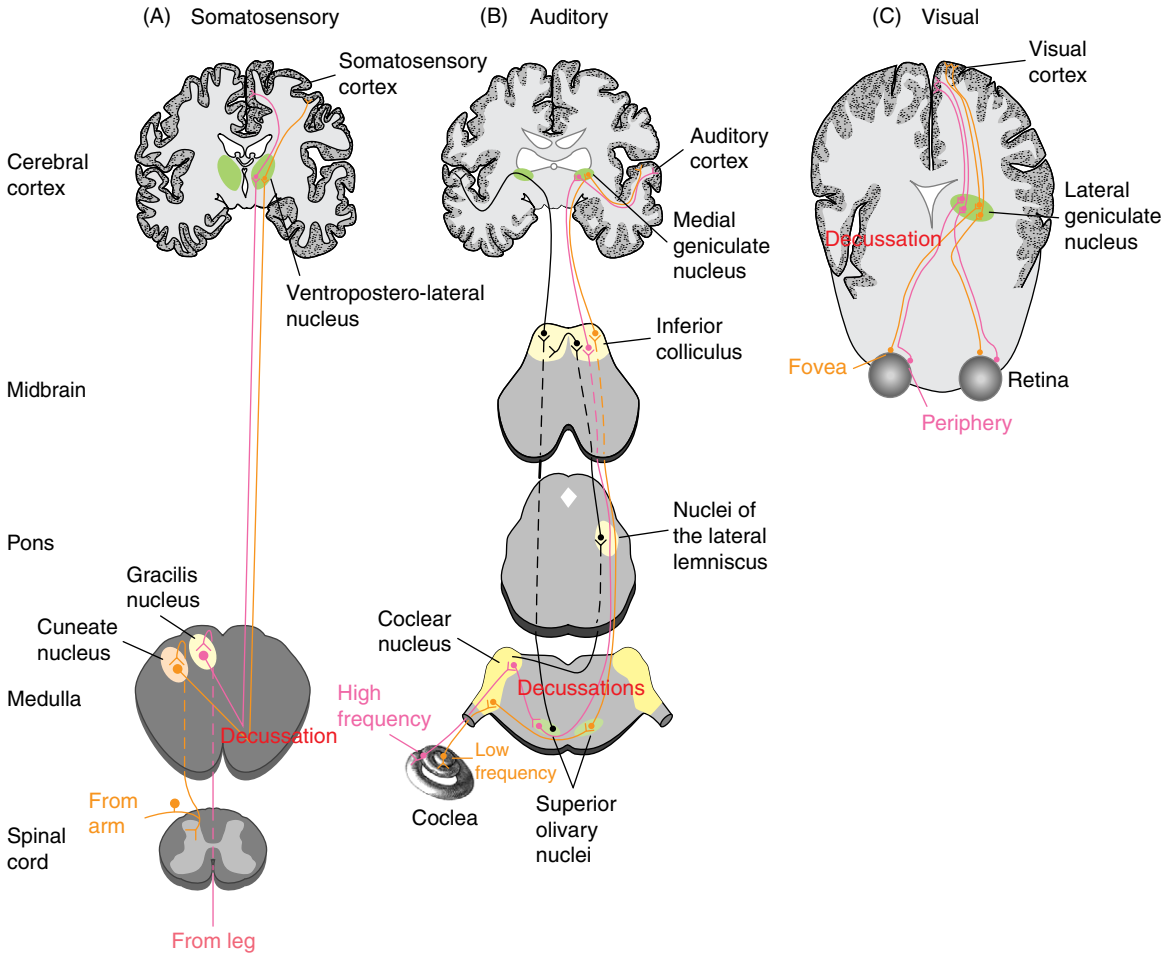

FIGURE 22.5 Comparison of central pathways of sensory systems. In every case, soon after peripheral input arrives in the brain, decussations result in one hemifield being represented primarily by the brain on the opposite side. Each pathway has a unique nucleus in the thalamus and several unique fields in the cerebral cortex. Within each of these areas, the organized mapping that is established by receptors in the periphery is preserved.

to reaching the thalamus, but those of the olfactory and gustatory systems do not. A single, incomplete decussation occurs in animals with frontally placed eyes, where slightly more than half the axons of the optic nerve cross the midline at the optic chiasm. Near complete decussations at the optic chiasm are seen in animals with laterally placed eyes. Decussation in the somatosensory system is nearly total, since all but a small group of axons cross the midline in the spinal cord or brainstem. These decussations serve two broad functions: They bring together into one hemisphere all axons carrying information from half the visual world or they bring somatosensory information into alignment with visual input and motor output. In contrast, multiple decussations occur in the auditory system prior to the thalamus, since comparison of input from the two ears is the dominant requirement of sound source localization. Nevertheless, at high levels in the auditory system, one side of the brain is concerned mainly with processing information about sound sources located toward the opposite side of the body, as demonstrated by lesion/behavioral studies of sound localization.

Specific Thalamic Nuclei Exist for Each Sensory System

Information from all sensory systems except the olfactory are relayed through the thalamus on its way to the cerebral cortex (Fig. 22.5). Olfactory information reaches primary olfactory cortex without a relay in thalamus. Yet even in this sense, perception of odorants and discrimination of one odorant from another occurs only after a thalamic relay. This relay of sensory input through the thalamus involves either a single large nucleus or, in the case of the somatosensory systems, two nuclei: one for the body and one for the face. In each thalamic nucleus, synaptic circuits are said to be secure because activity in presynaptic axons usually leads to a postsynaptic response. Within the

thalamic nuclei, neurons performing one function (e.g., relay of discriminative touch) are segregated from those performing another (e.g., relay of pain and temperature). Even within one function, mappings of neurons are preserved so that there is separation of neurons providing touch information from the arm versus from the leg and of neurons responding to low versus high sound frequencies (Fig. 22.5). Usually, for each thalamic nucleus, there is a population of large neurons and one or two populations of small neurons (Jones, 1981). In each case the larger neurons carry the most rapidly transmitted signals from the periphery to the cortex.

Multiple Maps and Parallel Pathways

Nuclei in the central pathways often contain multiple maps. For instance, in the auditory system, axons of spiral ganglion cells divide into branches as they enter the CNS and terminate in three subdivisions of the cochlear nucleus. Each division contains its own map of sound frequency that was originally established by the cochlea. The greatest number of maps generated from ganglion cell input is found in the visual system of primates, in which as many as 12 separate retinotopic maps are stacked on top of one another in the lateral geniculate nucleus (LGN, in the thalamus), which receives direct input from the retina. Such a large number of distinct maps in the LGN is indicative of inputs from ganglion cells that vary in location, structure, and function. For vision, one idea is that surface features such as color and form are carried along a path separate from the one that handles three-dimensional features of motion and stereopsis. The functional significance of multiple maps in general, however, remains to be clarified. Perhaps the need for multiple parallel paths exists because of the relatively slow speed and the limited capacity of single neurons. So rather than have the same group of neurons perform different functions in serial order, each of several parallel groups performs a separate function. This leads eventually to the problem of binding together all features of a stimulus into a coherent percept, the neural basis for which may be the synchronized activity of neurons across several areas of the cerebral cortex (Singer, 1995).

SENSORY CORTEX

Sensory Cortex Includes Primary and Association Areas

Axons of sensory relay nuclei of the thalamus project to a single area or a collection of neighboring areas of the cerebral cortex, thereby providing them with a precise topographic map of the sensory periphery. These parts of the cortex are frequently referred to as *primary sensory areas* (Fig. 22.6). Neighboring areas with which the primary areas communicate directly or by a single intervening relay area are sensory *association areas.*

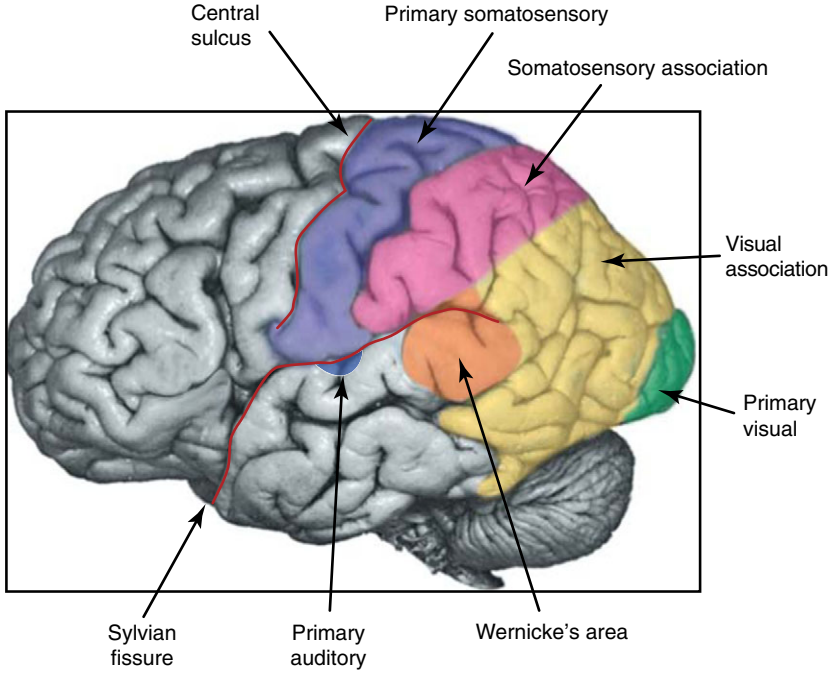

FIGURE 22.6 The location of primary sensory and association areas of the human cerebral cortex. The primary auditory cortex is mostly hidden from view within the Sylvian fissure. *From Guyton and Hall (2000).*

Response Mappings and Plasticity

Each area of sensory cortex shares with its subcortical components a map of at least part of the sensory periphery. Thus, retinotopic, somatotopic, and tonotopic maps are evident in the relevant areas of cortex; no such map exists for the chemical senses, however. The retina and skin are two-dimensional sheets so the map of the sensory periphery on the surface of the cortex is a simple transformation of the peripheral representation onto the cortex. In the auditory periphery, there is a one-dimensional mapping of frequency. This tonotopic mapping is faithfully represented along one dimension of cortical distance, and the orthogonal direction may map a second, as yet undiscovered, property.

As indicated above, the distribution of receptors is uneven for most systems. Thus, the fovea of the primate retina and the fingertips of the primate hand are regions that possess a high density of receptors with small receptive fields. Such an uneven distribution of neurons devoted to a structure is further amplified in the CNS. A much greater percentage of neural machinery subserves the representation of the retinal fovea or the fingertips than deals with the representation of other regions of the retina or body surface (Fig. 22.7). This expansion of a representation in the CNS, referred to as a *magnification factor*, appears particularly impressive in humans, in whom a very large part of primary visual cortex is devoted to the couple of millimeters of retina in and around the fovea. In the auditory cortex, such magnification of frequency representation is again seen in echolating bats, since the region devoted to the Doppler-shifted signaling frequency is much enlarged over that for any other set of frequencies.

It is now clear that maps of sensory cortex are not fixed and immutable but rather plastic. In the somatosensory system, if input from a restricted area of the body surface is removed by severing a nerve or by amputation of a digit, the portion of the cortex that was previously responsive to that region of the body surface becomes responsive to neighboring regions (Merzenich et al., 1984). In the auditory system, following high-frequency hearing loss, the portion of cortex previously responsive to high frequencies becomes responsive to middle frequencies. Frequency tuning of neurons or auditory cortex can also be shifted with classical conditioning methods (Weinberger, 2007). Such plasticity of cortical maps requires some time to be established and could result from strengthening of already established lateral connections or from growth of new connections. It is likely but not firmly established that the same types of mechanisms cause cortical changes during the processes of learning and memory.

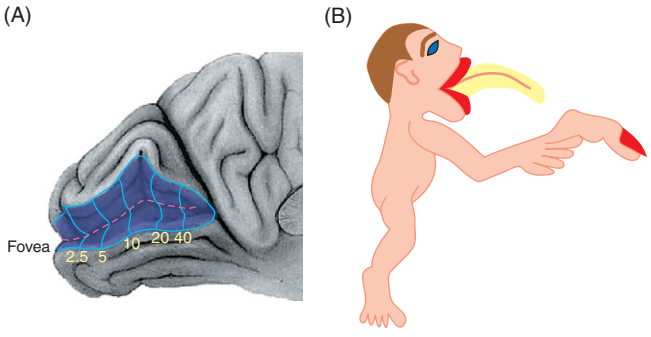

FIGURE 22.7 Examples of sensory magnification in the visual and somatosensory systems. (A) Determination of a visual field map in the human primary visual cortex shows that more than half this area is devoted to the central 10° of the visual field. Very little is devoted to the visual periphery beyond 40°. *From Horton and Hoyt (1991).* (B) Figure of how the human body would appear if the body surface were a perfect reflection of the map in the first somatosensory cortex. The mouth and tongue and the tip of the index finger enjoy a greatly enlarged representation in the thalamus and cortex.

A Common Structure Exists for Sensory Cortex

Neurons in areas of the sensory cortex (and most other areas of the cerebral cortex) are organized into six layers. The middle layers (III and IV) are the main site of termination of axons from the thalamus (Fig. 22.8). In the primary sensory cortices, these middle layers are enlarged and contain many small neurons. Because the small cells resemble grains of sand in standard histological preparations, the sensory areas are themselves referred to as granular areas of cortex.

Columnar Organization

Properties other than place in the periphery are mapped in primary sensory areas of the cortex. The third spatial dimension of the cortex, that of depth, arranges neurons in adjacent 0.5- to 1-mm-wide regions, referred to as *columns* (Mountcastle, 1997). In these columns, neurons stacked above and below one another are fundamentally similar but differ significantly from neurons on either side of them. One example of columns with a clear anatomical correlate is the division of the primary visual cortex of most primates and some carnivores into a series of alternating regions dominated by the right and left retinas. Each ocular dominance column contains cells driven exclusively or predominantly by one eye; adjacent columns are dominated by the other eye. Other properties, such as selectivity for the orientation of a visual stimulus and the contrast between it and the surround, are also arranged in columns of primary visual cortex (Hubel, 1988). Similar types of columns are evident in the somatosensory system as regions of modality and place specificity. They are most clearly seen in the representation of mystacial vibrissae in rodent somatosensory cortex, where a one-to-one matching of vibrissa with cortical territory gives rise to structures called barrels. In the auditory

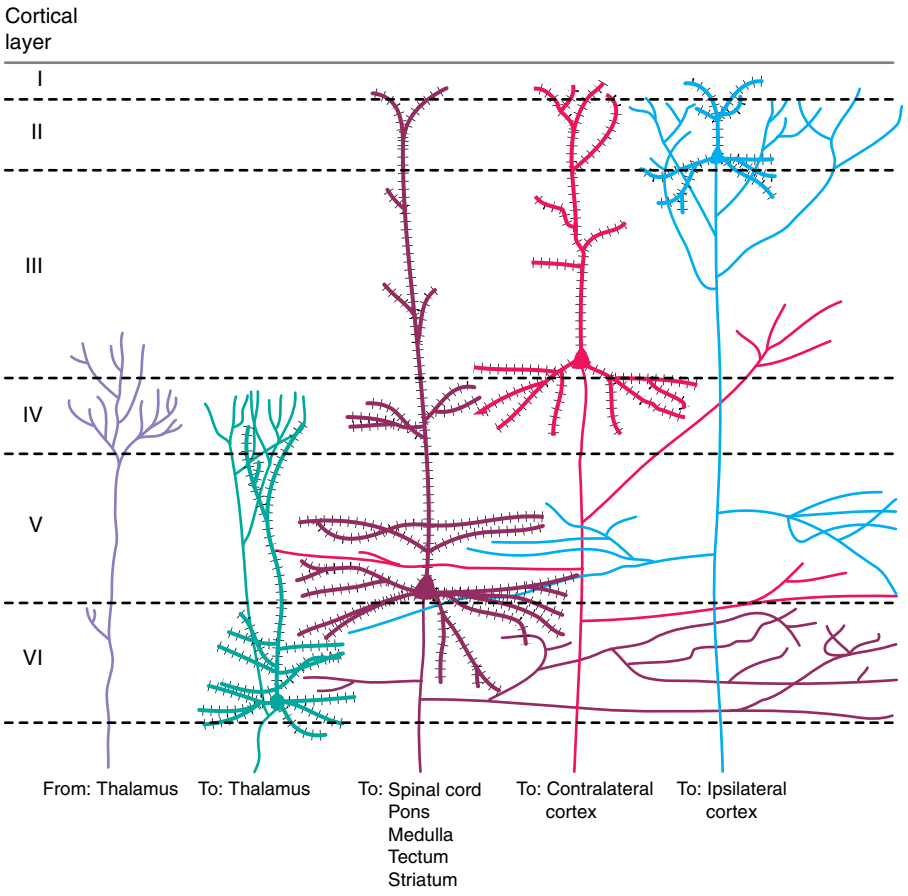

FIGURE 22.8 Cellular organization of the sensory cortex into six layers (I–VI). Inputs from the thalamus terminate mainly in layers III and IV. The main output neurons of the cortex are pyramidal cells, which are distributed in different layers according to their projections. Descending projections are to the thalamus (neurons in layer VI) or to the spinal cord, pons and medulla, tectum, or striatum (neurons at various levels in layer V). Ascending projections to other "higher" cortical centers are often from neurons located above layer IV; some of these projections are to the same hemisphere (layer II) or to the opposite hemisphere (layer III). *Adapted from Jones (1984).*

system, neurons within a column generally share the same best frequency and the same type of binaural interaction characteristic: either one ear excites the neurons and the other inhibits or suppresses the response to the first ear (suppression column) or one ear excites and the other ear also excites or facilitates the response to the first ear (summation column). Moreover, in areas of nonprimary cortex, the feature displayed most commonly by neurons of a particular area is one that often comes to occupy columns. A good example is found in the middle temporal area (MT or V5) of visual association cortex, where neurons are tuned for the direction of a moving visual stimulus. Neurons selective for one particular direction of visual stimulus movement are organized into columns through the depth of MT; these are flanked by columns of neurons tuned for other directions of movement (Albright, Desimone, & Gross, 1984). So consistent are these findings among sensory, motor, and association areas that columnar organization is viewed as a principal organizing feature for all of the cerebral cortex (Mountcastle, 1997).

Stereotyped Connections Exist for Areas of Sensory Cortex

Neurons of the cerebral cortex send axons to subcortical regions throughout the neuraxis and to other areas of the cortex (Fig. 22.8). Subcortical projections are to those nuclei in the thalamus and brainstem that provide ascending sensory information. By far the most prominent of these is to the thalamus: the neurons of a primary sensory cortex project back to the same thalamic nucleus that provides input to the cortex. This system of descending connections is truly impressive because the number of descending corticothalamic axons greatly exceeds the number of ascending thalamocortical axons. These connections permit a particular sensory cortex to control the activity of the very neurons that relay information to it. One role for descending control of thalamic and brainstem centers is likely to be the focusing of activity so that relay neurons most activated by a sensory stimulus are more strongly driven and those in surrounding less well activated regions are further suppressed.

A large number of cortical neurons project to other areas of cortex (Fig. 22.8). Cortico-cortical projections link primary and association areas of the sensory cortex and establish parallel paths so that different aspects of vision, audition, and somatic sensation come to be handled by different areas of cortex. These connections establish a hierarchy within a system, such that "ascending" or "forward" connections begin with neurons from superficial cortical layers (I–III) and end with axonal terminations mainly in layers III and IV of higher cortical regions. Similarly, the ascending projection from the thalamus terminates mainly in these layers in primary sensory cortices. Corresponding descending projections from higher to lower cortical regions begin in the deep or superficial cortical layers and project to layers outside of III and IV. In addition to projections to the ipsilateral hemisphere of cortex, there are also projections to the contralateral hemisphere via the corpus callosum and other commissures. In visual and somatosensory systems, these commissural connections are restricted in origin and termination; they exist to unite the representation of midline structures into a coherent percept (Hubel, 1988).

Response Complexity of Cortical Neurons

Responses of cortical neurons in primary sensory cortices are more complex than those seen for neurons in the periphery. One example is seen in the primary visual area of the cerebral cortex, where neurons are responsive to stimuli that are not concentric circles (center and surround) but elongated lines possessing a specific orientation. Comparable synthesis of simpler inputs to reconstruct more complex features of stimulus is apparent at higher levels in the visual system (Logothetis & Sheinberg, 1996) and in the somatosensory and auditory areas of the cerebral cortex.

Physiologically, processing and selectivity for stimulus features become progressively more complex within the hierarchically organized pathways that connect primary with association areas of the cortex (Gallant & Van Essen, 1994). In the visual system, separate "streams" involved in visuosensory and eventually visuomotor functions have been described; one is responsible for using visual cues to drive appropriate eye movements and the other for dealing with the tasks of visual perception (Gallant & Van Essen, 1994). In the somatosensory system, separate motor and limbic paths exist to perform much the same functions for the entire body, supplying sensory input to coordinate and adjust motor output and using complex input from many receptor types to match the shape of a tactual stimulus with one already stored in memory (Johnson & Hsiao, 1992). In the association pathways of the human auditory system, a specialized area of cortex, Wernicke's area, plays a fundamental role in processing speech and language information and in communicating with Broca's area to form a speech motor response. These streams are not separate because traditionally viewed "motor" areas such as Broca's are now known to become activated in comprehension tasks. Apparent from this pattern in association areas of the cortex is the continued pressure for a division of labor within each sensory system, not one that produces separate paths for analyzing elemental features of a stimulus but one that combines those features either to elicit appropriate movements or to match a stimulus with an internal representation of the world.

SUMMARY

The functional organization of sensory systems shares common themes of transduction, relay, organized mappings, parallel processing, and central modification. It is no surprise that a case has been made for a common phylogenetic origin of sensory systems. Differences among the systems, however, demonstrate that each has existed and operated independently for as long as there have been vertebrates. What remains in overview is a well-ordered basic plan from periphery to perception that has been modified in its details as variations in niche have led to specializations in function.

CHAPTER

23

Chemical Senses: Taste and Olfaction

Some of the most remarkable feats in the animal kingdom are accomplished using chemical detection. For example, the male silk moth follows the scent of a female for several miles to reach its mate. A great white shark is able to detect one drop of blood in an Olympic-size swimming pool to identify prey. More than 30 million chemical compounds have been catalogued. Different chemical combinations emitted by foods, predators, and mates allow animals to distinguish among them. The gustatory and olfactory senses allow detection of this enormous number of chemicals and translate this information into meaningful behaviors. The identification of large chemoreceptor families, the ability to monitor cell activity in the periphery and central nervous system, and the ability to genetically manipulate chemosensory systems in model organisms are revolutionizing our understanding of chemosensory systems and explaining how the brain encodes flavors and fragrances.

TASTE

The sense of taste is primarily involved in feeding, allowing animals to identify food that is nutrient-rich and to avoid toxic substances. The sensory cues detected by the gustatory system are soluble chemicals, limiting detection to a short range by direct contact with a chemical source. The concentration range for taste detection is broad and depends on the nature of the chemical stimulus. At one extreme, taste cells detect sugars and amino acids at very high concentrations (100 millimolar), allowing animals to detect food with high nutritional value. At the other extreme, taste cells can also detect minute amounts of noxious substances or toxins, compounds that are harmful at very low concentrations. Mammals are thought to perceive only five taste modalities: sweet, bitter, sour, salty, and umami (the taste of the amino acid glutamate), with several chemicals in most categories.

How the brain translates chemical detection into the perception of different taste modalities and taste behaviors is a basic problem in neural coding. Of course, the gustatory system does not work in isolation, and the smell, texture, and sight of food also contribute to flavor perception. For example, without our olfactory neurons, we are unable to recognize coffee, chocolate, or wine! However, it is the gustatory system that acts as the final checkpoint controlling food acceptance or rejection and is essential for the basic recognition of taste modalities. Understanding the neural coding of taste information begins with knowledge about how taste receptor cells detect chemical cues, an area of rapid advances. How taste quality is encoded in higher brain areas is an area of active investigation that will ultimately require unraveling neural circuits and neural activity underlying taste behavior.

Taste Cells Are Situated within Taste Buds Located in Several Distinct Subpopulations

In mammals, taste recognition begins on the tongue, where specialized cells detect chemical cues. Mammalian taste cells are derived from epithelial tissue rather than neural tissue, although they display neural properties such as depolarization and release of neurotransmitters. The apical tip of each receptor cell contains microvilli that project into the mucus of the oral environment. The microvilli are the site of taste detection, where taste ligands interact with membrane-bound receptors or ion channels. The basolateral membrane of taste cells forms chemical

synapses with primary gustatory nerve fibers. The nerve fibers enter the base of the taste bud and transmit taste detection to the brain.

Groups of 50 to 100 taste cells are clustered together into taste buds (Fig. 23.1). The apical center of the taste bud is the taste pore, where the microvilli of taste cells interact with the environment. Groups of taste buds are located primarily within papillae on the tongue, although they are distributed on other parts of the oral cavity as well (Fig. 23.2). Three classes of papillae are defined based on their location on the lingual epithelium: fungiform papillae on the anterior tongue, foliate papillae on the posterior sides, and circumvallate papillae on the posterior midline. In addition, taste cells are found on the palate and the epiglottis. Taste receptor cells undergo constant renewal, arising from an underlying population of basal epithelial cells.

Taste buds are innervated by dendrites of neurons that travel in the facial (VIIth), glossopharyngeal (IXth), or vagus (X) nerves to gustatory nuclei in the brainstem. Different regions of the tongue are innervated by different nerves. Fungiform papillae and the foliate papillae on the anterior tongue are innervated by the chorda tympani branch of the facial nerve. Taste buds on the soft palate receive fibers from the greater superficial petrosal (GSP) branch of the facial nerve. Circumvallate and posterior foliate papillae are innervated by the lingual-tonsillar branch of the glossopharyngeal nerve. Taste buds of the epiglottis and the esophagus are innervated by the internal branch of the superior laryngeal nerve (SLN), which is a branch of the vagus (Xth) nerve. A single nerve fiber may innervate cells in more than one taste bud, and each taste bud is innervated by several different afferent fibers.

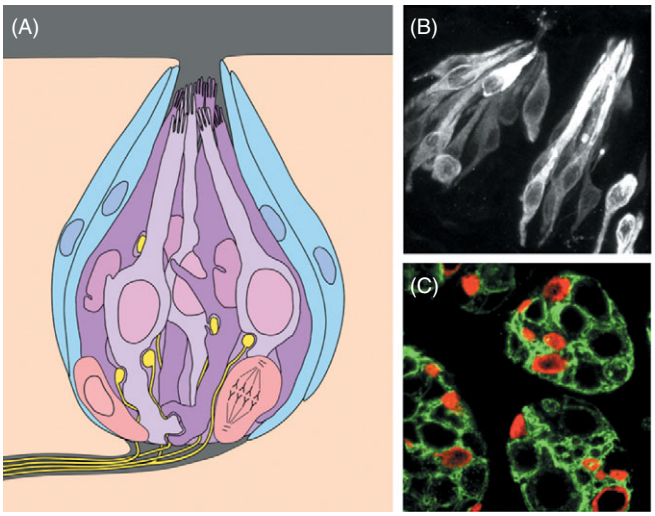

FIGURE 23.1 Cell types in mammalian taste buds. (A) The taste bud contains approximately 50–100 taste cells. These epithelial receptor cells make synaptic contact with distal processes of cranial nerves VII, IX, or X, whose cell bodies lie within the cranial nerve ganglia. Microvilli of the taste receptor cells project into an opening in the epithelium, the taste pore, where they make contact with gustatory stimuli. (B) The characteristic spindle shape of taste receptor cells is revealed when a subset of taste cells is labeled with an antibody against α-gustducin, a gustatory G protein. (C) Gustducin-positive cells appear round in cross section, as shown by α-gustducin immunoreactivity (red), whereas other cells are revealed with an antibody against the H blood group antigen (green).

Mechanisms of Taste Detection by Receptor Cells

Recent fundamental discoveries have begun to identify the receptor molecules that detect taste ligands. There are two different families of G-protein-coupled receptors that mediate the detection of sugars: amino acids and bitter compounds. In addition, candidate ion channels for the recognition of salts and sour compounds have been identified.

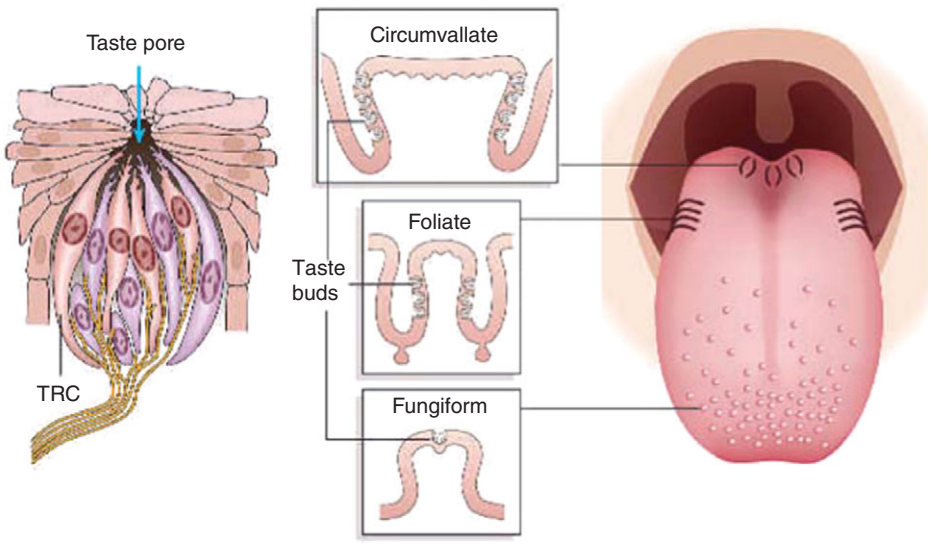

FIGURE 23.2 Diagram of a tongue showing the distribution of various taste bud populations, which are found in the fungiform papillae on the anterior tongue, the vallate and foliate papillae on the posterior tongue. These taste buds are innervated by branches of the VIIth, IXth, and Xth cranial nerves (see text). *Reprinted by permission from Macmillan Publishers LTD:* Nature 444*(7117): 288–94, copyright 2006.*

The T1R Receptor Family Mediates the Taste of Sugars and Amino Acids

In mammals, a small family containing three genes mediates the detection of sugars and amino acids. The Taste Receptor 1 family is comprised of the T1R1, T1R2, and T1R3 receptors (Hoon et al., 1999). These receptors are G-protein-coupled receptors with large extracellular domains similar to the metabotropic glutamate receptors. The receptors function as heterodimers. T1R2 plus T1R3 recognizes sugars and T1R1 plus T1R3 detects amino acids (Nelson et al., 2001, 2002).

The following evidence demonstrates that the combination of T1R2 plus T1R3 recognizes sugars. First, as expected for taste receptors, the T1Rs are expressed in taste cells on the tongue. Second, mice engineered to lack either T1R2 or T1R3 do not detect sugars, as determined by electrophysiological recordings of taste nerves (Fig. 23.3) and by behavioral taste tests. Whereas normal mice prefer sugar water to water, mice lacking these receptors do not. Third, heterologous cells that coexpress T1R2 and T1R3 respond to sugars, but those that express T1R2 or T1R3 alone do not. This argues that T1R2 and T1R3 act together to detect sugars. Equivalent experiments demonstrate that the combination of T1R1 and T1R3 recognizes amino acids. Thus, T1R1 is selective for amino acids, T1R2 sugars, and T1R3 is an obligate partner for both amino acid and sugar detection.

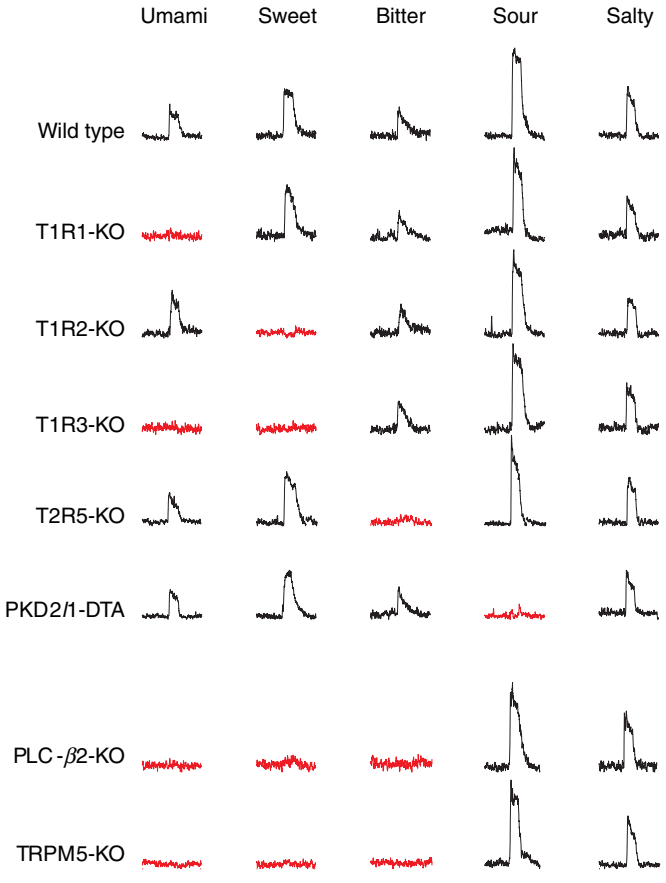

FIGURE 23.3 Mice lacking specific taste receptors have specific taste defects. Shown are nerve recordings showing taste-induced activity to amino acids, sugars, bitter compounds, sour compounds, and salts. Wild-type mice respond to all compounds. Mice lacking T1R1 do not detect amino acids, mice lacking T1R2 do not detect sugars, and mice lacking T2R5 do not detect specific bitter compounds. *Reprinted by permission from Macmillan Publishers LTD:* Nature 444*(7117): 288–94, copyright 2006.*

Mammals detect a wide array of sugars and amino acids only at high concentrations (10–100 mM), allowing them to recognize compounds that provide nutritional value. The T1R receptors have apparently solved the problem of detection by having low affinity ligand-binding sites. Differences in ligand recognition are found in different species. For example, the taste of umami in humans is the taste of the amino acid glutamate. The human T1R1 plus T1R3 amino acid receptor binds to glutamate with a tenfold higher affinity than other amino acids. In contrast, the mouse T1R1 plus T1R3 receptor recognizes all amino acids with similar affinity. Thus, mice have an amino acid taste, whereas humans have an umami taste. Although this may sound like humans are short-changed, it may not be the case. Because foods that have one amino acid generally contain many, the enhanced ability to detect glutamate in humans may actually enhance detection of all amino acids. The observation that T1R sequence variation underlies differences in taste detection also occurs for sugars. For example, we find aspartame (Nutrasweet) sweet, but mice and rats do not detect it due to amino acid differences in T1Rs. Interestingly, cats lack a functional T1R2 receptor, providing a plausible explanation for why they do not taste sugars. These studies highlight the role of T1Rs in sugar and amino acid taste detection in mammals and demonstrate that sequence differences in T1Rs can account for species-specific taste preferences.

The T2R Receptor Family Mediates Bitter Taste Detection

A common variation in human behavior is the ability to detect the bitter compound phenylthiocarbamide (PTC). In 1931, a scientist at the Dupont chemical company synthesized this compound and quickly came to the realization that although it was flavorless to him, his colleague found it unbearably bitter. Since then, numerous human taste tests (often done in high school classes) have revealed that the ability to detect PTC and a related compound, n-propyl uracil (PROP), behaves as a classic inherited recessive trait with taster and nontaster alleles (see Box 23.1). The identification of the genomic location linked to PTC detection enabled the identification of genes associated with this chromosomal interval and the seminal discovery of a large family of related mammalian bitter taste receptors.

The Taste Receptor 2 family (T2R) of bitter receptors is a family of G-protein-coupled receptors whose members, unlike T1Rs, contain a small extracellular domain, and most

BOX 23.1

IDENTIFYING A GENETIC LOCUS LINKED TO BITTER TASTE PERCEPTION

The ability to taste the compound phenylthiocarbamide (PTC) varies dramatically among humans. Approximately 75% of people find PTC intensely bitter, whereas 25% do not detect it. The ability to detect PTC was linked to a small region of chromosome 7 in human genetic studies. The taste receptor gene T2R38 is located within this interval, and variations in its sequence perfectly correlate with the ability to taste PTC. In the human population, there are two major sequence variations in T2R38, which differ by three amino acids. One variant (containing the amino acid substitutions AVI) accounts for the nontasters and the other variant (containing the amino acid substitutions PAV) is the major taster allele. Thus, people with two AVI alleles are nontasters, those with one PAV and one AVI are tasters, and those with two PAV alleles are super-tasters (Kim et al., 2003). These studies demonstrate that humans vary in their ability to detect taste compounds because of variations in the sequence of taste receptors.

Kristin Scott

resemble the opsin family of GPCRs (Adler et al., 2000). There are 25 functional T2R receptors in humans, 35 in mouse and rat, and 3 in chicken. Most T2R genes are linked in large chromosomal arrays, suggesting rapid expansion of this gene family.

A number of lines of evidence conclusively demonstrate the T2Rs are bitter receptors. First, T2Rs are specifically expressed in taste cells on the tongue. Second, the receptors are localized to taste cell dendrites decorating the taste pore, the site of taste detection. Third, heterologous cells expressing T2Rs respond to bitter compounds; for example, cells expressing mT2R5 respond specifically to cyclohexamide, whereas cells containing mT2R8 respond strongly to denatonium and weakly to PROP. Fourth, mice lacking specific T2Rs show specific bitter taste defects (Mueller et al., 2005) (Fig. 23.3).

Studies of the T2R receptor family provide important insights into how animals recognize a large number of bitter compounds and are able to detect them at very low concentrations. Each T2R receptor generally recognizes only a few bitter compounds with very high affinity, allowing for very specific detection. In addition, the large number of T2R receptors ensures that animals can recognize several bitter compounds.

Mechanisms of Taste Transduction for T1Rs and T2Rs

Activation of the T1R and T2R receptors leads to cell depolarization and neurotransmitter release. In general, signal transduction mediated by G-protein-coupled receptors involves a conformational change in the receptor leading to activation of a heterotrimeric G protein, in turn activating enzymes whose byproducts regulate the activity of ion channels. For T1Rs and T2Rs, the signaling cascade proposed is that activation of T1Rs or T2Rs leads to activation of gustducin, a heterotrimeric G protein, leading to activation of the enzyme phospholipase C-β2 (PLC-β2) and depolarization by the ion channel TRPM5 (Fig. 23.4). These signaling molecules are all specific to taste cells, arguing that they are specialized for taste transduction. Importantly, mice lacking gustducin, PLC-β2 or TRPM5 do not taste sugars or bitter compounds.

Ion Channels Sense Sour and Acid Taste

Unlike sweet and bitter taste detection that rely on activation of G-protein-coupled receptors and downstream signaling molecules to regulate channel activity, the tastes of sour and salty are likely to be directly mediated by ion channels.

Sour taste is produced by acids, and the degree of sourness depends primarily on proton concentration. Patch-clamp studies suggest that several different ion channels may participate in sour transduction, which is not surprising because protons are capable of modulating most ion channels. A recent study has identified the cells that detect sour taste and express cation channels named PKD1L3 and PKD2L1 (Huang et al., 2006). PKD1L3 and PKD2L1 are cationic ion channels of the TRP family (transient receptor potential) of ion channels. Transgenic mice have been produced such that the PKD2L1 promoter drives expression of a toxin gene to kill all cells that express the channel. Mice lacking these cells do not show electrophysiological responses to sour compounds, but still respond to sugars, salts, and bitter compounds. These experiments argue that cells containing PKD2L1 are necessary for sour detection.

The ion channel that mediates sodium salt taste is the epithelial sodium channel ENaC. This channel, which is responsible for sodium transport in a variety of epithelial tissues, is expressed on the apical membrane of salt-sensitive taste cells, where it mediates the passive influx of sodium. Sodium simply diffuses through the open channels to depolarize taste cells; and is presumably pumped out by a NaK-ATPase on the basolateral membrane. The first

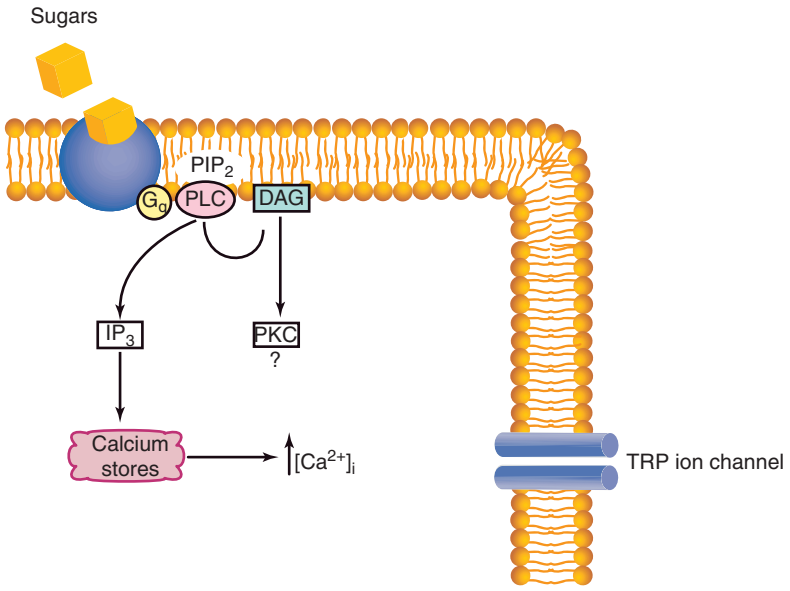

FIGURE 23.4 Taste transduction for sugars, amino acids, and bitter compounds uses a common signaling pathway. Activation of the receptor activates a heterotrimeric G protein. This activates phospholipase C-β2 (PLC-β2), producing the second messengers IP_3 and diacylglycerol (DAG). Activation of PLC-β2 leads to opening of the TRPM5 ion channel and cell depolarization.

evidence for a role of ENaC in taste came from experiments showing that the gustatory nerve response to NaCl was inhibited by amiloride, a diuretic drug known to block these channels in other transporting epithelial tissues. More recently, animals lacking ENaC only in taste cells have been shown to have specific defects in salt taste detection (Chandrashekar et al., 2010).

The Organization of Taste Receptor Genes on the Tongue

Taste receptors are segregated into different taste cells on the tongue. *In situ* hybridization experiments as well as immunohistochemistry have been used to determine the expression patterns of receptor mRNAs and proteins. These experiments demonstrated that T1Rs and T2Rs are not found in the same taste cells (Fig. 23.5). Among the T1Rs, T1R1 plus T1R3 and T1R2 plus T1R3 are segregated into different cells. In addition, the PKD1L3 and PKD2L1 candidate sour ion channel subunits are found in different cells than the T1Rs or T2Rs. This demonstrates that there are modality-specific taste cells on the tongue, with one taste cell population recognizing sugars, another amino acids (or glutamate for humans), a third bitter compounds, and a fourth sour cues. ENaC is expressed in a fifth cell population. An important conclusion is that different taste modalities are encoded by the activation of different taste cells. Our perception of only a few different tastes may stem from the fact that there are only a few different types of taste cells on the tongue. Sugar-sensing and bitter-sensing cells are also found in *Drosophila melanogaster*, suggesting that modality-specific cells are a common principle of taste systems (see Box 23.2).

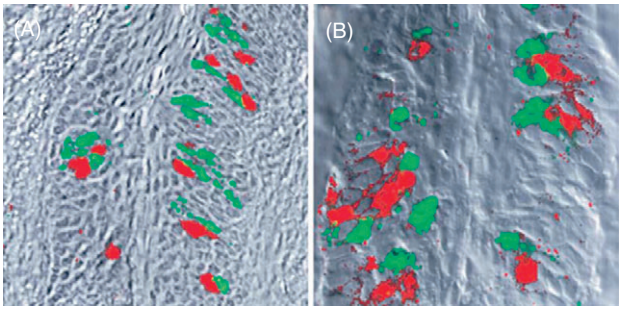

FIGURE 23.5 Different taste cells express different taste receptor genes. *In situ* hybridization experiments showing expression of T1Rs (green) and T2Rs (red) in mammalian tongue sections. *From Nelson et al. (2001).*

Activation of Taste Neurons Is Sufficient to Generate Taste Behavior

The finding that different taste compounds activate different populations of taste cells suggests that activation of different cells in the periphery leads to different taste percepts and different taste behaviors. To test this, transgenic mice were engineered to express novel receptors in taste cells. In an elegant experiment, transgenic mice were engineered to contain the human bitter receptor (hT2R16) for phenyl-β-D-glucopyranoside (a compound that humans perceive as bitter and mice do not detect) in either T2R (bitter) or T1R2 (sugar) cells (Fig. 23.6). If hT2R16 is expressed in T2R cells, mice avoid phenyl-β-D-glucopyranoside. If this human bitter receptor is expressed in T1R2 cells, however, mice prefer phenyl-β-D-glucopyranoside. Thus, expression of a bitter receptor

BOX 23.2

TASTE CELLS IN FRUIT FLIES

Drosophila melanogaster, like mammals, recognize sugars, salts, and bitter compounds, making them a model system for comparative studies of taste recognition. *Drosophila* taste with sensory neurons on their proboscis (mouth), legs, and wings. A family of 68 candidate Gustatory Receptor genes, unrelated to mammalian T1R or T2R receptors, may mediate taste detection because some members are expressed in taste tissue and recognize taste ligands in heterologous systems. Similar to mammalian taste, multiple receptors are expressed in each *Drosophila* taste cell. Two different classes of taste cells have been identified based on the receptor subsets they contain. One population detects bitter compounds and a second population detects sugars. Additional subpopulations of taste neurons likely recognize other taste categories. Thus, although flies and mammals are separated by more than 500 million years of evolution, they both have taste cells that selectively recognize bitter compounds or sugars. This suggests that modality-specific taste cells may be a general strategy that organisms use to distinguish nutrients from toxins.

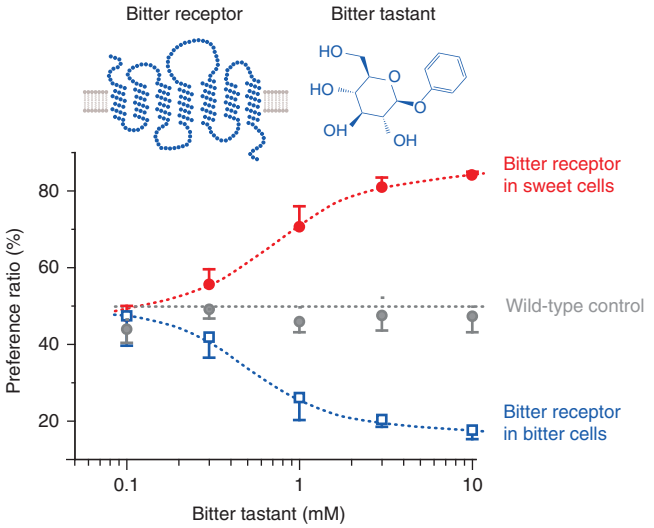

FIGURE 23.6 Activation of different taste cells is tethered to specific taste behaviors. Mice were engineered to contain a human bitter receptor in either T1R2 sugar sensing or T2R bitter sensing cells. Mice avoid the specific bitter compound when the receptor is expressed in T2R cells and prefer the same compound when the receptor is expressed in T1R2 cells. This demonstrates that the same compound can elicit different behaviors depending on which cells detect it. *Reprinted by permission from Macmillan Publishers LTD:* Nature 444*(7117): 288–94, copyright 2006.*

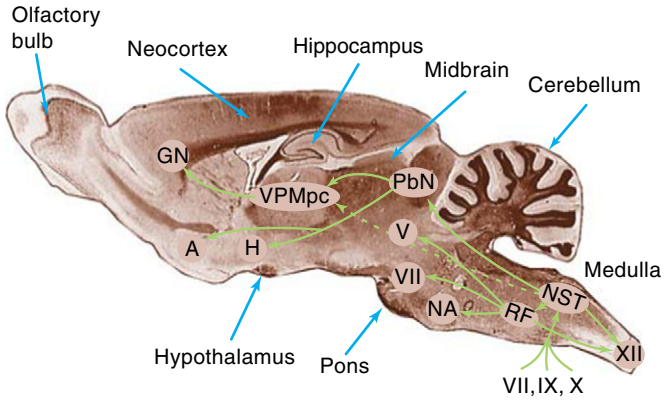

FIGURE 23.7 Schematic diagram of the ascending gustatory pathway; descending projections are not shown. Connections of the rodent gustatory system within the CNS are shown by solid lines; the projection from NST to VPMpc in primates is indicated by a dashed line. NST, nucleus of the solitary tract; PbN, parabrachial nuclei; VPMpc, ventero-posteromedial nucleus (parvi cellularis) of the thalamus; GN, gustatory neocortex; A, amygdala; H, hypothalamus; NA, nucleus ambiguus; RF, reticular formation; V, VII, and XII, trigeminal, facial, and hypoglossal motor nuclei; VII, IX, and X, axons of peripheral gustatory fibers in the facial, glossopharyngeal, and vagal cranial nerves.

in sugar cells triggers attraction to the bitter compound. These experiments demonstrate that activation of sugar cells leads to taste acceptance behavior and activation of bitter cells leads to avoidance. This argues that the activity of different taste cells is hardwired to different behaviors.

Transmission of Taste Information from the Tongue to the Brain

The three nerves that contact taste cells have cell bodies in ganglia and send axons to the solitary tract nucleus (NST) of the medulla in a topographic order (Fig 23.7). Dendrites from the chorda tympani (a branch of the facial nerve VII) contact the anterior tongue, cell bodies reside in the geniculate ganglion, and axons terminate in the rostral pole of the NST. Dendrites from the lingual-tonsillar branch (glossopharyngeal nerve IX) contact the posterior tongue, have cell bodies in the petrosal ganglion, and have axons that invade the NST at intermediate regions. Dendrites from the superior laryngeal branch (vagus nerve X) innervate the epiglottis and esophagus, have cell bodies in the nodose ganglion, and send axons to the caudal regions of the NST. Thus, information from the anterior-posterior tongue is represented from the rostral to caudal NST.

This segregation continues throughout the gustatory pathway to the cortex, where there are separate terminal fields for VIIth and IXth nerve inputs. From the NST, ascending fibers project in most species to third-order cells within the parabrachial nuclei (PbN) of the pons. A thalamocortical projection arises from the PbN to carry taste information to the parvicellular portion of the ventroposteromedial nucleus of the thalamus (VPMpc) and on to the gustatory neocortex (GN), located in rodents within the agranular insular cortex. In primates, taste fibers bypass the pontine relay and project directly to the VPMpc.

Arising in parallel with the thalamocortical projection is a second projection that carries gustatory afferent information into limbic forebrain areas involved in feeding and autonomic regulation, including the lateral hypothalamus, the central nucleus of the amygdala, and the bed nucleus of the stria terminalis. Descending axons within the gustatory system arise from the insular cortex and several ventral forebrain areas and project to the PbN and NST. There are also numerous local connections among neurons within the NST and with cells of the oral, facial, and pharyngeal motor nuclei (V, VII, ambiguous, and XII), either directly (as with XII) or via interneurons in the reticular formation. These hindbrain systems form the substrate for many taste-mediated somatic and visceral responses related to ingestion and rejection of tastants.

Models of Encoding Taste Quality

The nature of the neural coding of taste quality has been debated vigorously for many years, with considerable disagreement about whether taste quality is represented by activity in specific neural channels (a labeled line code) or by the relative activity across the responsive neurons (a population code) (Fig. 23.8). The labeled line model of taste coding proposes that different taste qualities are encoded by the activation of different cells. In this model, cells respond to selective cues in the periphery, and this information remains segregated in the brain. This hypothesis suggests that "sweetness" is coded by activity of neurons that respond selectively to sugars, "saltiness" by activity of neurons that respond selectively to salt, and so forth. Activity in a given cell type provides complete information about the quality of the stimulus.

In the population coding model of taste quality (across-fiber patterning), each cell responds to multiple taste modalities with different activity levels for different taste ligands, such that taste quality is coded by the pattern of activity across taste fibers. In this coding hypothesis, the pattern of activity generated across the entire array of taste neurons encodes taste quality, whereas activity in any one cell cannot unambiguously represent both stimulus quality and intensity. This population approach to quality coding makes the multiple sensitivity of gustatory neurons an essential part of the neural code for taste quality; it stresses that the code for quality is given in the response of the entire population of cells, placing little or no emphasis on the role of an individual neuron. In this scenario, the animal then discerns different tastes by differences in the ensemble activity of taste neurons.

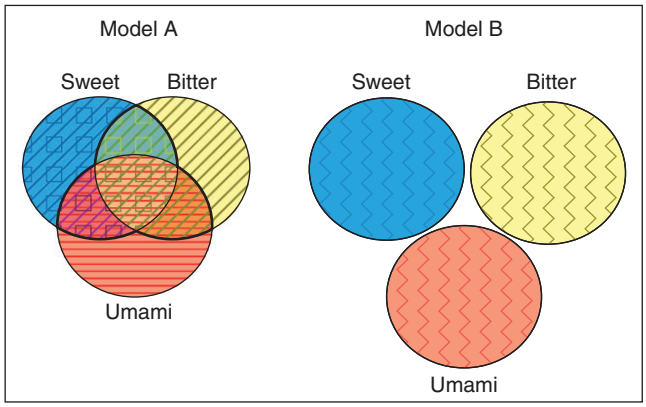

FIGURE 23.8 Two models of taste coding have been proposed. The left panel depicts the labeled line model in which different taste cells recognize different taste qualities, such that one cell population is activated by sugars and different cells are activated by bitter compounds. The right panel depicts the population coding model in which cells respond to multiple taste modalities. The pattern of activity across the ensemble of taste neurons encodes for specific tastes. *From Amrein and Bray (2003).*

Taste Coding in the Periphery

The studies of taste receptor genes strongly argue for the labeled line encoding of taste information in the periphery. Different taste cells contain different taste receptor genes and respond to different taste ligands. T1R2 plus T1R3 cells detect sugars, T1R1 plus T1R3 cells detect amino acids, T2R cells detect bitter compounds, and PKD2L1 cells detect acids. There is no overlap in the expression of different receptor types and thus no cell that detects both sugar and bitter compounds. Thus, "sweetness" is encoded by the activation of sugar cells, and "bitter" by the activation of bitter-sensing cells.

Not only do different cells identify different tastes, but these different cell types are necessary and sufficient for taste detection and behavior. Mice lacking T1R2 do not detect sugars, but still detect bitter, salt, sour, and amino acids. Similarly, mice lacking cells containing PKD2L1 do not detect sour, but do detect sugar, bitter, salt, and amino acids. Moreover, simply activating the sugar cells artificially generates taste acceptance behavior and activating the bitter cells generates avoidance behavior. These experiments are difficult to reconcile with population coding models. In population coding, the relative activity of nonselective neurons dictates taste quality, and loss of any subpopulation of taste cells would affect detection of all

compounds. In addition, in population coding, activation of a subset of taste cells would only be meaningful in the context of the ensemble activity. Instead, different taste cells recognize different taste modalities and mediate specific taste behaviors, arguing that there are labeled lines of taste information from peripheral activation to behavior.

Taste Coding in the Central Nervous System

Although the selectivity of taste cells in the periphery strongly argues for labeled lines of taste information, neurophysiological recordings of both primary gustatory nerves and central gustatory neurons typically show that individual fibers or cells respond to more than one of the stimuli representing the salty, sweet, sour, or bitter taste qualities, often to as many as three or four. Accumulating evidence suggests that there are functional classes of neurons that correspond in some way to primary taste qualities—that is, "sucrose-best" cells and "sodium-best" cells. However, analyses show that no single class of neurons in isolation can discriminate well between different taste qualities. As a result, an "across neuron pattern" theory suggesting that taste quality is coded by the relative activity across a population of neurons was proposed.

The current debate in the mammalian taste field is how to reconcile the evidence of labeled lines for different tastes in the periphery with the evidence for mixed lines in the central nervous system. One possibility is that a single nerve fiber synapses onto taste cells of many different taste qualities on the tongue, such that the labeled lines in the periphery become mixed at the first synapse. Alternatively, electrophysiological studies of single neurons with defined connections to taste cells, rather than random recordings of neurons in the solitary tract nucleus or gustatory cortex, may reveal populations of higher-order taste neurons that show selective responses to single taste qualities, supporting labeled line encoding.

Summary

The sense of taste allows animals to recognize different chemical compounds and gives rise to a limited number of taste sensations (saltiness, sweetness, sourness, bitterness, and umami/amino acids). Two families of taste receptors, the T1R and T2R families, mediate the detections of sugars, amino acids, and bitter compounds. These receptors are G-protein-coupled receptors that activate a heterotrimeric G protein, phospholipase C, and TRPM5, leading to cell depolarization and neurotransmitter release. Ion channels have been implicated in the detection of salts and sour compounds.

The transduction machinery for taste detection is found in receptor cells within taste buds distributed in several subpopulations, innervated by different peripheral nerves. These nerves project into the nucleus of the solitary tract in the medulla. From there, projections arise to the parabrachial nuclei in the pons and then to the thalamus and gustatory neocortex. A parallel pathway carries taste information into the ventral forebrain to areas involved in autonomic regulation. How gustatory information is encoded in the brain is an area of active investigation. In the periphery, an individual taste cell is tuned to a single taste quality, arguing that there are labeled lines of taste information. More centrally, gustatory neurons appear broadly tuned to stimuli of different taste qualities, leading to a debate whether the labeled lines in the periphery become mixed centrally. The ability to determine the connectivity of higher order taste neurons and their taste response profiles will enhance our understanding of taste neural circuits and the coding mechanisms underlying taste perception.

OLFACTION

The number of volatile cues in the environment that animals can detect is colossal. Humans, although not known to have particularly keen noses, can sense over 10,000 different odors, with detection thresholds in the parts per million and even parts per billion. Scent-tracking dogs, especially bloodhounds, have even more sensitive noses, approximately 10 million times more sensitive than humans, allowing them to follow scent trails a few days old. The ability to detect chemicals a distance from the source allows animals to direct their movement toward food and potential mates and away from harmful or dangerous environments. Although many animals rely on their olfactory system for survival, the sense of smell in humans is primarily an aesthetic sense, enhancing our enjoyment of foods and evoking memories of past experiences.

How does the olfactory system allow for the recognition and discrimination of thousands of different odors? A large family of 1,000 olfactory receptors provides the molecular diversity necessary for recognizing numerous ligands. The discovery of the olfactory receptor genes has provided molecular tools to probe the molecular underpinnings of olfactory detection. The logic of olfactory detection in the periphery is discussed next.

Odor Molecules Are Transduced by Olfactory Receptor Neurons

The nasal epithelium is the site for odor detection in mammals (Fig. 23.9). Olfactory sensory neurons have ciliated endings that terminate in the mucosal layer exposed to the environment. Axons of olfactory neurons cross the cribiform plate and synapse in the olfactory bulb, the most rostral region of the brain. Olfactory receptor molecules on the ciliated endings detect odors, causing a change in neural activity that is transmitted to the brain. The detection of odors by sensory cells and the organization of synaptic connections provide insight into the

problem of how diverse odors are recognized and distinguished, as discussed below.

G-Protein-Coupled Receptors Are the Initial Site of Odor Transduction in Mammals

The 2004 Nobel Prize in Medicine was awarded to Dr. Richard Axel and Dr. Linda Buck for their seminal discovery of a large family of mammalian olfactory receptors. Their search for olfactory receptors was based on three assumptions: first, that olfactory receptors would be G-protein-coupled receptors (GPCRs) similar to visual receptors; second, that they would be exclusively expressed in nasal epithelium; and third, that there would be a large number of receptors, given the large number of odors that mammals smell. This led Axel and Buck to search for novel GPCRs in nasal tissue and to the discovery of the odorant receptor gene (OR) family (Buck et al., 1991).

There are approximately 1,300 olfactory genes in mouse (5% of their genome), 500 in humans (2% of the genome), and 100 in zebrafish and catfish. They are members of the class A family of GPCRs, which includes opsin and β-adrenergic receptors. These receptors contain a short extracellular amino terminus, seven membrane-spanning (TM) domains, and an intracellular carboxyl terminus. Hypervariable regions in TM 3, 4, and 5 likely form the ligand-binding pockets, based on the ligand binding domains of other GPCRs such as the β-adrenergic receptor. Individual human olfactory receptor genes share between approximately 50 to 95% sequence identity. Large gene families comprising olfactory receptors have also been identified in nematodes (see Box 23.3) and insects (see below), although they bear little sequence similarity to mammalian ORs.

Olfactory receptor genes are organized in the genome in large linked arrays on several chromosomes. The size of the arrays ranges from 6 to 138 in humans and up to 15 in *C. elegans*. The *Drosophila* genome, with fewer olfactory receptors, contains small arrays of 2 to 3 genes, as well as many singly distributed genes. The large arrays in mammals and nematodes suggest that odor receptor gene families are rapidly evolving by duplication and expansion.

The identification of odor receptors provided fundamental insight into the molecular basis of odor perception. The large number of receptors dedicated to binding odor molecules provides an elegant solution to the problem of how animals detect a large number of smells. In addition, identifying receptors opened the door to examine interactions of different receptors with different odors, the organization of olfactory receptors in olfactory neurons, and the representations of olfactory receptors in the olfactory bulb.

BOX 23.3

SENSING THOUSANDS OF CHEMICALS WITH A HANDFUL OF NEURONS

The nemode worm *Caenorhabditis elegans* lives in the soil, lacks a visual system, and relies largely on chemical detection to survive in the environment. This small animal has only 302 neurons, but displays complex olfactory behaviors, making it a model system to study chemosensory processing. Thirty-two sensory neurons mediate chemical detection and contain members of a large chemoreceptor gene family. These receptors are G-protein-coupled receptors, but are not related to mammalian olfactory receptors. There are approximately 1,500 chemoreceptor genes in *C. elegans*, comprising 7% of all its genes. Thus, of all animals whose genomes have been sequenced, *C. elegans* dedicates the most genes, and the highest fraction of its genes, to chemical sensing.

Many receptors are found in the same chemosensory cell, as might be expected given the large number of receptors and the small number of sensory cells. This organization differs from the olfactory systems of mammals and flies but resembles mammalian and fly gustatory systems. Parceling many receptors into a single cell allows these animals to detect many chemical compounds despite the limited number of chemosensory neurons.

C. elegans shows sophisticated behavioral responses to chemical cues, including attraction and avoidance of different volatiles cues, adaptation to specific odors, as well as learned associations. For example, worms can learn to avoid pathogenic bacteria based on their smell after one exposure to the bacteria (Zhang et al., 2005). This is similar to conditioned taste aversion in mammals where one encounter with a nausea-producing food leads to aversion to the smell and taste of the food.

Evidence that ORs Detect Odors

The large number of ORs and the large number of odor molecules, as well as technical difficulties in expressing ORs in heterologous cells, has limited the ability to determine the ligands that different ORs recognize. In the first demonstration that ORs detect volatile cues, the "I7" odor receptor was overexpressed in most olfactory neurons of the rat. The electro-olfactogram (EOG) response of the epithelium to a battery of odors was examined. Among some 80 compounds tested, only longer-chain aldehydes gave increased responses over controls, with octyl aldehyde giving the peak response, and lesser responses for flanking long-chain aldehydes. This experiment demonstrated that a single OR detects a small subset of odors (Zhao et al., 1998).

More recently, advances in the ability to express receptors in heterologous cells have resulted in the identification of receptor-ligand pairs for several different ORs (Saito et al., 2009). Some ORs bind very few ligands (specialists), whereas others are broadly tuned (generalists). These receptor-ligand studies have shown that one OR will bind more than one odor and one odor will activate more than one OR. Thus, a single odor will activate multiple receptors and different odors will activate different combinations of receptors.

One Olfactory Receptor Gene Is Expressed in Each Olfactory Neuron

Studies of olfactory receptor expression in mammals revealed that each olfactory neuron contains only one member of the OR gene family. OR gene expression was determined by *in situ* hybridization experiments, showing that each OR is found in approximately 0.1% of olfactory neurons. In addition, isolating OR receptor sequences from single olfactory neurons demonstrated that each neuron expresses mRNA for only one OR. Finally, several pairs of ORs were examined to determine if two receptors were found in the same cell, but none of the ORs examined were co-expressed. Instead, receptors label nonoverlapping cell populations.

Not only is one receptor expressed per cell, but only one allele of a receptor is expressed per cell. An olfactory neuron expresses either the maternal or paternal allele but not both. The consequence of allelic exclusion is that each olfactory neuron contains only genetically identical receptors. Small changes in the nucleotide sequence of an allele might alter its ligand-binding properties, such that the maternal and paternal alleles recognize different odors. Segregating these alleles into different cells might expand the repertoire of odors that different olfactory neurons detect.

The general rule that each olfactory neuron expresses only one olfactory receptor gene has important implications for olfactory coding in the periphery. This organization dictates that the neural activity of a sensory neuron reports the activity of a single receptor and the activation of different olfactory receptors produces responses in different cells. Parcelling receptors into different cells allows the animal to distinguish which receptor has been activated by which cells have been activated.

Olfactory Signal Transduction Utilizes Adenylate Cyclase and a Cyclic Nucleotide Gated Ion Channel

The olfactory signal transduction cascade is similar to other G-protein-coupled signaling cascades (Fig. 23.10). Ligand-binding to an odorant receptor induces a conformational change that results in activation of a heterotrimeric G protein. The Gα subunit is an olfactory-specific G_s protein (G_{olf}) that activates an adenylate cyclase type III (AC3). AC3 is an enzyme that catalyzes the conversion of ATP to 3′,5′-cyclic AMP (cAMP). A cyclic nucleotide-gated (CNG) channel is activated in response to increases in cAMP, leading to cell depolarization, the generation of action potentials, and neurotransmitter release.

Mice lacking the G_{olf}, the AC3, and the CNG channel have been generated and the phenotypes of these mutants highlight the critical roles of olfactory signaling. Olfactory neurons from the AC3 mutants and the CNG channel mutants do not respond to odors. Mice lacking the G_{olf}, AC3, or CNG channel generally die within 1 to 2 days of birth without milk in their stomach, unable to nurse. This reduced survival rate is consistent with the idea that olfactory cues are necessary for newborn pups to suckle. These studies demonstrate that the G_{olf}, the AC3, and the CNG channel are essential components of the olfactory signal transduction cascade.

Axons of Olfactory Neurons Project to the Olfactory Bulb

Olfactory neurons in the nasal epithelium send axons directly to the mammalian brain, to paired structures in the most rostral region called the olfactory bulbs. The olfactory bulb is the primary relay station for smell. It is comprised of multiple cellular layers. Most peripheral is the glomerular layer where the axons of olfactory neurons reside, with deeper layers containing cells that synapse with olfactory neurons.

Axons of olfactory neurons terminate in the rounded regions of neuropil termed glomeruli. Anatomical studies from the time of Ramon y Cajal have shown that the glomerulus is an anatomical unit for the convergence of axons from many ORNs. In rats, the 15 million olfactory neurons converge onto 1,500 glomeruli, giving an average overall convergence of some 10,000:1. *In situ* hybridization and gene-targeting methods showed that ORNs expressing the same odorant receptor protein converge onto one or a few glomeruli in the olfactory bulb (Mombaerts et al., 1996) (Fig. 23.11). Neurons with different ORs send axons to different glomeruli. Activation of different olfactory receptors in the periphery leads to the activation of different glomeruli in the olfactory bulb. This suggests that the animal knows what it is smelling by the combination of glomeruli that are activated.

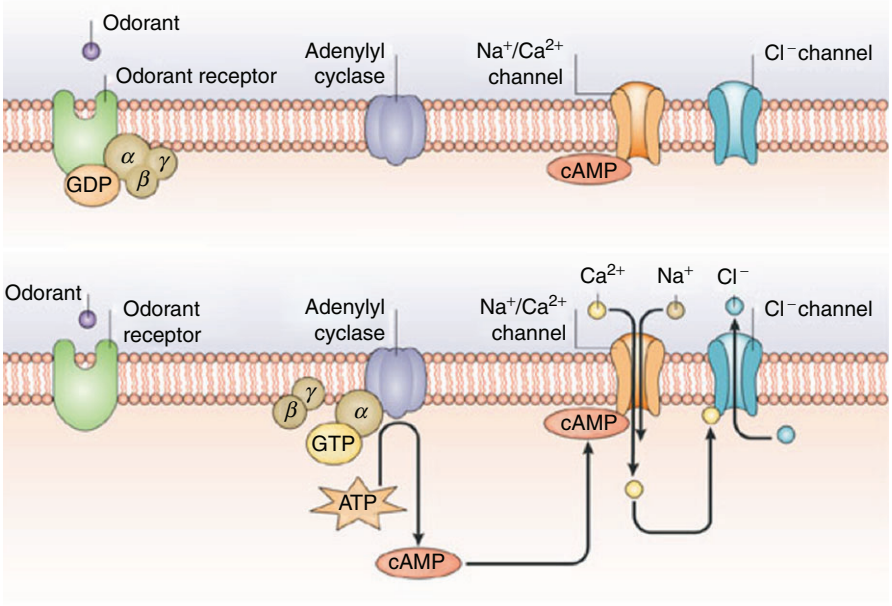

FIGURE 23.10 Sensory transduction of odor molecules involves a cyclic AMP second messenger pathway. Activation of a receptor by odor molecules activates a GTP-binding protein ($\alpha\beta\gamma$) that activates an adenylate cyclase, which produces cyclic AMP (cAMP), and a cationic cyclic nucleotide-gated channel and a chloride channel. *Reprinted by permission from Macmillan Publishers LTD:* Nature Reviews Neuroscience 5*(4): 263–78, copyright 2004.*

DIFFERENT ODORS ACTIVATE DIFFERENT COMBINATIONS OF GLOMERULI

The functional significance of glomeruli is seen when an animal is exposed to an odor and the activity patterns in the olfactory bulb are observed. The key observation is that different odors evoke different patterns of active glomeruli in the olfactory bulb. Thus, the focal glomerular activity elicited by the odor of clove is different from the pattern of glomeruli activated by coffee (Fig. 23.12). Some individual compounds are shared in coffee and clove and these activate the game glomeruli. Other compounds are not shared, leading to different overall patterns of activity. Each odor activates a different combination of glomeruli such that odors can be distinguished by their unique patterns of glomerular activation in the bulb (Xu et al., 2000). Thus, odors are thought to be represented by a combinatorial code in the olfactory bulb, where different combinations of glomeruli report different smells.

The Olfactory Bulb Is the Primary Relay for Smell

The olfactory bulb provides the first stage of synaptic processing of the sensory information in the olfactory pathway. The axons of olfactory neurons with the same odorant receptor converge onto 1 or 2 glomeruli in the olfactory bulb. Mitral/tufted cells are second-order neurons that synapse onto the olfactory axons and relay this information to higher brain centers. In addition to feedforward connections, there are also lateral connections. Periglomerular cells are inhibitory interneurons that make connections within and between glomeruli. Granule cells are interneurons that synapse onto mitral/tufted cells. The synaptic connections of different cell types in the olfactory bulb serve as the initial stage for olfactory information processing (Shepherd et al., 2007) (Fig. 23.13).

Within a glomerulus, olfactory axons make glutamatergic excitatory synapses onto the dendrites of the mitral/tufted neurons. Each mitral/tufted cell sends dendrites to one glomerulus, and thus relays the activity of one olfactory receptor to the brain. The dendrites of mitral/tufted cells also form reciprocal synapses with the periglomerular cell. The mitral/tufted dendrites make glutamatergic connections onto periglomerular cell dendrites, and dendrites of periglomerular cells form both GABAergic and dopaminergic synapses onto mitral/tufted cell dendrites. These connections are believed to mediate numerous types of interactions, including serial excitatory synapses (which spread excitation widely within a glomerulus), as well as recurrent and lateral inhibitory synaptic circuits (Urban et al., 2009).

In addition to intraglomerular processing, there is interglomerular processing. The axons of the periglomerular cells make synapses onto periglomerular cells in neighboring glomeruli and onto the dendritic shafts of neighboring mitral/tufted cells. One action of these synapses may be to inhibit periglomerular cells and mitral/tufted dendrites, thus providing contrast enhancement between neighboring glomeruli.

The second level of synaptic processing in the olfactory bulb occurs through inhibitory connections between granule cells and mitral cells. Reciprocal dendrodendritic synapses that mediate mitral/tufted-to-granule excitation and granule-to-mitral/tufted inhibition cause activated mitral/tufted cells to mediate feedback inhibition on themselves and lateral inhibition on their neighbors. Granule cells may participate in lateral inhibition onto a large population of neighboring cells that belong to neighboring glomerular units.

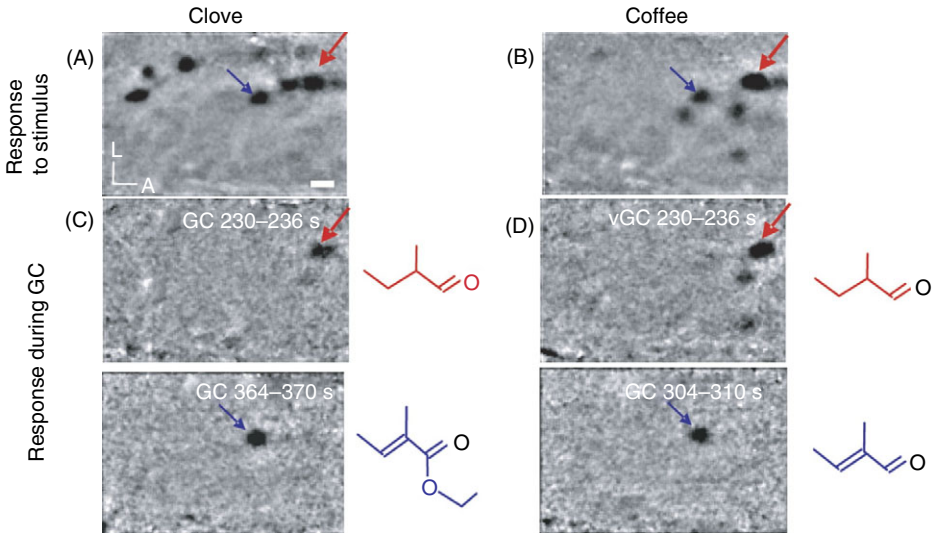

FIGURE 23.12 Odor maps. (A, B) Visualization of odor-elicited activity in glomeruli of the dorsal olfactory bulbs by intrinsic imaging for clove and coffee odors. Arrows mark glomeruli that are activated by compounds in both clove and coffee (C, D). Isolation of single compounds in coffee or clove odor, showing that the same compound is in coffee and clove and activates the same glomerulus. *From Lin et al. (2006).*

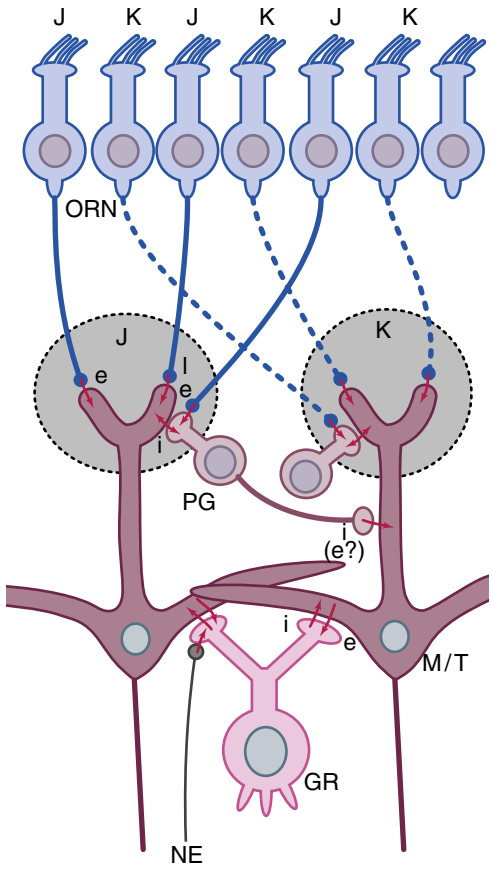

FIGURE 23.13 Diagram summarizing the synaptic organization of the glomerular layer. Olfactory neurons with the same receptor project to the same glomerulus. Mitral/tufted cells synapse onto a single glomerulus. Periglomerulur cells are inhibitory interneurons that synapse within and between glomeruli. Granule cells are inhibitory interneurons that synapse between mitral/tufted cells.

The current model is that the main function of the dendrodendritic synapses present at both the glomerular and granule cell levels is to mediate lateral inhibition and the role of this lateral inhibition is to enhance contrast between different odors.

Olfactory Bulb Output Goes Directly to Olfactory Cortex

The output of the olfactory bulb is carried by the axons of mitral cells and their smaller counterparts, the tufted cells. These axons project directly to olfactory cortex in the forebrain, the only sensory system to have this immediate access to the forebrain. Like cortical regions in other systems, the olfactory cortex is differentiated into several different areas (Fig. 23.14). The main area is the pyriform (sometimes called the prepyriform) cortex. This area receives input from mitral/tufted cells. It projects to the mediodorsal thalamus, which in turn projects to medial and lateral orbitofrontal areas of the neocortex. It is at this level that conscious perception of odors presumably takes place. Second is the olfactory tubercle, which receives input mainly from tufted cells. Third is the cortico-medial group of amygdalar nuclei, which receive specific input from the accessory olfactory bulb. Fourth is the lateral entorhinal area, which projects to the hippocampus. Last is the anterior olfactory nucleus, a sheet of cells just posterior to the olfactory bulb.

The *Drosophila* Olfactory System

The olfactory system of *Drosophila* shares many common principles with the mammalian olfactory system, although scaled down in size. The smell organs of the fly are its antennae and maxillary palp (Fig. 23.15). Olfactory neurons have dendrites that are exposed to the external

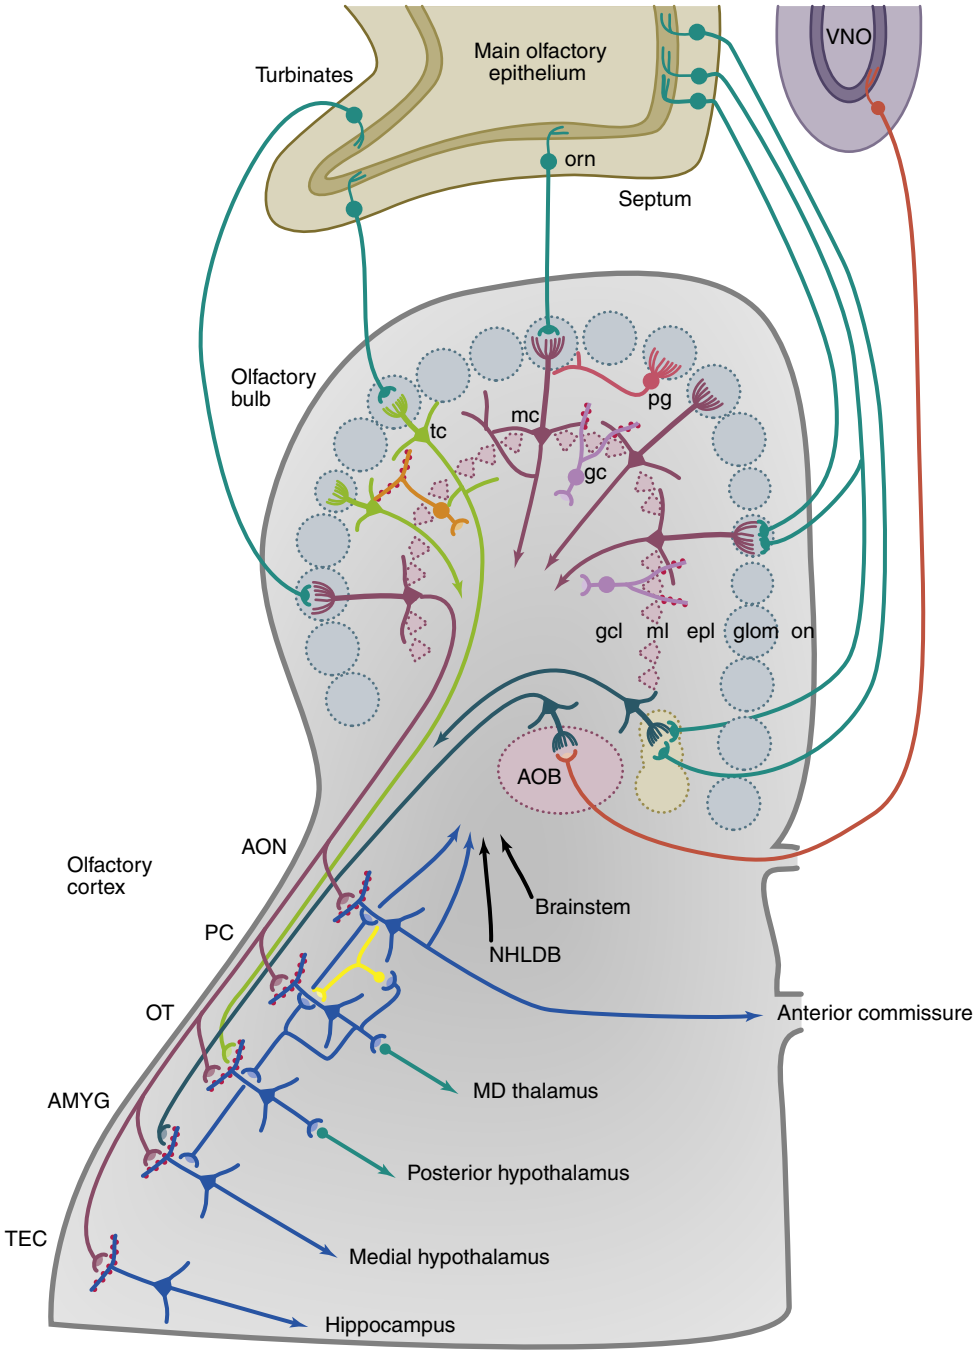

FIGURE 23.14 Summary of main projection pathways in the olfactory system. AON, anterior olfactory nucleus; PC, pyriform cortex; OT, olfactory tubercle; AMYG, amygdala; TEC, transitional entorhinal cortex; NHLDB, nucleus of horizontal limb of diagonal band; MD, mediodorsal.

environment for the detection of odors and axons that travel to the antennal lobe, the insect equivalent of the olfactory bulb. A family of approximately 60 *Drosophila* odorant receptors (dOR) detects volatile cues. Each receptor is expressed in a small subset of olfactory neurons, except for one receptor that is found in nearly all olfactory neurons. This receptor, dOR83b, is necessary to localize other odor receptors to the dendritic membrane and is essential for olfactory function (Larsson et al., 2004). Each olfactory neuron contains dOR83b as well as one other specific olfactory receptor. Neurons with the same specific receptor project to a single glomerulus in the antennal lobe. Thus the organization of the olfactory system in *Drosophila* is remarkably similar to the mammalian system in which neurons with different receptors project to different glomeruli.

Olfactory receptor neurons send axons to the antennal lobe. The second-order neurons are projection neurons. Each projection neuron sends dendrites to a single glomerulus and axons that branch to terminate in the protocerebrum (implicated in innate behavior) and mushroom bodies (involved in associative learning) of the fly brain. In addition, there are excitatory and inhibitory local interneurons in the antennal lobe that serve to shape the response of projection neurons. These interneurons act to amplify weak

olfactory signals and dampen strong ones. Thus, they serve as a gain control mechanism to allow an animal to detect odors over a broad dynamic range (Wilson, 2011).

In general, although flies and mammals are separated by approximately 400 million years in evolution, the principles of olfaction are conserved in these organisms. In fly olfaction, as in mammalian olfaction, one receptor is expressed per cell, and neurons with the same receptor project to the same glomerulus. Comparative studies of the olfactory systems of different organisms highlight the general strategies that animals use for chemical recognition.

PHEROMONE DETECTION

The Accessory Olfactory System May Mediate Pheromone Detection

In addition to the main olfactory pathway, an accessory olfactory pathway exists for the detection of pheromones in many species. Pheromones are species-specific and gender

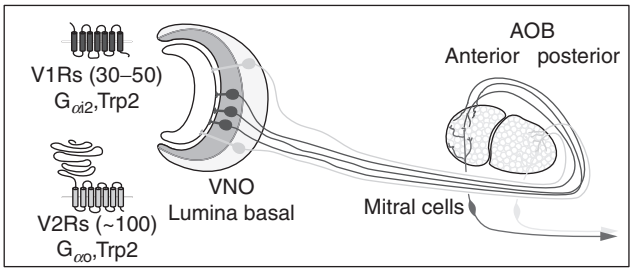

FIGURE 23.16 The accessory olfactory system of the mouse. The vomeronasal organ in the nasal cavity contains two layers. The apical layer expresses the V1R family of pheromone receptors, and the basal layer contains the V2R family. These neurons project to the accessory olfactory bulb (AOB) where they form several glomeruli. *From Dulac (2000).*

specific chemical cues emitted by an individual and detected by other members of the species that provide information about the individual's social, sexual, and reproductive status. In general, pheromones cause stereotyped and innate changes in conspecifics' behavior, either by direct, short-term effects on animal behavior or longer-term changes that alter the endocrine state. For example, one of the few vertebrate pheromones isolated is the sex pheromone of the red-sided garter snake. Female snakes produce this substance, which is sufficient to induce courting behavior in males. Another well-described pheromone is made by slave-maker ants. They emit a blend of chemicals that serve as an "alarm" signal, causing the slave-makers to attack other ants' nests, and the resident ants to flee.

The sensory structure for pheromone detection in mammals is the vomeronasal organ (VNO), also referred to as Jacobson's organ (Fig. 23.16). The VNO is a cigar-shaped cavity in the anterior nasal septum surrounded by bone. Openings in the anterior cavity contact either the oral cavity or the nasal cavity, depending on the species, for the detection of pheromonal cues. The sensory epithelium of the VNO is divided into anterior and posterior layers. Each layer contains sensory neurons that detect soluble and volatile cues. Different receptors and signaling molecules are found in the two layers, suggesting that they serve different functions.

Axons of sensory neurons travel from the VNO to the accessory olfactory bulb (AOB), which is located at the dorsal posterior surface of the main olfactory bulb (MOB) in rodents. Projection neurons then send axons to the bed nuclei of the accessory olfactory tract and stria terminalis, and the posteromedial cortical and medial nuclei of the amygdala. These projections do not overlap with projections from the main olfactory bulb, demonstrating that there is segregation of processing from the two systems.

Information Flow from the VNO to the AOB

The sensory epithelium of the VNO is divided into an apical and a basal layer. Neurons in the apical layer

express V1R receptors and those in the basal layer express V2R receptors (see following, Signal transduction in the VNO). In general, each sensory neuron expresses one receptor, similar to the olfactory system of mammals. This suggests that each sensory neuron detects a small subset of chemical cues.

Neurons from the apical layer project to the anterior region of the AOB and neurons from the basal layer project to the posterior AOB. Unlike the olfactory system, neurons with the same receptor do not project to one or a few glomeruli (Fig. 23.16). Instead, neurons with the same receptor converge onto multiple glomeruli (from 6 to 30) in spatially restricted domains, forming a complex pattern that is loosely conserved from animal to animal. Dendrites of mitral cells synapse onto several glomeruli in a complex fashion. Mitral cell dendrites have been reported to contact glomeruli from neurons with the same receptor as well as from neurons with different receptors. Thus unlike the olfactory system, a single mitral cell does not synapse onto a single glomerulus. The complex connectivity suggests that integration of different sensory inputs occurs in the AOB. One hypothesis is that this organization allows the animal to respond only to the relevant mixture of pheromone cues. For example, the simultaneous activity of different sensory receptors may be necessary to activate mitral cells, such that mitral cells respond to specific blends of pheromones. In this model, only the right mix of pheromones will trigger stereotyped innate behavior.

Signal Transduction in the VNO

Different signaling molecules reside in the apical and basal compartments of the VNO. In the apical layer, the V1R family of candidate pheromone receptors is expressed (Dulac et al., 1995). There are approximately 165 full-length V1R genes in mice, 106 in rats, and only 2 in humans. These G-protein-coupled receptors all contain a short amino-terminus extracellular domain and are distantly related to the T2R family of mammalian bitter receptors. Mice lacking 12 V1Rs do not detect a subset of candidate pheromones by electrophysiological studies of VNO field responses. These mice also show behavioral defects in stereotyped behaviors thought to be mediated by pheromones: for example, the female mice do not show maternal aggression (normally, nursing mothers fend off intruders). These findings argue that the V1R family detects pheromones and mediates behavior. Neurons that express V1Rs also contain the Gαi2 alpha subunit of heterotrimeric G proteins and the ion channel TRPC2, as shown by *in situ* hybridization and immunocytochemical staining. This suggests that these molecules transduce information from the activation of V1Rs to cell depolarization.

The V2R family of chemoreceptors is expressed in the basal layer of the VNO. This receptor family has a long amino-terminal extracellular domain and shares sequence similarity with the mammalian T1R family of taste receptors. There are approximately 60 intact V2R receptor genes in mice and rats. All genes are expressed exclusively in the VNO, suggesting that they mediate pheromone detection. The Gαo subunit of heterotrimeric G proteins is expressed in the basal layer along with V2Rs. In addition, the TRPC2 ion channel that is expressed in the apical layer is also found in the basal layer.

Mice Lacking TRPC2 Show Behavioral Defects

Because the TRPC2 ion channel is expressed in both the apical and basal layer of the VNO, it may act as an ion channel mediating detection of pheromones. To test this, mice were generated that lack the TRPC2 channel (Stowers et al., 2002). The VNO is not activated by candidate pheromones in these mice by electrophysiological recordings, demonstrating a deficit in VNO function. If the VNO is not functional, one prediction is that these mice will lack pheromone-driven social behaviors such as mating and aggression. Consistent with this, mice lacking TRPC2 do not show aggressive behavior. Surprisingly, male mice without TRPC2 indiscriminately mate both females and males. The simplest interpretation of these studies is that mating does not require the VNO; instead, the VNO is required to inhibit male-male courtship behavior and promote discrimination between the sexes.

Pheromone Detection in Humans?

Although evidence is accumulating that the VNO participates in pheromone-driven behavior in mice, the role of the VNO in human behavior is far less certain (Meredith, 2001). Anatomical studies of the vomeronasal organ argue that this structure exists but lacks sensory neurons and nerve bundles in the adult. The accessory olfactory bulb exists in the fetus but regresses and is not present in the adult. Genomic studies demonstrate the TRPC2 gene is a non-functional pseudogene in humans. Moreover, almost all V1R pheromone receptors are pseudogenes (115/117). Taken together, these studies strongly argue that the accessory olfactory system does not function in humans.

The loss of VNO in humans can be interpreted in two ways. One possibility is that humans do not detect pheromones and have evolved other strategies to ensure appropriate detection of mates and attackers. Alternatively, it is possible that humans detect odors through the main olfactory system that act as pheromones to elicit innate, stereotypical behaviors involved in reproduction and aggression.

Comparison of the Main Olfactory System and the Accessory Olfactory System

Although the accessory olfactory system has been classically thought to detect pheromones and the main olfactory system to detect a vast array of volatile cues, the distinction between the two noses is blurred both in terms of the compounds they detect and the behaviors they mediate. For example, electrophysiological studies show that sensory neurons in the VNO respond to volatile and nonvolatile compounds. Similarly, olfactory neurons depolarize in response to compounds classified as pheromones. Mice that have a defective VNO (lacking TRPC2) lack many pheromone-mediated behaviors, but not all. For example, pup suckling is a stereotyped behavior that is normal in TRPC2 mutants. Mice with a defective main olfactory epithelium (lacking the olfactory cyclic nucleotide-gated channel) do not mate, fight, or suckle, showing that the olfactory system is also required for innate stereotyped behavior. Thus, the best ways to distinguish the main and accessory olfactory systems are not by the ligands they recognize or the behaviors they mediate, but by their anatomical segregation in the periphery and central nervous system.

Summary

The olfactory system enables animals to detect and discriminate between thousands of different odors. The enormous number of olfactory receptors enables the ability to detect a vast array of odors. Each olfactory receptor recognizes a subset of chemical cues, with one odor activating more than one receptor and one receptor recognizing more than one odor. In the periphery, each olfactory neuron expresses only one olfactory receptor. Neurons with the same OR are randomly distributed in the nasal epithelium but they all project to the same glomerulus in the olfactory bulb. Thus, the activation of different olfactory receptors leads to the activation of different glomeruli in the central nervous system. Different combinations of activated glomeruli represent different smells. In *Drosophila* as well as mammals, one receptor is expressed per cell and neurons with the same receptor project to the same glomerulus, demonstrating that the logic of olfaction has been maintained through evolutionary time. In addition to the main olfactory pathway in vertebrates, a parallel accessory pathway exists for transmitting signals from less volatile odorous compounds called pheromones.

Higher order processing begins in the olfactory bulb, where mitral/tufted cells synapse onto olfactory neurons and transmit this information to the olfactory cortex. Periglomerular cells and granule cells provide inhibitory connections in the bulb that shape olfactory responses. Information is then relayed to five different brain regions where it is ultimately translated into different odor percepts and behavior.

CHAPTER

24

The Somatosensory System

The somatosensory system has many responsibilities. Beyond the obvious need to bring to consciousness the events that occur along the skin surface, this system provides an organism with knowledge of where it is in space, and it provides the motor system with feedback to control and coordinate action. Those are functions so diverse that minute variations on a common theme cannot accomplish them all. That is, the many demands on the somatosensory system cannot be met by subtle changes in gene expression or pattern of synapses or location of cell bodies. As a result, single neurons, large ensembles and groups of interconnected regions in the somatosensory system use different tactics and strategies to achieve the goals of perception, homeostasis and sensory guidance of movement.

PERIPHERAL MECHANISMS OF SOMATIC SENSATION

All Somatic Sensation Begins with Receptors and Ganglion Cells

Neurons of the dorsal root ganglia (DRG) and trigeminal ganglia are the only routes by which mammals receive information from the periphery of the body and of the face. These are classic pseudo-unipolar cells. Each has a single axon that divides close to the cell body and sends separate branches to the periphery and into the central nervous system (Fig. 24.1). Under normal circumstances neurons in somatosensory ganglia receive no synapses. Although that situation can change with damage to the peripheral branches of ganglion cells, the normal lack of synapses means the cell body of a somatic sensory ganglion cell is a factory for all that must be made to keep its two axon branches functioning properly. Its major function—to keep a long axon healthy enough to avoid conduction failure—it does very well, as the incidence for conduction failures in a ganglion cell axon is near zero. Even where failures are reported, as in the small ganglion cell bodies of some vertebrate species, the effect appears deliberate and is tied to the difference in action potential shape seen in large and small cells.

Neuronal cell bodies in somatosensory ganglia vary in size (Fig. 24.2). Although the details of size vary among species according to differences in body size, all species examined to date include two populations, one with somata at least half again larger than the cell bodies of the other. The population with smaller somata outnumbers those with larger somata by at least 2-to-1.

Peripheral branches of somatosensory ganglion cells enter peripheral nerves. In a mixed nerve, with both sensory and motor axons, the ganglion cells provide more than a fair share of the large, myelinated axons and all of the thinly myelinated and unmyelinated axons. Conduction velocities vary because of these differences in axon diameter and degree of myelination. Classic studies divide the sensory axons in human peripheral nerve into the following groups with conduction velocities in parentheses: Group I or Aα (70–120 meters/second), Group II or Aβ (40–70 meters/second), Group III or Aδ (12–36 meters/second), and Group IV or C (0.5–2.0 meters/second). These groups correspond to functional classes that carry proprioceptive, mechanosensory, thermoreceptive or nociceptive information from muscles, tendons and skin to the spinal cord (Table 24.1).

What sets apart ganglion cells of the somatosensory system from ganglion cells of other systems is the requirement for double duty. Not only do they carry information into the CNS, but they also transduce all forms of somatosensory energy into a change in membrane potential. That means somatosensory ganglion cells are also receptor cells. To do both, ganglion cells insert two types of cation

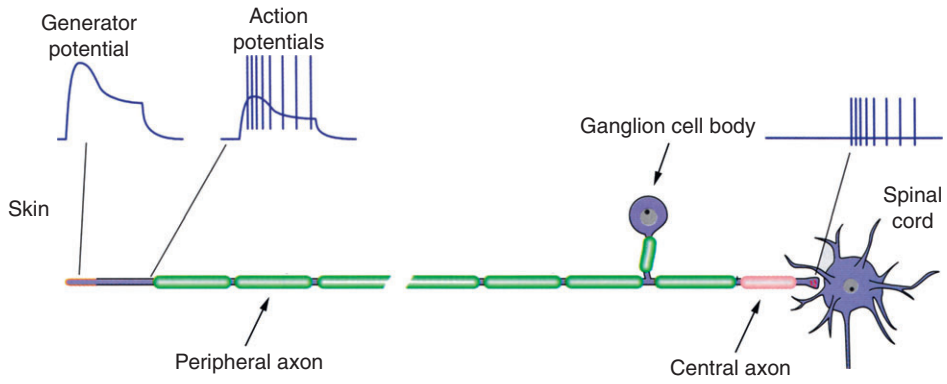

FIGURE 24.1 A dorsal root ganglion cell is a pseudo-unipolar neuron with an axon that divides at a T-junction into a peripheral branch and a central branch. At the tip of the peripheral branch are receptor proteins that, through opening of cation channels, produce a depolarization called a generator potential. With sufficient depolarization, voltage-gated Na^+ channels open to initiate action potentials. These action potentials are conducted down the axon and into the central branch that innervates second-order neurons in the spinal cord or in the medulla.

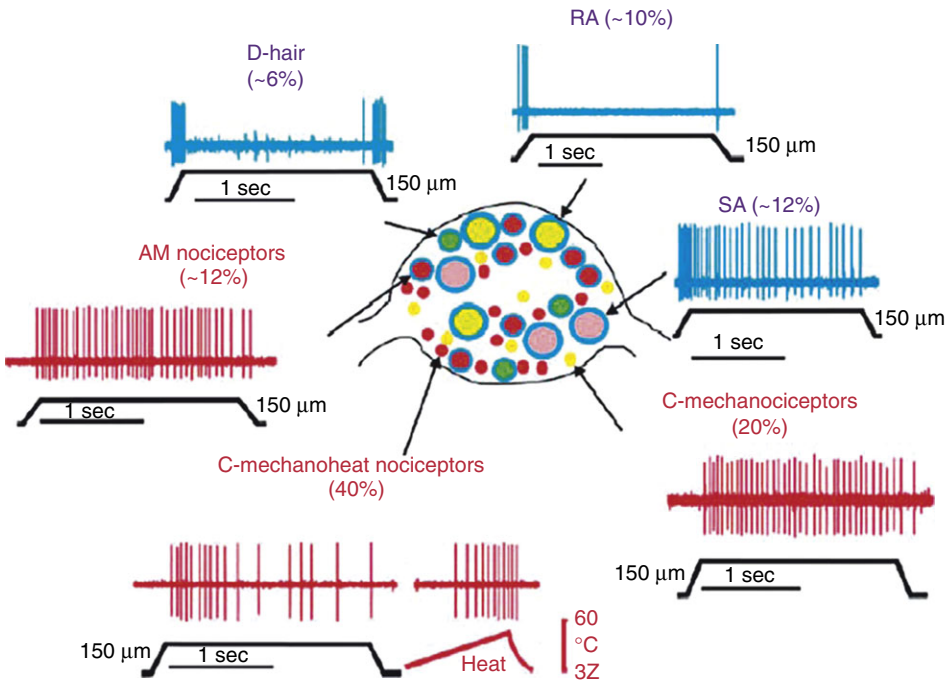

FIGURE 24.2 A somatosensory ganglion (center) is populated by a broad range of neurons that differ in size, gene expression and receptive field properties. Mechanoreceptors (in blue) differ in how they respond to a sustained stimulus. Rapidly adapting (RA) afferents of the glaborous skin and D-hair receptors or hair follicle receptors generate short bursts of action potentials at stimulus onset and offset. Slowly adapting (SA) afferents respond to a sustained indentation of skin with a prolonged series of action potentials. Nociceptors (in red) also vary in size and conduction velocity of their axons (Aδ vs. C) and in their response to noxious mechanical stimulation, such as a hard pinch. Some receptors respond specifically to this stimulus (AM nociceptors and C-mechanonociceptors) whereas others respond to a broad range of noxious stimuli (C-mechanoheat nociceptors). From Lewin and Moshourab (2004).

channels into the plasma membrane at the tips of their axons. One opens in response to a stimulus. Either it is physically tethered to peripheral tissue, and opens to an appropriate mechanical deformation, or it opens in response to changes in temperature, pH or the concentration of circulating factors that signal tissue damage. By way of these channels the tips of ganglion cell axons are depolarized to produce generator potentials. The second type of channel, voltage-gated Na^+ channels, turns generator potentials into action potentials that the axon conducts along its length and into the central nervous system. The best evidence suggests the voltage-gated channels are present at the first node of Ranvier in myelinated axons and at a similar distance from axon tip in unmyelinated axons (Fig. 24.1).

Many Types of Somatosensory Receptors Innervate Skin and Deep Tissues

The modern tradition breaks up the axons of sensory ganglia into 13 varieties of receptors. These include 4 types of proprioceptors, 3 types of nociceptors, 2 groups of thermoreceptors (one each for cooling and warming), and 4 types of mechanoreceptors. That is a decidedly conservative point of view. At a minimum it leaves unmentioned the class of D-hair receptor or hair follicle afferent and it recognizes only the major types of nociceptors. Molecular and functional distinctions among the nociceptors alone add enough additional types to make the list approach 20. The point here is not to split peripheral receptors into the greatest number of types but to

TABLE 24.1 Summary of Primary Afferent Fibers and Their Roles

Afferent type	SA1	RA	PC	SA2
Receptor	Merkel	Meissner	Pacinian	Ruffini
Location	Tip of epidermal sweat ridges	Dermal papillae (close to skin surface)	Dermis and deeper tissues	Dermis
Axon diameter	7–11 μm	6–12 μm	6–12 μm	6–12 μm
Conduction Velocity	40–65 m/s	35–70 m/s	35–70 m/s	35–70 m/s
Sensory function	Form and texture perception	Motion detection, grip control	Perception of distant events through transmitted vibrations, tool use	Tangential force, hand shape, motion direction
Effective stimulus	Edges, points, corners, curvature	Skin motion	Vibration	Skin stretch
Response to sustained indentation	Sustained with slow adaptation	None	None	Sustained with slow adaptation
Frequency range	0–100 Hz	1–300 Hz	5–1000 Hz	0–? Hz
Peak sensitivity	5 Hz	50 Hz	200 Hz	0.5 Hz
Threshold for rapid indentation or vibration (best)	8 μm	2 μm	0.01 μm	40 μm
Threshold (mean)	30 μm	6 μm	0.08 μm	300 μm
Receptive field area (measured with rapid 0.5 mm indentation)	9 mm^2	22 mm^2	Entire finger or hand	60 mm^2
Innervation density (finger pad)	100/cm^2	150/cm^2	20/cm^2	10/cm^2
Spatial acuity	0.5 mm	3 mm	10+ mm	7+ mm

emphasize the unusual nature of somatosensory transduction: the system responds to a broad range of stimuli because it has so many receptor types.

Mechanosensory Axons of Glabrous Skin Are Split into Four Types

Four types of mechanosensory axons are found in the hairless or glaborous skin and immediately adjacent deeper tissues of the human body (Fig. 24.3). Whereas a decade ago it would have seemed a radical thought, we now recognize the four receptors are responsible for specific functions. These include peripheral events that lead to perception of form and texture (Johnson, 2001), detection of object slip leading to adjustment of grip, sensory feedback necessary for the use of tools, perception of vibration and perception of hand shape and limb position (Table 24.1).

All mechanoreceptors conduct action potentials in the Aβ (type II) range, so no distinction can be made among them in that property. Rather it is in their response to the steady indentation of the skin that the difference among the four types becomes clear. Two types of afferents respond with a train of action potentials for as long as a blunt mechanical stimulus is applied to its receptive field. These are slowly adapting (SA) afferents, and they can be further divided into SAI and SAII types based on differences in spontaneous activity and in their sustained response to the applied stimuli (Fig. 24.2). Two other types of mechanoreceptor afferents are frequently called rapidly adapting (RA), or sometimes fast adapting or quickly adapting, because their response to a prolonged indentation of skin is a spike or two at onset of the stimulus, a single spike or two at offset and nothing in between. They, too, are split into two varieties, RA and PC, differing principally in their sensitivity and response to vibrating stimuli (see following). We should also point out some investigators object to the use of the term, adaptation, to describe this change in a mechanoreceptor axon's response because, as we will see, it is not the axon that adapts but the tissue around it. Nevertheless, the terms rapidly adapting and slowly adapting are illustrative and are in common usage, so will we use them here.

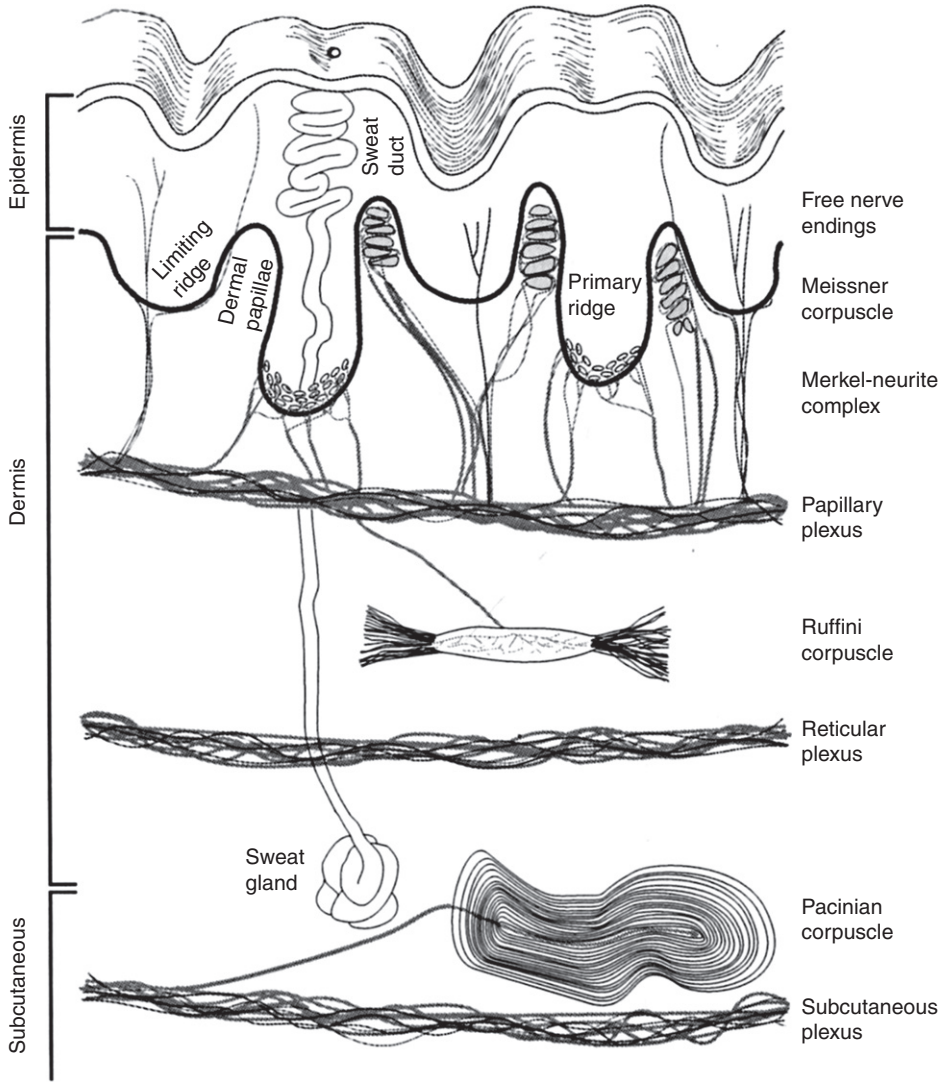

FIGURE 24.3 Peripheral receptors of the hairless (glaborous) skin are present in dermis, epidermis and subcutaneous tissue. Superficial receptors at the dermis-epidermis border include the free nerve endings of nociceptors and thermoreceptors, the rapidly adapting afferents associated with Meissner's corpuscle and the type I slowly adapting afferents that end as Merkel's disks. Deep receptors include a rapidly adapting receptor enclosed by a Pacinian corpuscle and a type II slowly adapting afferent in some species. Those SAII afferents are associated with Ruffini corpuscles in domestic cats but appear to have some other arrangement in most of the human hand. SAII afferents are missing from the skin of macaques and mice. From Johnson (2002).

Pacinian Corpuscles

The work of Iggo and Muir (1969) in the late 1960s established a consistent relationship among the four types of peripheral mechanoreceptor axons and the morphology of axon tips, or more properly of the axons' relationship with nonneural cells. For three of the axons this structure-function relationship has held up well. The clearest example is that of the PC afferent, the tip of which ends as part of a Pacinian corpuscle. Unmistakable in its onion skin-like structure, the Pacinian corpuscle filters out low frequency mechanical stimuli such as sustained pressure applied to the skin (Fig. 24.3).

PC afferents are exquisitely sensitive to vibration. When the frequency of vibration approaches 200 cycles/second (Hz), a PC afferent responds to skin indentations of no more than 10 nm. Yet a single, steady indentation of the skin surface produces only a couple of spikes from these axons. Careful dissection of the connective tissue that surrounds the PC axon shows that the axon itself adapts to only a limited degree. It stops responding because the fluid-filled capsule around it carries the energy of a continually applied probe away from the axon tip. That closes the cation channels responsible for mechanical transduction. By contrast, repeated application of a mechanical stimulus, such as a tuning fork that vibrates at 200 Hz, produces a series of discrete transduction events and a series of action potentials. We can say with great confidence, then, that PCs respond to high-frequency vibration at even the smallest magnitude. This extreme sensitivity to vibration turns the PC afferent into a detector of remote events: they respond to the minute vibrations of the skin produced whenever we use tools, such as pencils, screwdrivers, and keys.

Meissner's Corpuscles

Lower-frequency vibration, sometimes called flutter, produces a maximal response in RA afferents. As for PCs, the correlation between this type of response and

the structure of the afferent axon and its surrounding tissue is consistent. Each RA afferent ends as a stack of broad terminal disks within a Meissner's corpuscle composed of nonneural cells. Meissner's corpuscles exist in dermal pockets, as close to the epidermis as any dermal structure can be (Fig. 24.3), and their density is extraordinary, approaching 50/mm^2 in the index fingertip of a young adult. The result is an afferent very sensitive to even the slightest movement of skin, as happens when an object slides across the hand (Friedman et al., 2002). Yet every Meissner's corpuscle has at least two RA axons curled around it, and every RA axon innervates between 20 and 50 separate corpuscles. This convergence of two or more RA axons to a single corpuscle and divergence of a single RA axon to many corpuscles leads to large receptive fields (5 mm^2). So even though RA afferents are numerous and very close to the skin surface, their receptive field size and the filtering properties of the connective tissue capsule produce a response that is inappropriate for form and texture perception. RA afferents are responsible, instead, for the detection of objects slipping across the hand and fingers. They provide the sensory information that leads to the adjustment of grip force.

Merkel's Disks

Of the two slowly adapting afferents, SAIs end in a manner that prompts no arguments. A single SAI axon breaks into several branches that end in several closely packed dermal ridges (Fig. 24.3). Each branch ends in a series of axon terminals and each terminal is enfolded by an epidermal Merkel cell, all of which produces a surface elevation called a touch dome.

Merkel cells contact the tips SAI afferents by what looks to be a chemical synapse, and vesicles in the Merkel cell are filled with neurotransmitters. When a gene mutation deletes Merkel cells early in embryonic development—before ganglion cell axons reach the skin surface—SAI responses fail to develop; when deletion occurs later in development, SAI responses persist. These data indicate Merkel cells play a fundamental role in the development of SAI afferents but contribute little to the transduction of mechanical stimuli.

SAI Afferents Are Responsible for Form, Texture, and Curvature

SAI afferents are the source of peripheral information used by the CNS to perceive form, texture, and object curvature. Form perception has been carefully studied by a combination of psychophysics and neurophysiology because the dimensions of form are readily quantifiable. When the performance of individual receptors on the surface of a monkey's finger pad is compared with the performance of the monkey itself, only one type of afferent is found to be sensitive enough to account for an animal's ability to discriminate the form of a mechanical stimulus. That receptor is at the tip of SAI afferents ending in Merkel's disk. One example is seen in the response to the type of dots used in Braille (Fig. 24.4). Only the SAI afferents respond to the minute edges present in these embossed dots (6.0 mm high or greater) so accurately as to account for the ability a monkey or a human has in telling one pattern from the next.

In contrast to tactile form, texture has relatively few dimensions (rough-smooth, hard-soft, and sticky-slippery are the most prominent), but they are difficult to quantify. Nevertheless, a series of careful studies has documented that for variations in roughness, only the response of SAI afferents matches human perceptual ability. That is, the variation in firing rates among SAI follows precisely the perception human subjects have of surface roughness. Much the same can be said for the detection of surface hardness. Only the response of SAI afferents can account for human perception of how hard or soft is the surface of an object scanned by the fingertips. In summary, a combination of physiological and psychophysical studies leads one to conclude that SAIs provide the central somatosensory system with all the information it needs to detect the shape, hardness, and the roughness of objects pressed or scanned across the skin.

SAII Afferents

A second slowly adapting afferent in human skin, the SAII afferent, differs from an SAI in the greater size of its receptive field, the reduced sensitivity to simple indentation of the skin, and the greater sensitivity to skin stretch.

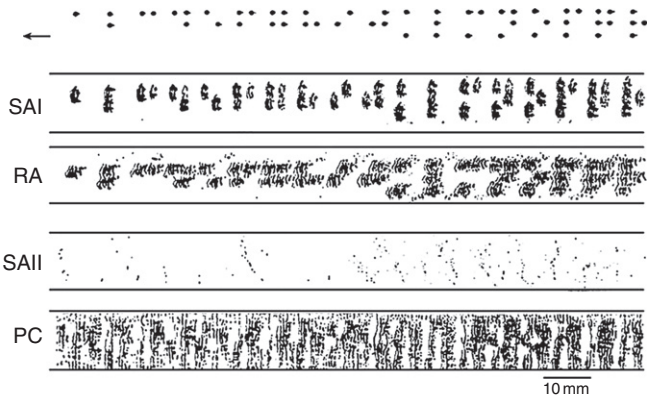

FIGURE 24.4 Responses of peripheral axons to a Braille pattern of dots scanned over the surface of a human fingertip at a rate of 60 mm/s with 200-μm shifts in position after each pass. Dots represent individual action potentials. Only the response of the SAI afferents (Merkel disk receptors) follows the Braille pattern faithfully, whereas RA afferents and Pacinians (PC) produce a response that distorts the input. SAIIs display little response to this stimulus. Adapted from Phillips *et al.* (1990).

One surprising feature of these afferents is their less-than-universal presence across the few mammals that have been studied. Direct recordings from the peripheral nerves of humans and domestic cats show these afferents to be a commonly encountered feature of both species, but they are rarely encountered in monkeys or mice. Just as perplexing is the poor correlation between structure and function with this receptor. SAII responses in cats arise from axons terminating in skin as Ruffini endings. These structures were first described in human skin at the turn of the twentieth century, but a very recent study found true Ruffini endings in human skin very rarely and only in the bed of fingernails (Pare et al., 2003). And so it appears SAII responses over most of the human hand arise from some other interaction of mechanoreceptor axon and connective tissue sheath. A conservative conclusion from these findings is that an arrangement of nonneural cells, perhaps a classic Ruffini corpuscle in cats but another configuration in humans, leads to the cardinal feature of SAII afferents—namely, a robust response to skin stretch. That configuration could vary from one species to another and from one area of skin surface to the next, but in the end, the nonneural tissue serves as a mechanical filter. After subtracting from the activity of a SAII afferent any response to simple deformation of the skin, the nonneural tissue leaves behind an unambiguous response to anything that stretches the skin.

Hair Follicle Afferents

In addition to receptor types found in glaborous skin, hairy skin is innervated by a separate receptor, called the D-hair receptor or hair follicle afferent (HFA). It is the most sensitive receptor in hairy skin. The HFA threshold is said to be one-tenth that of any other afferent in mouse skin, and displacement of a hair follicle by as little as 1 μm produces robust responses in this population of receptors. Single afferents innervate more than one hair follicle and as a result, the receptive field of an HFA is large (>10 mm^2 in mice). Unlike other mechanoreceptors, HFAs conduct action potentials in the Aδ range, which translates into a velocity of 20–25 m/s for humans but a much lower velocity in mice.

Receptor Density

A plot of SAI and SAII receptors along the human skin surface shows receptive field size and density vary by a factor of four in the short distance from the fingertip to the wrist. As is the case for other sensory systems, wherever receptor density declines, receptive field size ascends. This inverse variation in receptive size and density is reflected in the ability of a human subject to discriminate the two-dimensional shape of an object. Regions of high spatial acuity include the tips of the fingers and the face, whereas regions of low spatial acuity include the thigh and back.

Muscle Spindles and Golgi Tendon Organs Are Proprioceptors

The most prominent receptors fulfilling the function of sensing position and movement are muscle receptors and tendon receptors. These two have in common their sensitivity to stretch and the large diameter of the axons that carry the receptors' activity into the CNS. The manner in which they are arranged, however, makes all the difference in the world. Muscle receptors are arranged in parallel with the muscle fibers and as a result, these afferents respond when the muscle is stretched. As a common occurrence, muscle fibers stretch when load is added to them in the form of weight or resistance. The resulting stretch of the extrafusal or work muscle fibers produces a simultaneous stretch of the much smaller intrafusal muscle fibers. The intrafusal fibers have their own motor innervation and a sensory innervation from the largest diameter axons in a sensory nerve (Fig. 24.5). These sensory axons are called Ia afferents and they end in two configurations around the non-contractile portion of an intrafusal muscle fiber, where they signal the static and dynamic aspects of muscle stretch. A connective tissue capsule surrounds all of these—sensory axons, intrafusal muscle fibers, and motor axons—to form a muscle spindle. What the motor axons do to all this is simple to envision: by adjusting the contractile state of the intrafusal muscle fiber, they adjust the sensitivity of the muscle afferent. When the intrafusal fiber is contracted the spindle is at its most sensitive and when the intrafusal fiber is relaxed, the spindle is least sensitive.

Much as muscle receptors are sensitive to muscle stretch, tendon receptors (referred to as Golgi tendon organs) are sensitive to tendon stretch and provide information about muscle force. Because tendons are arranged in series with the muscles, so too are tendon receptors. What stretches the tendon is muscle contraction. In this regard, muscle spindles and Golgi tendon organs signal opposite trends. Spindles fire when a muscle is relatively inactive and stretched whereas tendon organs fire when the muscle is most active and contracted.

Proprioception Involves More Than Proprioceptors

By a definition of proprioception as an awareness of the position of the body and limbs, the two most prominent proprioceptors are necessary but not sufficient. More than just muscle and tendon receptors are at work to provide us with information about limb position. The related sense of kinesthesia, or awareness of position of moving body parts, is equally complex. Often used interchangeably for position sense, these two are percepts that require the contribution of receptors in muscle, skin and joints as well as a sense of muscle exertion. Studies in the

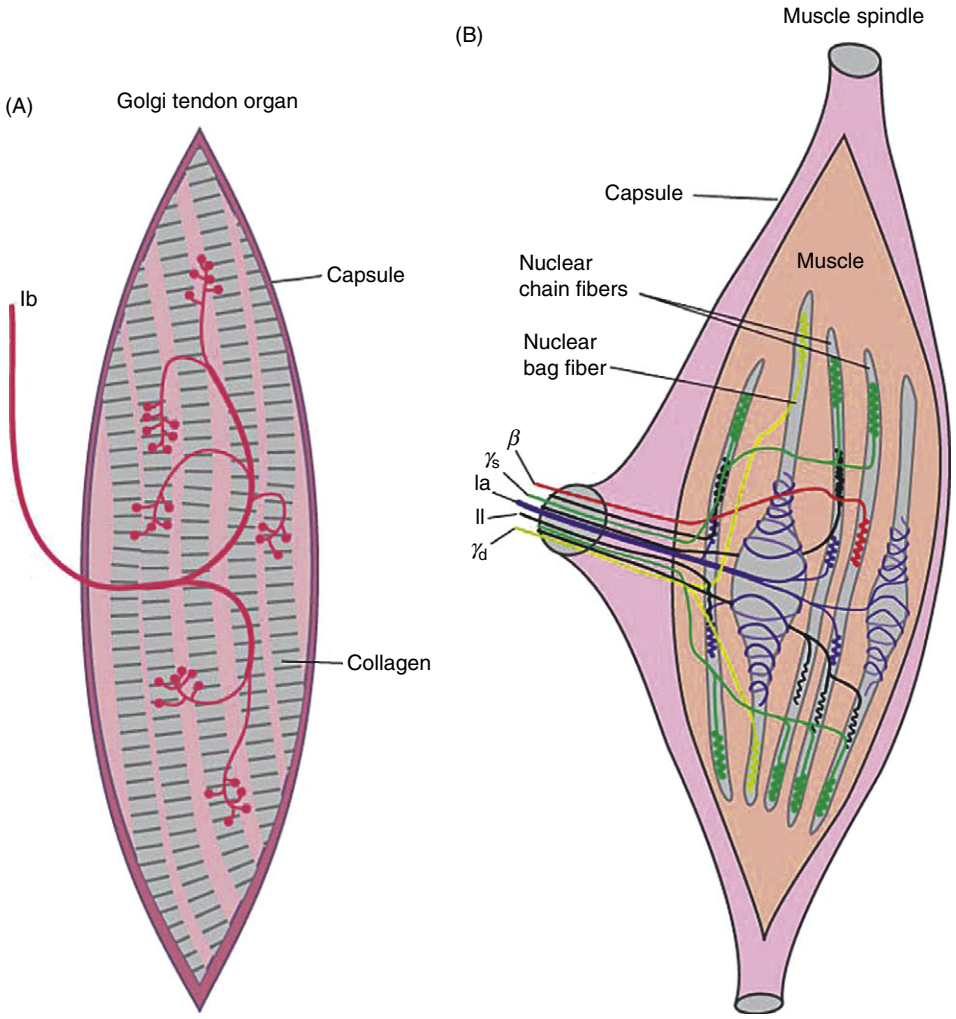

FIGURE 24.5 Proprioceptive afferents. (A) Golgi tendon organs and afferent termination along collagen fibers of the tendon capsule. These afferents respond when the entire capsule is stretched, usually by overvigorous contraction of the muscle. (B) Muscle spindle afferents (Ia and II) terminate on the noncontractile portions of intrafusal muscle fibers. They are arranged in parallel with working muscle fibers and respond to stretch of the entire muscle. Specialized motoneurons (γ) provide the motor innervation of the intrafusal muscle fibers and control the overall sensitivity of the muscle spindle.

1950s and 1960s focused on the contribution of joint afferents to a sense of limb position. Yet a series of findings in the 1970s made it clear that a sense of position survives joint removal; the joint afferents themselves respond only at the extreme limits of joint flexion. With no response in the usual, midrange of joint movement, these afferents could not signal position under most circumstances.

Studies of more recent vintage have dealt with muscle spindle afferents as a major source of the position signal. Since all muscles are organized as antagonistic pairs, contraction of one delivers a robust stimulus (muscle stretch) to afferents of the antagonistic muscle. From these sorts of inputs, limb position and movement would appear to require a simple neural computation. That position sense is significantly affected by stimulation, anesthesia and disengagement of spindle afferents adds weight to the argument that signaling limb position and movement requires these receptors. Perhaps the most convincing data are from studies of illusory movements produced by tendon vibration. This type of stimulus selectively activates spindle afferents and leads to the perception of limb movement when none has occurred. Illusory movement is muscle specific, so activation of arm flexors gives rise to the percept of an arm that has extended (a movement that normally produces activation of flexor muscle spindles). The illusion is so strong it gives rise to the Pinocchio effect: if arm flexor afferents are activated when a subject is touching his or her nose with an index finger, the nose itself is perceived to grow.

Only recently has proper attention been paid to the role of cutaneous receptors in position sense. SAII afferents, in particular, respond in a unique manner to any position a limb or digit might adopt. Particularly compelling is the role these skin stretch receptors play in signaling the position of fingers. For the hand and fingers, therefore, a conscious sense of position appears to arise from the cooperative activity of SAII afferents, muscle afferents and (at the extremes of movement) joint afferents.

NOCICEPTION

Nociceptors Respond to Noxious Stimuli

For most purposes, anything that has produced tissue damage or that threatens do so in the immediate future is defined as noxious; the type of axon that responds selectively to the noxious quality of a stimulus is a nociceptor. These are not pain receptors because nociception is not pain. Whereas nociception is a peripheral phenomenon that occurs when tissue has been or soon will be damaged, pain is a percept that requires regions of the CNS to become active.

All nociceptors end simply in skin and other peripheral tissues. These are usually described as free nerve endings because, unlike mechanoreceptive afferents, nociceptors do not end in a specialized capsule of nonneural cells. Nothing extraneuronal serves as a filter or buffer between the nociceptive axon tip and its immediate environment. The only thing that determines the response of a nociceptor, then, is the type of protein receptor and ion channel it inserts into its plasma membrane.

Nociceptors also differ from mechanoreceptors in how broadly the terminals of the peripheral axon branch as they reach target. Take the tip of the human index finger as an example. An individual SAI and SAII axon ends in a well-confined cluster of terminals over a distance as small as a few millimeters. Terminals of a single C fiber, by contrast, end over an area of more than a dozen millimeters. This is the first of several anatomical features along the nociceptive pathway that produce a much coarser spatial sense for pain than exists for mechanosensation. Only the simultaneous activation of mechanoreceptors as occurs with puncture wounds or damaging compression permits a person to accurately detect the location of a nociceptive stimulus.

The afferents that make up the nociceptive population can be subdivided into groups that are named by their axon conduction velocity (Aδ vs. C) and the response to noxious mechanical stimuli and noxious heat. Thus, an AM receptor conducts in the Aδ range and responds to intense mechanical stimuli, whereas a CMH receptor conducts in the C range and responds to both noxious mechanical energy and noxious heat. Other permutations of conduction velocity and response type are evident in the peripheral nerves of humans and other mammals, but these two are most common. They are frequently referred to as specific mechanical nociceptors and polymodal nociceptors.

First and Second Pain

Afferents responding specifically to a mechanical stimulus (AM receptors) carry the most rapid signals into the CNS, whereas those responding to the broad range of noxious stimuli (CMH receptors) conduct action potentials more slowly. These are the peripheral components to the two very different qualities of pain perceived by humans (Fig. 24.6). First pain or epicritic pain is rapidly perceived and carries with it much that is discriminative. A person can quickly and with some ease figure out what has happened and where it has happened when he or she drops a heavy object onto a toe or touches a hot stove surface with a couple of fingers on the right hand. First pain is informative and the peripheral component of it is the population of Aδ nociceptors. What follows later is second pain or protopathic pain. This is agonizing pain that carries much less information about location or source of energy. Second pain is punishing pain that serves to change the behavior of a person. Its peripheral component is the population of C nociceptors.

Two varieties of C nociceptors are found in mammalian skin. One variety is characterized by the presence of fluoride-resistant acid phosphatase (FRAP) in its cytoplasm and cell-surface glycoproteins recognized by the isolectin I-B4 and the monoclonal antibody LA4. Because none of these proteins is known to contribute to the physiological features of this C fiber type, their presence is currently a convenient feature that allows anyone studying them to recognize them. The situation is very different in the second type of C nociceptor. Present in its cytoplasm are two neuroactive peptides: calcitonin gene-related peptide (CGRP) and substance P. These play major roles in the function of the peptide-containing type of C nociceptor.

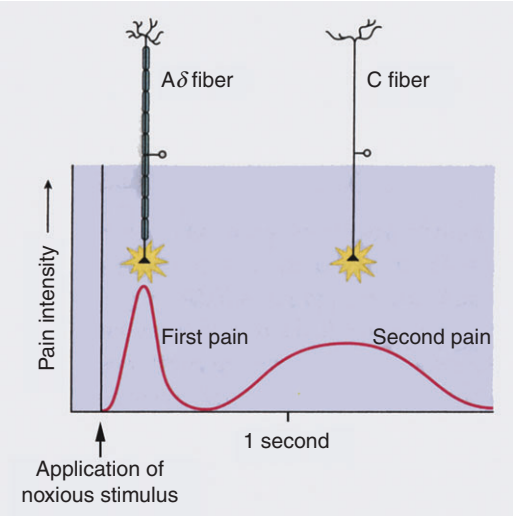

FIGURE 24.6 The two classes of nociceptors that conduct action potentials in the C and Ad ranges are peripheral components for two types of pain. First pain carried by Ad axons reaches consciousness rapidly and is discriminative. Both the location and the subjective intensity of the stimulus can be judged with relatively good precision in first pain. Second pain, in contrast, is much slower and is agonizing pain, with greatly reduced discriminative value.

The Axon Reflex

Release of neuropeptides from the second type of C nociceptor is responsible for the axon reflex. Injury to the skin surface is often well confined, as happens with a paper cut, for example. Yet within a short time of that injury, tissue surrounding the cut becomes reddened, in what is referred to as flair, and edema or swelling sets in as the tissue fills with fluid. Most importantly, the region surrounding a punctate wound becomes painful to touch even though it is outside the zone of direct damage.

Recall that an individual C fiber terminates over a wide area in skin, and so it is very likely that a punctate wound directly affects only a fraction of all that fiber's many branches. Action potentials generated at those directly affected branches invade all the peripheral branches, as well as the parent axon that conducts the signal to the CNS. At all the peripheral terminals, substance P and CGRP are released onto two principal targets: the smooth muscle surrounding peripheral blood vessels and histamine-rich mast cells. By causing the arterial smooth muscles to relax, the peptides increase the flow of blood into the damaged tissue and produce a flow of water and electrolytes out of capillaries and into extracellular space. This process is referred to as extravasation. Histamine released from mast cells leads to a pronounced inflammatory response. All of this is important for the infiltration of damaged tissue with cellular elements that will protect against infection and promote repair. Yet what is most obvious about the axon reflex is the much greater sensitivity of the tissue surrounding a wound to anything that might be noxious. This primary hyperalgesia is a direct result of the axon reflex. It occurs because the protein receptors inserted into nociceptive axons are sensitive to chemical changes produced by that reflex (Sandkiller, 2009).

Both the histamine released by mast cells and the edema resulting from extravasation affect the response of nociceptors. Histamine's effects are more selective, as only a subclass of the most slowly conducting C fibers insert histamine receptors into the membranes of their axon terminals. A considerable body of evidence suggests these are peripheral receptors whose activity leads to the unpleasant percept of itch. A parallel system for itch that operates independently of histamine release has been discovered recently but the population of afferents involved is not yet known.

Edema causes a general reduction in pH of extracellular fluid from 7.4 to below 6.0. A general feature of protein receptors inserted into nociceptive axons is their sensitivity to the concentration of H^+. Through this sensitivity to pH, activation of one branch of a C fiber leads to increased sensitivity of all its branches and all neighboring nociceptors to noxious stimulation. At least some of those neighboring nociceptors are likely to be silent nociceptors, so named because they are unresponsive to intense mechanical stimulation under normal circumstances. When activated by changes in pH or the presence of factors that signal the presence of tissue damage, the silent nociceptors become responsive to noxious stimuli.

Chemical Sensitivity of Nociceptors

Two of the most powerful pain-inducing chemicals that can be delivered to a human observer are natural products of tissue damage. They are lipids of the prostaglandin family and the peptide bradykinin. Prostaglandins are derivatives of the membrane fatty acid, arachidonic acid, which is itself a major component of the lipid bilayer. Damage to tissue and the resulting disruption of cell membranes releases arachidonic acid into extracellular fluid. The enzyme cyclo-oxygenase (COX) breaks down arachidonic acid to form prostaglandin. Inhibitors that target COX are referred to as nonsteroidal anti-inflammatory drugs (NSAIDS) and they include both aspirin and ibuprofen. Their popularity is a powerful indication of effectiveness in suppressing pain by interfering with the production of prostaglandins.

Nociceptor Proteins

Detection of noxious heat occurs by way of channels that are members of the transient receptor potential (TRP) family. Two members of the TRPV class—they are referred to as TRPV1 (Fig. 24.7) and TRPV2—pay particularly important roles in nociception (Tominaga et al., 1998). The V in the channel's name refers to its sensitivity to vanilloids, the active ingredients of chili peppers. TRPV1 is a nonspecific cation channel with approximately ten times more permeability to Na^+ than to Ca^{2+}. Like other members of the TRPV subfamily, TRPV1 is a molecular thermometer that opens in response to increased temperature. It has a threshold of 42^o C. TRPV2 channels, by contrast, open only when skin temperature reaches 50^o C. Although they are primarily detectors of noxious heat, nociceptors with TRPV1 channels are typically polymodal (they respond to other noxious stimuli), in part because of the TRPV1's properties and in part because these afferents express other receptor proteins. Because H^+ directly gates TRPV1 channels, any reduction in pH (the acidosis that accompanies tissue swelling) comes to depolarize these afferents. Other channels, the Acid Sensing Ion Channels (ASICs), also open in response to an increase in H^+ concentration. One of these, referred to as ASIC-3, is especially sensitive to the presence of lactic acid and, therefore, is a prime candidate for a receptor of ischemic pain in cardiac muscle.

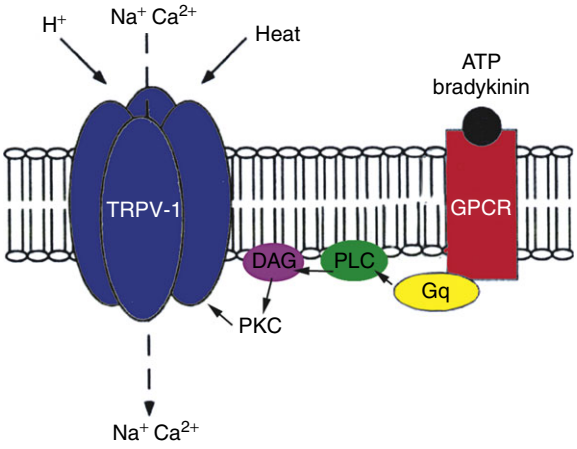

FIGURE 24.7 The receptor protein, TRPV1, provides a nociceptor with the ability to respond to many noxious stimuli. In addition to heat, TRPV1 is directly gated by a reduction in pH (afferent of H^+) produced in response to tissue swelling. Either or both opens a nonspecific cation channel that, through an influx of Na^+, depolarizes the nociceptor axon. Circulating agents that signal the presence of tissue damage (ATP and bradykinin) bind to a G-protein coupled receptor (GPCR). Through a series of steps PKCε is activated and TRPV1 subunits are phosphorylated, leading to a sensitization of the receptor. One result of this cascade is an opening of the cation channel at body temperature.

Two other proteins, both G-protein coupled receptors, broaden the response of polymodal nociceptors to include anything that produces tissue damage. One is a receptor for two molecules—bradykinin and ATP—released when the plasma membranes of cells are damaged. Their binding to plasma membrane receptors sets up an intracellular cascade that lowers the threshold temperature at which TRPV1 channels open. As that threshold descends to normal body temperature, TRPV1 channels open without any thermal stimulus at all and initiate action potentials in nociceptor axons. Finally, most polymodal nociceptors express GPCRs that bind prostaglandin and drive open an unusual population of Na channels. This, too, provides the afferents with a depolarizing stimulus when tissue is damaged.

One major outstanding question is the nature of the channel that opens in response to noxious (high-threshold) mechanical stimulation, such as a hard pinch. The same question exists for the low-threshold mechanically gated channel in SA and RA afferents, in proprioceptors, and in other cells, such as hair cells of the inner ear. Whereas common wisdom has long thought the somatosensory mechanoreceptors to be members of either the Epithelial Sodium Channel (ENaC) family or the TRP superfamily, very recent work suggests they are part of a novel group that has been dubbed Piezo. Caution is advisable, however, because the search for a mechanically gated channel has had its fair share of blind alleys and false starts.

CNS COMPONENTS OF SOMATIC SENSATION

The central paths taken by large diameter afferents and small diameter afferents tell two stories worth attention. The first is that the path for mechanosensation and proprioception is separate and largely distinct from the path for nociception, thermoreception, and itch. These separate paths continue through the CNS to the cerebral cortex and represent one of the clearest divisions of labor seen in any sensory system. The second story is seen in the many regions of the CNS contacted by each population of axons. Here the lesson repeats a statement made at the beginning of this chapter: the somatosensory system has many tasks to perform, from the input side of motor reflexes to the higher-order functions of perception, comprehension, and emotion. To accomplish them, mechanosensory/proprioceptive and nociceptive/thermoreceptive axons send information along several pathways, performing separate functions.

An Outline of Ascending Paths to Perception

Primary afferents in the somatosensory system terminate on second-order neurons in either the spinal cord (nociceptors and thermoreceptors) or medulla (mechanoreceptors and proprioceptors) (Fig. 24.8). Second-order neurons in the spinal cord and medulla send their axons across the midline to terminate in thalamus. Convergence is kept to a minimum so that second-order mechanosensory and nociceptive neurons end in separate nuclei and subnuclei of the thalamus. In addition, axons of particular submodalities (e.g., muscle spindle afferents vs. cutaneous afferents) end in different subnuclei of the thalamus. The major thalamic nuclei involved are the various parts of the ventral posterior complex (referred to as ventral caudal in human studies). The lateral and medial subnuclei of VP, logically named VPL and VPM, are the recipients of discriminative inputs from the body and face, respectively. Both innervate the first somatosensory cortex (SI) and a third subnucleus, VPI, sends its axons to the second somatosensory area (SII).

SI and SII are recognized in the cerebral cortex of all mammals that have been examined (Fig. 24.9). Yet the organization of each appears to vary considerably across that class. If we take human cerebral cortex as a starting point, SI is traditionally divided into four structurally distinct areas named (from rostral to caudal) areas 3a, 3b, 1, and 2. The same is seen for the best-studied genus of monkeys, the macaques. What stands out in the organization of these four areas is the combination of serial and parallel processing. Parallel processing is seen in the types of thalamic neurons that innervate each area and the receptive field properties displayed by those

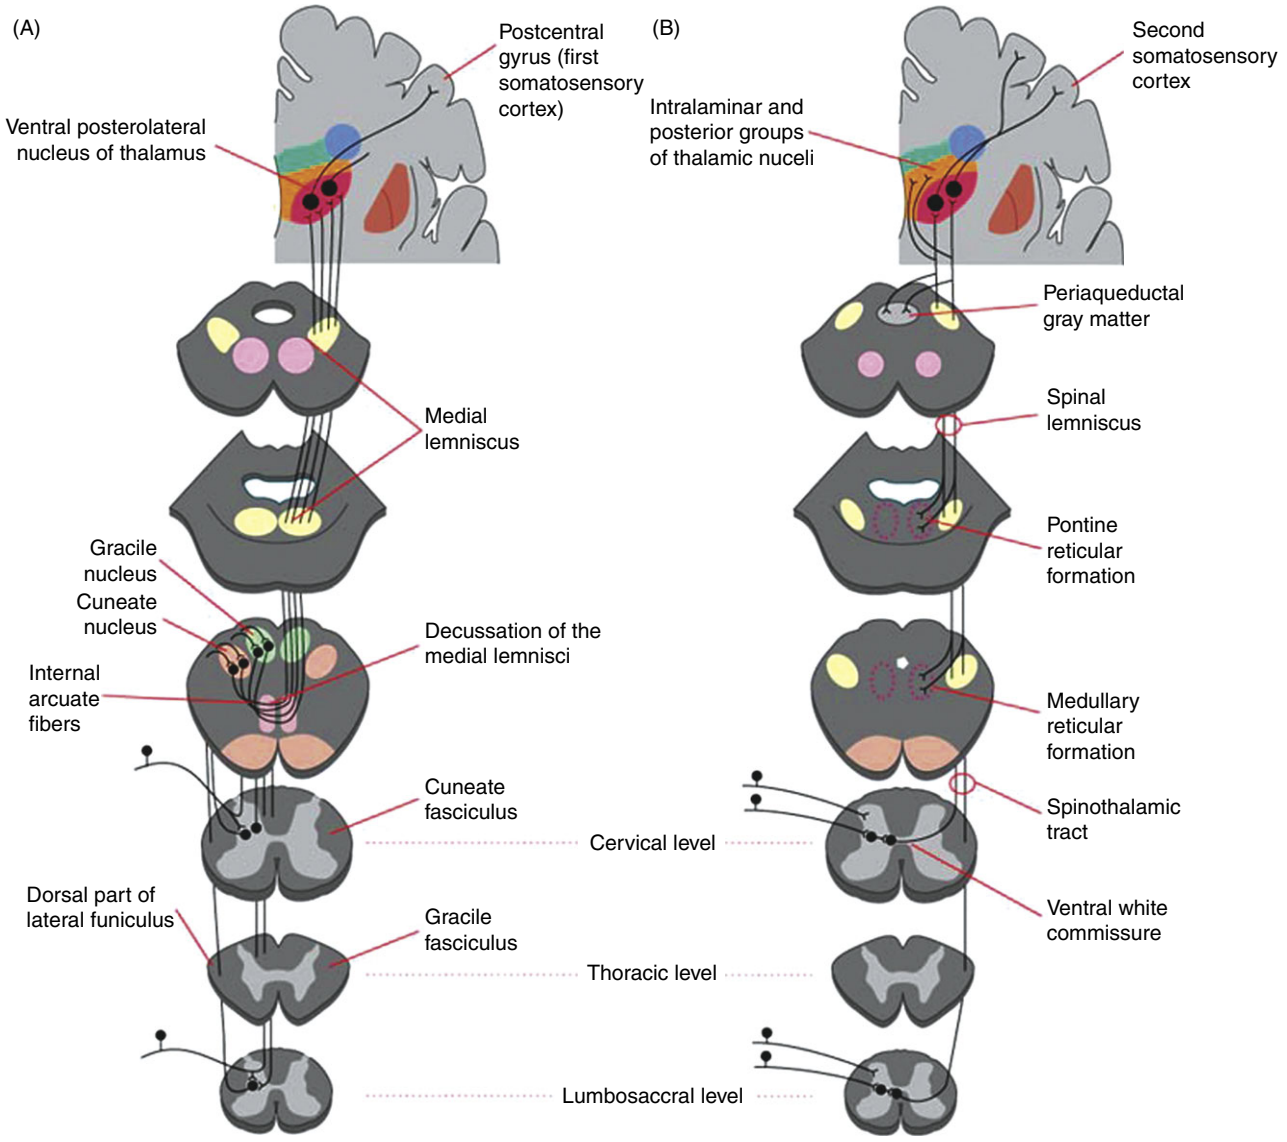

FIGURE 24.8 Anatomy of ascending somatosensory paths. (A) Organization of the dorsal column-medial lemniscal system from entry of large diameter afferents into the spinal cord to the termination of thalamocortical axons in the first somatosensory area of the cerebral cortex. An obligatory synapse occurs in the gracile and cuneate nuclei, from which second-order axons cross the midline and ascend to the ventral posterolateral nucleus of the thalamus (VPL) by way of the medial lemniscus. (B) Organization of the spinothalamic tract and the remainder of the anterolateral system. Primary axons terminate the spinal cord itself. Second-order axons cross the midline and ascend through the spinal cord and brainstem to terminate in VPL and other nuclei of the thalamus. Collaterals of these axons terminate in the reticular formation of the pons and medulla.

cortical neurons. Areas 3b and 1 are most often characterized by the response of neurons to cutaneous inputs, SAs and RAs, whereas neurons in area 3a are found to respond exclusively to stimulation of deep receptors and neurons in area 2 respond to both.

Serial processing of information is evident in both the physiology and connectivity of these areas. Area 3b is much more richly innervated by VPL and VPM than any of the other three areas of SI and, in terms of its structure and connectivity, appears much more of a primary sensory area. Comparative studies suggest that area 3b of rhesus monkeys and humans is in most ways equivalent to all of SI in other mammals and so this area is often referred to as SI Proper. The principal outputs of area 3b are directed caudally to areas 1 and 2; and in a similar fashion, area 1 sends its own rich set of axons to area 2. From these considerations, a hierarchy emerges, with area 2 at something of a pinnacle, in that it receives a direct deep receptor input from the thalamus, indirect deep input from 3a and an indirect cutaneous input from areas 3b and 1.

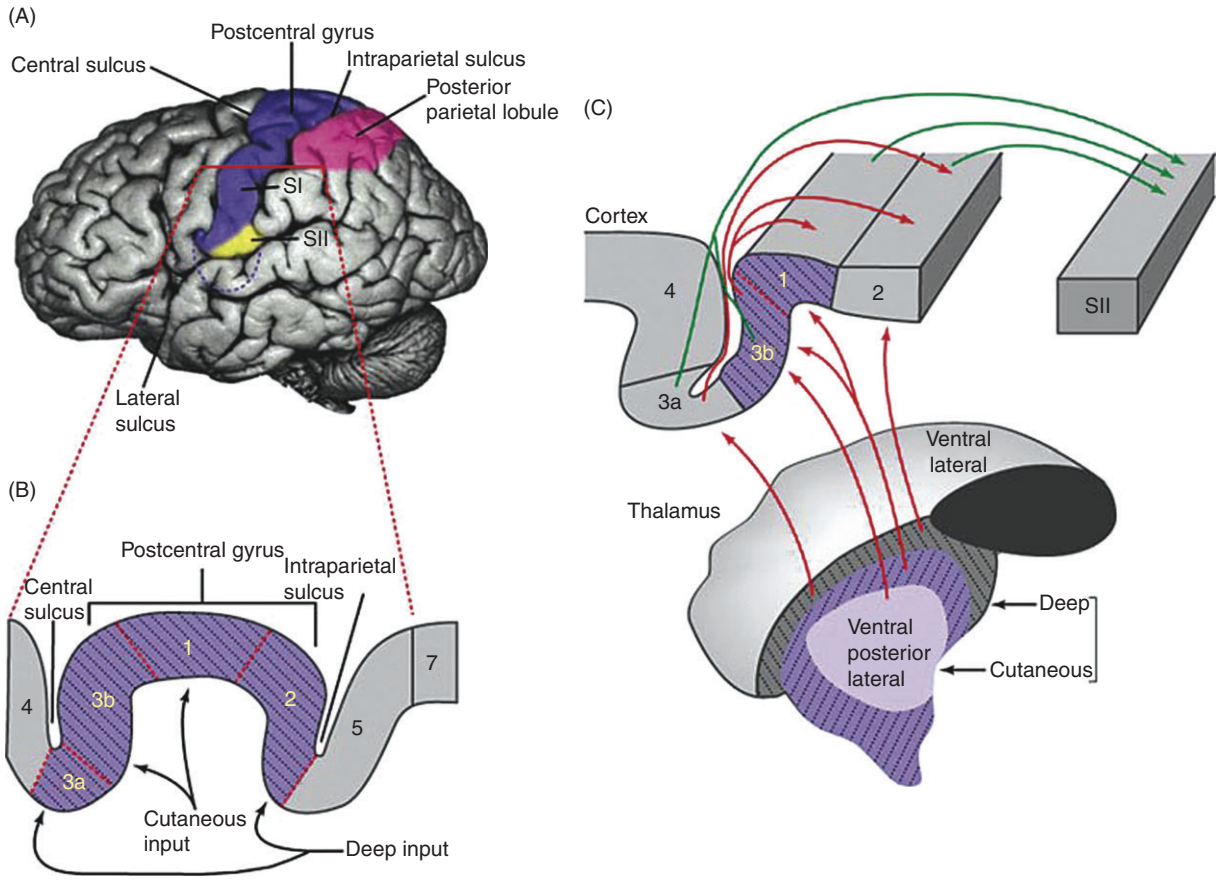

FIGURE 24.9 The first somatosensory cortex of humans and other primates is an amalgam of four areas, each of which has a complete map of the body surface. (A) SI and SII are located posterior to the central sulcus. (B) SI is shown at higher magnification. Areas are numbered according to the original scheme by Brodmann as areas 3a, 3b, 1, and 2 (from rostral to caudal in the postcentral gyrus). (C) Thalamic input from the core of VPL and VPM carries cutaneous mechanosensory information to areas 3b and 1, while a parallel route from the shell of VPL and VPM carries deep (e.g., muscle spindle) information to areas 3a and 2. Intracortical connections from area 1 to area 2 make up a route by which cutaneous information also reaches area 2. As a site of convergent deep input from thalamus and cutaneous input from area 1, area 2 is the most likely location in which a complete proprioceptive map emerges.

The output of SI as a whole is in two directions (Fig. 24.10):

1. A ventral path to SII and from there to the caudal insula, to areas of the temporal lobe, and to premotor and prefrontal cortical areas. Eventual convergence of somatosensory, auditory, and visual information in the medial temporal lobe is viewed as the path toward shape and form processing. This ventral path is vital for inserting new information into declarative memory and accessing established memories for comparison with ongoing events.
2. A dorsal path to superior parietal lobule, providing areas in that lobule with somesthetic information for control of voluntary movements, selective attention, and information about how to perform different tasks, sometimes known as the "how" pathway.

With these essential elements in mind, we will consider separately the paths for mechanosensation and nociception from the entry of primary afferents into the spinal cord to the areas of cortex in which the elements of sensation are brought together into a perceptual whole.

The Path for Mechanosensation for the Body

Dorsal columns are the principal routes for spinal mechanoreceptor axons. All axons of sensory ganglion cells enter the CNS by way of dorsal roots and the trigeminal nerves. At a gross level the spinal cord is segmented by the existence of separate dorsal root ganglia. Because the peripheral tissue innervated by any one dorsal root ganglion is restricted, the entire innervation of the body surface can be seen as a series of overlapping bands. These are the dermatomes. As a practical matter, then, a mechanical stimulus applied to a restricted region of the body surface leads to action potentials conducted in one or at most two dorsal roots.

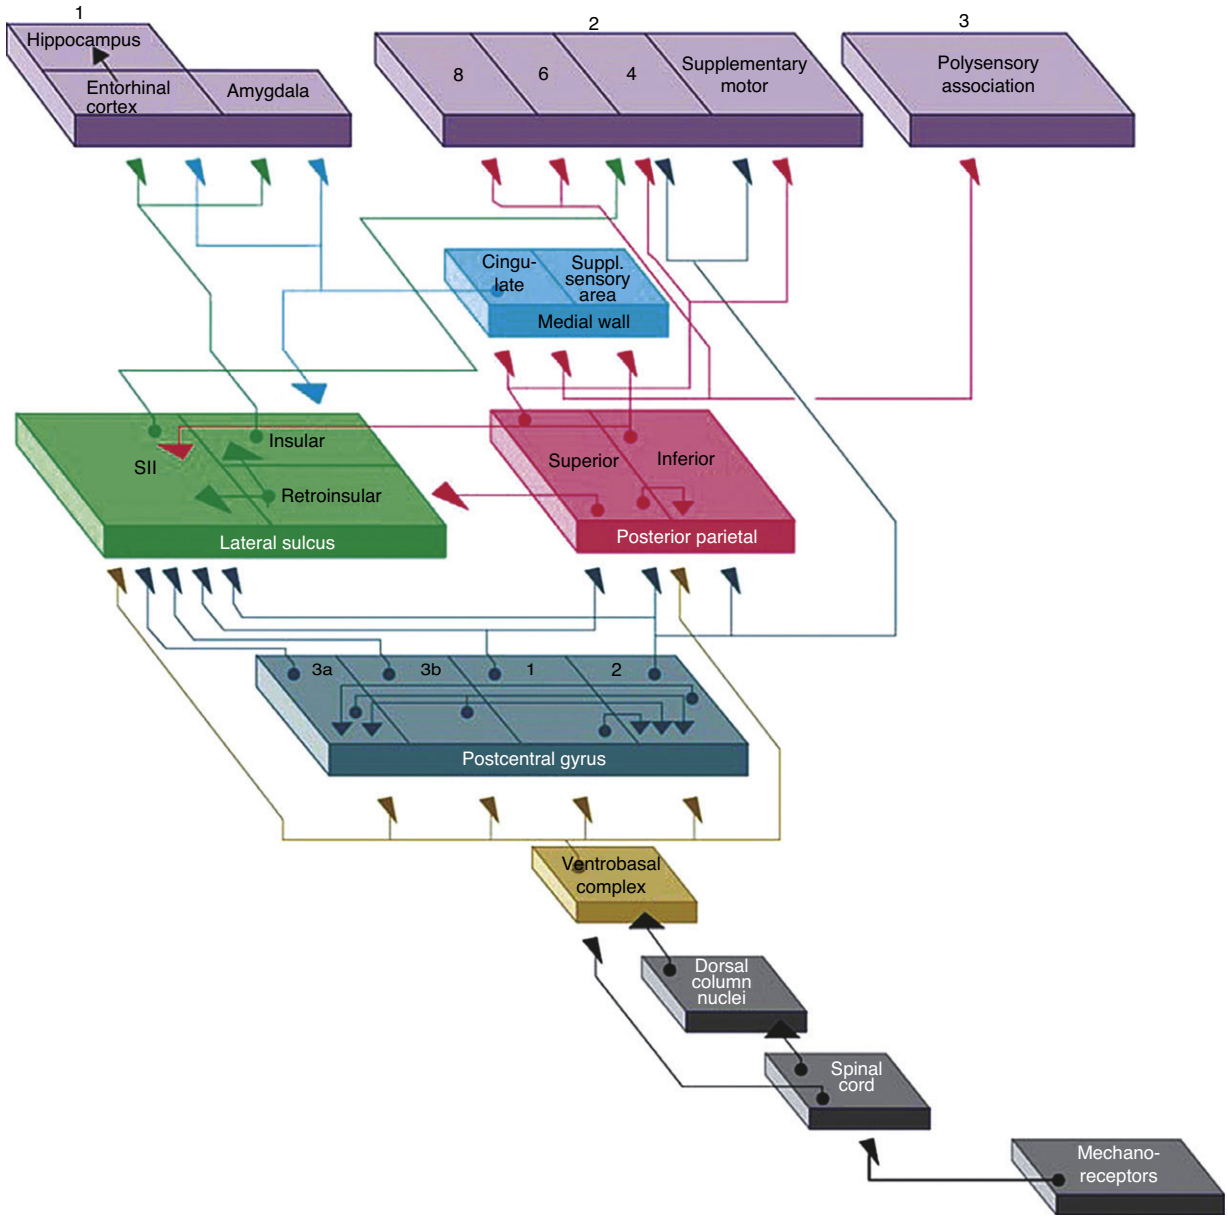

FIGURE 24.10 Schematic representation of the path taken by mechanoreceptor input to eventually reach three cortical targets. All relevant information reaches the ventrobasal complex and most is relayed to the areas of SI. From there, by steps through SII and the posterior parietal areas, somatosensory information reaches (1) the limbic system (entorhinal cortex and hippocampus), as a means for becoming part of or gaining access to stored memories; (2) the motor system (primary and supplementary motor cortex), where the continuous sensory feedback onto the motor system occurs; and (3) the polysensory cortex in the superior temporal gyrus, in which creation of a complete and abstract sensory map of the external world is thought to occur.

Mechanosensory and Nociceptive Axons Enter the Cord along Different Paths

The dorsal roots divide after they have penetrated the dura mater but before they are have entered the spinal cord itself. A medial division of large diameter, heavily myelinated axons enters at the dorsal funiculus of the cord, and the majority of those axons turn at right angles after they have entered the cord and ascend toward the brain. From level T7 of the cord to the terminal coccygeal segment, the large diameter axons enter one fiber tract called the gracile fasciculus. And as they do so they stack up as thin sheets with the earliest entering axons (coccygeal) occupying the most medial part of the funiculus and the last entering (7th thoracic) occupying the most lateral part. That same medial-to-lateral pattern continues with large axons that enter from T6 up to the first cervical segment but at those levels the axons form a separate fasciculus, called the cuneate fasciculus. Together the gracile

and cuneate fasciculi are called the dorsal columns. The orderly pattern established by the axons of the dorsal columns as they ascend means there is a body map or somatotopy to the ascending mechanosensory system. Large diameter axons ascend on the same side of the spinal cord as the one they entered to reach the lowest levels of the medulla.

Dorsal Column Nuclei

In a path toward sensory perception, the majority of axons in the dorsal columns ascend to reach the dorsal column nuclei at the junction of the spinal cord and medulla. The dorsal column nuclei are neither simple nor homogeneous. At the grossest level, each nucleus is divided into at least three regions in which axons of different mechanoreceptors terminate separately. Neurons receiving muscle spindle inputs are sufficiently distinct in some species to be given their own name: nucleus Z. All of this serves to accent the role played by subcortical somatosensory nuclei in keeping segregated the input from different functional classes of receptors.

Despite an anatomical convergence of primary afferents onto single neurons of the dorsal column nuclei, convergence and comparison of receptor input appears minimal. The coupling between a single neuron in the gracile or cuneate nucleus and a single afferent axon is extremely tight (Rowe, 2002). As a result of this coupling, a single action potential in the afferent axon reliably produces an action potential in the postsynaptic cell. That phenomenon is seen for RA, PC, and SAI afferents of the glabrous skin and hair follicle afferents of the hairy skin. These findings indicate that for a neuron in the gracile and cuneate nuclei, receptive field locations, sizes and properties are a matter of which primary afferent innervates that neuron.

The Lateral Cervical Nucleus

A cluster of mechanosensitive relay neurons starts in the dorsal horn at cervical segments 1 and 2 and extends into the caudal one-third of the medulla. This is called the lateral cervical nucleus. Innervated by mechanosensory neurons in the dorsal horn throughout all segments of the spinal cord, the neurons in the lateral cervical nucleus display predominantly cutaneous receptive fields that cover large patches of hairy skin and usually some part of glabrous skin. Most axons of cells in the nucleus decussate immediately and reach the contralateral VPL by way of the medial lemniscus. In the VPL, the cervicothalamic axons responding to low-threshold mechanical stimulation of skin or hair appear to converge with axons that arise in dorsal column nuclei. Unlike other nuclei of the somatosensory system, the lateral cervical nucleus is an inconstant feature of the mammalian nervous system. Whereas it is a robust part of the spinal cord and medulla in rodents and carnivores and has been found consistently in nonhuman primates, it is present in only half the humans studied and is well defined in very few of them. Comparison across species also shows a marked difference in the density of cervicothalamic terminations in the VPL, with the density in cats far exceeding that in rhesus monkeys. These findings lead to the assumption that functions parceled out to the lateral cervical nucleus in rodents and carnivores are sequestered in the dorsal column-medial lemniscal system of primates, and particularly of humans.

THALAMIC MECHANISMS OF SOMATIC SENSATION

Segregation of Place and Modality Continues in Thalamus

Medial lemniscal axons terminate on large neurons of the VPL and VPM. As in the dorsal column nuclei, the synaptic means to generate lateral inhibitory influences exists in the thalamus, but evidence for robust lateral inhibition is seldom found in these nuclei. Where inhibition has been detected, its strength across the neuron's receptive field matches that of the excitation so that the region of greatest inhibition is also the region of greatest excitation. Missing from this stage of somatosensory processing, then, is the synaptic means to produce contrast, by which activity produced by stimulation of one spot on the skin surface is compared with activity produced by stimulation of surrounding regions.

Neurons in the VPL and VPM display a cluster of features labeled as lemniscal properties. Static lemniscal properties are place and modality specificity. Thalamic circuits maintain these features much as they exist in the lemniscal afferents themselves. As a result, mixing of inputs is avoided in the thalamus and the specific properties of where on the body surface something has occurred and what exactly has occurred remain anatomically distinct. Dynamic properties characteristic of these cells include the ability to follow a rapid train of stimuli. Here the synaptic organization of the thalamus favors the ability of a thalamic neuron to behave much like the axon that innervates it.

Anatomical and physiological studies demonstrate that as lemniscal afferents terminate in the VPL, they do so as clusters of axon terminals elongated in the rostro-caudal dimension. They are referred to as rods. Rods appear to be the major organizing principle to somatosensory thalamus, as lemniscal axons carrying information of the same type (e.g., SAI input) from the same part of the body terminate in a rod-like formation. On the output side, thalamocortical neurons that send axons to a 1-mm-wide patch in SI occupy the same sort of formation. Thus, thalamic rods are the anatomical basis for the most salient

feature of somatosensory thalamus: the strict segregation of place- and modality-specific responses.

THE PATH FROM NOCICEPTION TO PAIN

Spinal Cord Pathways

In stark contrast to the pattern of input by mechanosensory axons, nociceptive axons terminate in the dorsal horn of the spinal cord. These lightly myelinated and unmyelinated axons enter the cord by way of a lateral division of the dorsal root and divide to send branches up and down the cord for a segment or two. The tract they form is a cap on the surface of the dorsal horn called Lissauer's tract. Nociceptive axons terminate, therefore, on dorsal horn neurons across four or five segments, and a single dorsal horn neuron is innervated by nociceptors that cover a broad swath of the body or limb surface. Second-order neurons innervated by the nociceptive axons give rise to axons that decussate and ascend in the anterolateral quadrant of white matter to reach the brainstem and thalamus.

Spinal cord circuits for nociception form two ascending routes with distinct functions (Fig. 24.11). Recall that the peripheral basis for first and second pain is the division of nociceptors into relatively fast-conducting Aδ axons and slow-conducting C fibers (Braz et al., 2005).

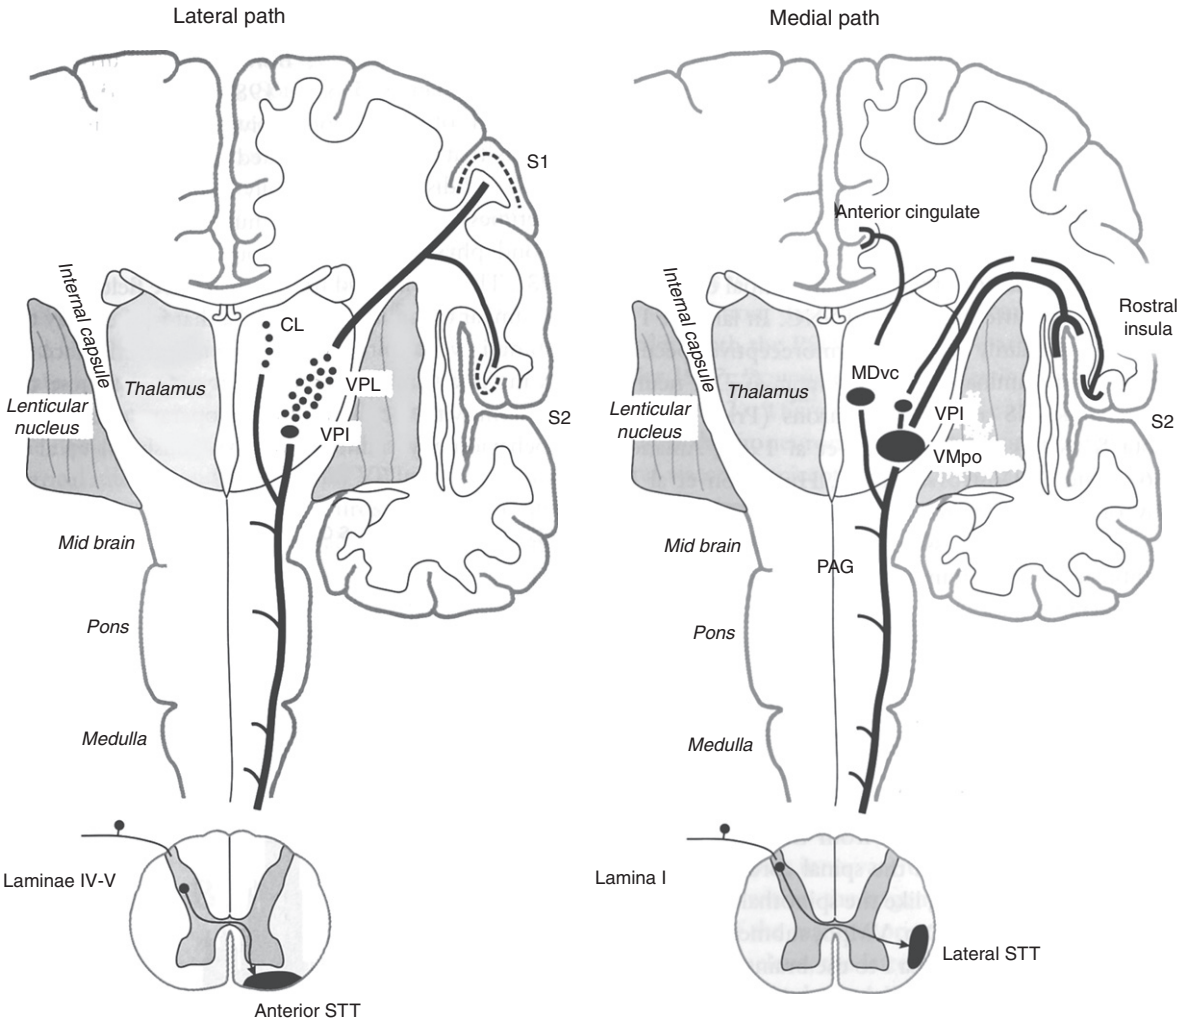

FIGURE 24.11 The medial path taken by spinothalamic neurons in lamina I (driven by C fibers) differs from the lateral path taken by neurons in laminae IV and V (driven by C and Aδ nociceptors and Aβ mechanoreceptors). Anterior spinothalamic tract axons are given off by the deeper neurons and terminate in lateral thalamus (VPL and VPI and the centrolateral nucleus). Lateral spinothalamic tract axons given off by lamina I neurons innervate medial thalamus, including the ventral caudal division of the mediodorsal nucleus (MDvc) and a region in posterolateral thalamus. In this figure, the region is labeled a separate, nociceptive/thermoreceptive-specific nucleus called VMpo, but several lines of evidence indicate lamina I neurons also innervate VPL and VPM, as well as VPI. From this varied thalamic innervation, nociceptive information reaches SI and SII for discriminative aspects of pain and temperature and the anterior cingulate and rostral insula for the affective, punishing aspects of pain.

Yet the discriminative versus agonizing components of pain is a CNS construct, produced by the difference in central circuits driven by Aδ and C fibers. To appreciate that difference, it is best to start with the population of spinothalamic neurons.

Spinothalamic Neurons

Spinal cord neurons that directly innervate thalamus (therefore, spinothalamic neurons) occupy several laminae in rhesus monkey spinal cord. The major populations, however, are found in the most superficial layer of dorsal horn (lamina I) and a second region deeper in the dorsal horn (lamina V). Nociceptive innervation of these two populations differs fundamentally. Lamina I neurons are innervated predominantly by C fibers, both directly and indirectly by way of excitatory interneurons in the immediately adjacent superficial half of lamina II. Theyalso receive an indirect innervation from Aδ fibers by those same interneurons and can be thought of as nociceptive-specific cells. Lamina V neurons, on the other hand, are innervated predominantly by Aδ fibers that end deep in lamina II on a population of excitatory interneurons. Many of these deeper spinothalamic neurons also receive a convergent input from mechanosensory axons (Aβ axons). Because they respond to both nociceptive and mechanosensory stimulation, these neurons are often referred to as wide dynamic range cells.

Ascending Paths to the Thalamus

Axons from both lamina I neurons and laminae IV/V neurons decussate and enter fiber tracts in the anterolateral quadrant of spinal cord, but the tracts they enter differ from one another in location and termination (Fig. 24.11). Neurons of laminae IV and V enter the anterior spinothalamic tract and terminate in lateral parts of the thalamus, including the VPL and VPI, and an intralaminar nucleus, the central lateral nucleus. The innervation of ventral posterior thalamus does not mean both nociceptive and mechanosensory information converge in the thalamus. The two remain segregated as medial lemniscal axons terminate on groups of large neurons, whereas spinothalamic axons innervate clusters of smaller neurons. Response properties of the smaller neurons in the VPL are much like those of the wide dynamic range neurons that innervate them, both in the type of stimuli to which they respond and the size of their receptive fields.

Nociceptive specific neurons of lamina I enter the lateral spinothalamic tract and terminate in several nuclei of the thalamus, including two that receive few deep lamina inputs (Fig. 24.11). Targets in which convergence of lamina I and lamina V inputs are strongly suspected or known to occur include the nucleus of the ventral posterior complex. Although the most compelling data in support of convergence has been reported for VPI, several careful studies have documented termination of lamina I inputs in the clusters of small neurons in VPL and VPM. This represents what has become a traditional view of the nociceptive pathway, that discriminative pain is driven by nociceptive inputs to both lamina I and lamina V, through a relay in the ventral posterior nuclei, and that nociceptive information reaches SI and SII (Perl and Kruger, 1996).

Outside the ventral posterior complex are two sites of spinothalamic terminations predominantly from lamina I (Fig. 24.11). One of these is a subnucleus of the mediodorsal nucleus (Mdvc) in which spinothalamic terminations are surprisingly rich. The other is posterior to the classically drawn borders of VP and includes the medial nucleus of the posterior group (POm). Neurons in this region are innervated by spinothalamic axons and display the same chemical signature (immunoreactivity for the calcium-binding protein, calbindin) as spinothalamic-recipient neurons of VPL and VPM (Craig and Dostrovsky, 1999).

Considerable disagreement exists about the spinothalamic innervation in posterolateral thalamus of monkeys and humans. One part of the disagreement deals with the proportion of lamina I afferents that end inside the bounds of the VPL and VPM and those that end caudal and medial to it. A conservative reading of the literature leads us to recognize spinothalamic innervation of four regions, each with its own cortical target. Spinothalamic terminations in the VPL and VPM are relayed to SI and those in VPI to SII. Together, they can be seen as a lateral path to first or discriminative pain. A second medial path to anterior cingulate by way of MDvc and to the insula by neurons of VMpo appears to be the central route for second or punishing pain.

SI and Pain

Nociceptive responses in SI have been difficult to record, and where neurons responding to noxious stimuli have been encountered, their location (e.g., area 3a) has not been easy to fit into a general scheme of what these areas do. Nevertheless, ablation studies in monkeys show SI's involvement in pain perception, and studies of human cerebral cortex regularly show that SI responds to stimuli judged to be painful. Perhaps the most compelling story can be told for area 1 of SI in monkeys, where evidence exists of clustered organization for nociceptive neurons (Kenshalo et al., 2000). Yet these neurons do not form columns. They are largely confined to layer IV of that area and are intermixed with mechanosensory neurons. These data suggest that nociceptive and mechanosensory inputs converge in area 1, perhaps as a means to accurately locate the source of pain.

The Human Axis of Pain

Functional imaging studies of the human brain indicate four areas of cerebral cortex are active during the application of a painful stimulus. Activation of SI and of SII occurs

as part of a discriminative component to painful stimuli. A subject's ability to report the location and to grade the intensity of a stimulus is correlated with activity in these areas. Two other areas appear tied to the cognitive and emotional content of pain. These are the rostral half of the anterior cingulate gyrus and the rostral insula, both of which display elevated activity during the anticipation of painful stimuli and the infliction of pain on a loved one (empathetic pain). And it is these areas that show a reduction in activity when the administration of a placebo produces reports of lessened pain. As a group, then, studies of the cortical representation of pain point to a distributed network of four main areas (SI, SII, rostral anterior cingulate, and rostral insula) in which the noxious stimulus applied to some peripheral region becomes a painful sensation with both discriminative and punishing components.

Nonperceptual Elements of Nociception

Several paths are taken by first- and second-order nociceptor axons that reach neither spinothalamic neurons nor regions of the thalamus. Targets of these axons include spinal interneurons that mediate the withdrawal and crossed-extensor reflexes; the pontine reticular formation, where the startle reflex is generated; and the midbrain periaqueductral gray (PAG) as a means for controlling pain. The last of these is a well-studied mechanism. Neurons of the PAG are innervated by second-order nociceptive neurons in laminae V. They provide PAG neurons with an indication of the source and intensity of nociceptive input. By way of a relay from serotonin neurons in nucleus raphe magnus and norepinephrine neurons in the locus coeruleus, activity in PAG drives a population of interneurons in the lamina II of the spinal cord. Two characteristics of those interneurons are worthy of consideration. First, they end not only on the populations of spinothalamic neurons but also on the axon terminals of C and Aδ axons. Through postsynaptic inhibition these inhibitory interneurons are able to suppress the response of spinothalamic cells and through presynaptic inhibition they are able to suppress release of the neurotransmitter, glutamate, from primary nociceptive afferents. The combination of pre- and postsynaptic inhibition reduces activity in the population of spinal neurons that carries nociceptive information to the brain. Second, the inhibitory neurons release the pentapeptide, met-enkephalin as a neurotransmitter. Met-enkephalin is an opioid peptide that binds to a member of the opiate receptor family. Its actions are mimicked by the administration of morphine and synthetic opiates accounting for at least part of the analgesic properties those compounds possess.

Pain is such a rich experience with an obvious impact on the well-being of a person that unusual phenomena associated with pain have been studied in considerable depth. Among the best studied are referred pain, secondary hyperalgesia/allodynia, and phantom limb pain. Each has been explained by referring to the circuitry and chemistry of normal nociceptive processing. Referred pain is the experience in which noxious stimuli in the viscera (e.g., ischemia of cardiac muscle) is felt as pain in a peripheral location such as the shoulder. A classic explanation for referred pain notes the widely branching nature of C and Aδ fibers as they enter the cord, so that lamina I neurons innervated by nociceptors of the shoulder are also innervated by nociceptors of the pericardium. When the latter are driven to fire a series of action potentials the percept is one of a more common occurrence, shoulder pain.

Central or secondary hyperalgesia and allodynia are related phenomena that occur in response to synaptic plasticity at the level of the spinal cord. Secondary hyperalgesia is a phenomenon in which a greater degree of pain is felt upon application of a noxious stimulus to a place other than the wound site. Allodynia, by contrast, is the perception of pain when the stimulus, itself, is not noxious. Each occurs when the application of an intense or prolonged noxious stimulus leads in spinal circuits to a rearrangement in synaptic strength, much like long-term potentiation. With secondary hyperalgesia, the potentiation is homosynaptic, leading to a greater postsynaptic response in spinal neurons to a noxious stimulus. Plasticity with allodynia is thought to be heterosynaptic. Under normal circumstances, activity in Aβ fibers to a benign mechanical stimulus (e.g., the movement of a cotton swab across the skin) modulates a response to noxious stimuli but fails to drive spinothalamic cells. Yet when the synapses formed by the Aβ fibers are potentiated in response to an intense or prolonged barrage of C fiber activity, spinothalamic neurons are driven by that mechanical stimulus. The result is perception of pain where only nonnoxious mechanical stimulation has occurred.

Unlike allodynia, phantom limb pain appears to involve synaptic plasticity at each of several levels in the somatosensory system. Removal of a digit or limb in experimental animals and in humans leads to a robust functional plasticity. Surgical removal of digits produces a short-lived silent zone in the somatotopically appropriate part of SI, but quickly thereafter, the previously silent region becomes responsive to tactile stimulation. The newly acquired response is to adjacent body parts, as the activity evoked in neighboring receptors fills in the zone where the cortex had been silent. Subsequent work has shown that following amputation of a digit or limb, this process of filling in takes place through synaptic changes in the spinal cord, medulla and thalamus, as well as in cerebral cortex. It is assumed that phantom limb pain works much the same way. Thus, stimulation of the shoulder and chest in amputees drives regions of cerebral cortex that had been responsive to stimulation of an arm prior to its amputation. The result is the percept of arm pain even in the absence of an arm (Box 24.1).

BOX 24.1

THE TRIGEMINAL SYSTEM

Mechanoreceptive, nociceptive, and thermoreceptive afferents for the face have their cell bodies in the pair of trigeminal ganglia (Fig. 24.12). The central processes of trigeminal ganglion cells enter the mid-pons as the trigeminal nerve. In many ways, the central trigeminal system is organized along parallel lines with the spinal somatosensory system.

Three nuclei make up the somatosensory part of the trigeminal system. The largest of these is the principal or main sensory nucleus, the cell bodies of which are in mid-pons, at the level of entry for the trigeminal nerve. Acting much like the dorsal column nuclei, the principal sensory nucleus is innervated by large diameter afferents of the ipsilateral half of the face. Its neurons respond to skin indentation and to vibrotactile stimuli. Most of these neurons send their axons across the midline in the pons, where they join the fibers of the medial lemniscus. The trigemino-thalamic axons ascend in the most medial part of the lemniscus (next to the axons that carry information about the hand) and terminate in the VPM.

The spinal trigeminal nucleus is an elongated nucleus, split into three subnuclei distinguished geographically by reference to the obex. Pars oralis occupies the lower pons and upper medulla to the level of the obex. It gives way to the pars interpolaris at the obex and then to pars caudalis

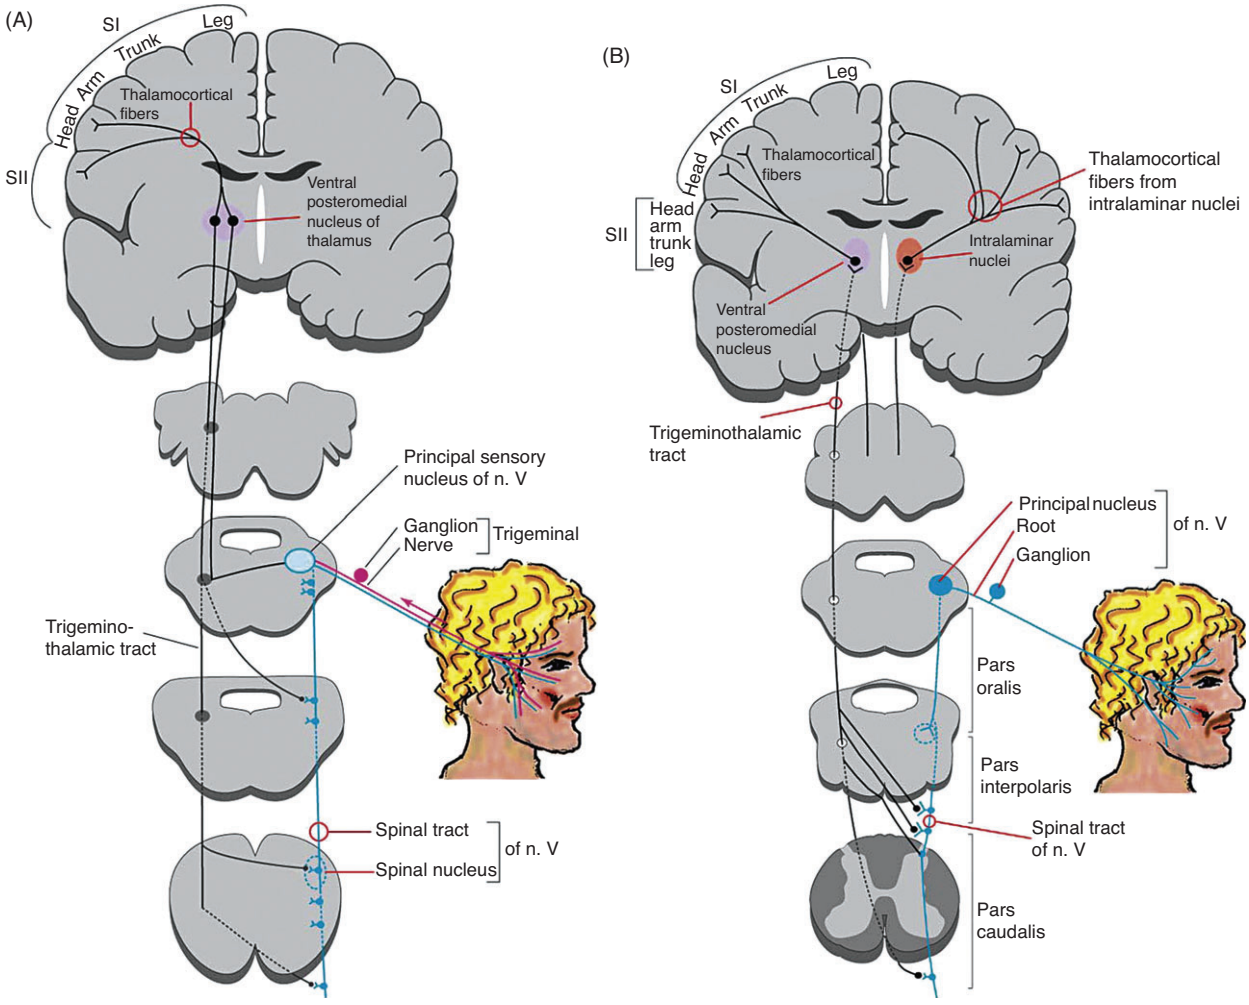

FIGURE 24.12 Sensory components of the trigeminal system. (A) Path for discriminative touch. Large diameter afferents from the face innervate second-order neurons in the spinal trigeminal nucleus (pars oralis) and the principal sensory nucleus. Neurons in these nuclei give rise to axons that cross the midline, ascend in the trigeminothalamic tract, and terminate in the ventral posteromedial (VPM) nucleus of the thalamus. (B) Path for pain and temperature in the trigeminal system. Small diameter afferent axons descend in the spinal trigeminal tract and terminate in the pars caudalis of the spinal nucleus. Second-order axons cross the midline and ascend to the thalamus.

BOX 24.1 (*cont'd*)

through the lower medulla and into the first two cervical segments of the spinal cord. Borders between these subdivisions are hardly distinct as afferents innervating a restricted part of the face may end across two or all three parts of the spinal trigeminal nucleus. The traditional subdivision of the spinal nucleus into functional units accents the mechanosensory functions of pars oralis, the deep receptor functions of pars interpolaris and the nociceptive and thermoreceptive functions of pars caudalis. In this context, the relay of input from pars caudalis to VPM is viewed as the equivalent of the spinothalamic system for the face. Yet studies of C fibers that innervate tooth pulp find these afferents terminate in a long, continuous sheet from the caudal half of the principal nucleus to the caudal-most aspect of pars caudalis. These data indicate a great deal more intermixing of mechanosensory neurons and nociceptive neurons takes place in the trigeminal system than is seen for the spinal somatosensory system.

CORTICAL REPRESENTATION OF TOUCH

Neurons of SI Are the First in the Somatosensory System to Show Clear Signs of Lateral Inhibition

Between the level of the peripheral afferent and the level of the cerebral cortex, the somatosensory system keeps information from individual afferents from coming together. Even though the synaptic means exist to generate lateral inhibition in the dorsal column nuclei and in thalamus, the response of single neurons in those regions appears very much like the response of the axon that drives it best. Neurons in SI, however, display true inhibitory surrounds. For area 3b in monkeys, such surrounds are one-third larger than the central excitatory region and can occupy one or more (but rarely all four) sides of the excitatory center. Many neurons in area 3b also exhibit a strong temporal component to their response. Spatial inhibition maintains the response selectivity of neurons when objects scanned across the skin surface at different speeds (as in reading Braille); receptive fields of neurons in area 3b are velocity insensitive. Temporal inhibition performs a parallel function by producing a progressive increase in response rate to surface elements that are scanned more quickly. The lag between the initial excitatory response and the delayed inhibitory one liberates more activity when the velocity of scanning increases. This more than makes up for the reduction in contact time between peripheral receptor and surface feature that accompanies any increase in scanning velocity.

Orientation Selectivity

As a result of circuits in cerebral cortex, the roughly circular receptive fields that enter SI by way of thalamocortical axons become orientation-selective responses in 70% of cortical neurons. The synaptic mechanism for generating a receptive field tuned to the orientation of a stimulus could be convergence of excitatory inputs, much like the mechanism proposed originally for orientation tuning in visual cortex. Yet examination of spatial-temporal response of neurons in SI indicates orientation selectivity is best explained by the presence and spatial distribution of inhibitory regions.

Serial Processing in SI

Area 3b is considered an early step in the cortical processing of tactile information. Much of the data supporting that conclusion come from studies that show ablation of area 3b produces a general decline in tactile discrimination behavior whereas ablation in other areas of SI leads to functional loss that is more selective. These deficits include difficulties in discriminating the texture of a surface following ablation of area 1 and deficits in three-dimensional form perception with ablation of area 2. From these data we conclude that areas of SI are organized as a hierarchy. A similar conclusion is seen in physiological properties of SI neurons as receptive fields become larger and their properties become more complex in going from area 3b to one of the more caudal somatosensory areas (Pons et al., 1992). One example is selectivity for the direction of object movement across the skin. Neurons in area 3b show no sign of direction selectivity, but in areas 1 and 2 this property emerges from the cortical circuitry (Luna et al., 2005).

Columnar Organization

Responses of like type are organized as columns in SI. For SI in macaques one obvious place for columnar processing is in the RA and SA responses. Neurons in layer IV of monkey area 3b, directly innervated by thalamocortical axons, show strong specificity for either RA or SA inputs (Sur et al., 1984). Yet superficial to layer IV, almost all neurons display slowly adapting responses. In other words, the response of neurons outside layer IV makes it appear as though rapidly adapting inputs are incorporated into a slowly adapting output. Nevertheless neurons in areas 3b and 1 are clearly involved in the discrimination of vibrotactile stimuli at low frequencies, such as those

carried into the CNS by RA afferents (Meissner's corpuscles). Response of SI neurons in a macaque is tied to the frequency of a stimulus applied to the monkey's fingertips. And so his ability to discriminate between two stimuli of different frequencies is only as good as an SI's neuron's ability to signal that difference.

The Role of SII in Somatic Sensation

Ablation studies reveal three features of SII's role in somesthesis:

1. Removal of all SII leaves a macaque incapable of discriminating the shape and texture of a tactile stimuli. These data show any or all subdivisions of SII play a pivotal role in tactile behavior.
2. Removal of SII has no effect on the response of neurons in SI. So, even though SII provides feedback projections to SI, the dominant input to SI comes from neurons of VPL and VPM.
3. Removal or cooling of SI eliminates the tactile responses in SII.

These results extend to modality-specific loss in SII following ablations restricted to one area in SI (removal of area 1 disrupts response to stimulus texture in SII). These observations place SII at a higher level on a series of steps that leads from SI into the medial temporal lobe, where access to memory is achieved

Several Body Representations in SII

At first glance, the division of labor that is a hallmark of SI—its division into four areas—contrasts strongly with the presence of a single area called SII. Recent functional and anatomical studies show, however, that the region in the upper bank of the lateral fissure that normally defines SII in macaques is divided into multiple functionally distinct areas (Fitzgerald et al., 2006). In monkeys three separate regions have been described, referred to as SIIa, SIIc, and SIIp (some researchers prefer the terms SII, PV, and PR; Krubitzer et al., 1995). Anatomical studies in humans suggest there are also four separate regions called OP1–OP4, yet how the human studies relate to the monkey studies is not known. So a modern view of SII indicates it is a complex of at least three functionally distinct areas. The anterior and posterior portions (SIIa and SIIp) are involved in integrating proprioceptive inputs with cutaneous input as a means for representing the size and shape of objects held in the hand. In addition, a central field (SIIc) responds to cutaneous inputs and is important for processing information about 2D shape and texture discrimination.

SII Receptive Fields

Receptive field properties of neurons in macaque SII support the conclusions that SII is part of a serial processing scheme. Neurons in SII are selective for more complex features of a stimulus than are neurons in SI. Moreover, orientation selectivity is seen in fewer than one out of three neurons in SII as receptive fields of single neurons grow to encompass two or more fingers. Neurons such as these appear to represent a sparse code for objects such as the edge of a keyboard or large curved shapes that span several digits.

SII and Attention

Psychophysical studies show that attention is a spotlight that can move freely across somatosensory functions: it has finite boundaries and improves performance on many tactile discrimination tasks. Single unit studies show SII to be one of the major targets of attention as the response of individual neurons changes with shifts in attention. Mechanisms by which attention appears to exert its effects include a change in the response rate—90% of SII neurons in macaques increase their response to a tactile stimulus when the animal attends to the stimulus—and a shift across a population of neurons so that they become active at the same time. Pairs of neurons in macaque SII become more synchronous in their response to a tactile stimulus when an animal pays attention to that stimulus. As the task becomes more difficult, when the difference between two stimuli is deliberately reduced, the degree of synchrony increases by a factor of four. These data show that not only is SII a nodal point for the discrimination of form and texture, but it is also a site at which cognitive mechanisms like selective attention are likely to exert their greatest influence.

At a more global level, SII can be viewed as a gateway through which somatosensory information reaches the medial temporal lobe. There, ongoing events along the skin surface are deposited into long-term memory and compared with previous events stored in memory. This temporal path in somatic sensation underlies object identification—the kind of processing that permits us to pull out from our pockets the right set of keys as we approach our front doors in the middle of the night. The next logical act, inserting the right key into the right lock, demands sensory guidance of movement, and that is the role of the output from SI to posterior parietal lobe. Proprioceptive inputs guide our arms and hands to the correct configuration (the height of the arm, the angle of the hand and the extension of the fingers), while central processing of cutaneous mechanoreceptors, particularly Pacinians, informs us whether the key has struck the side of the lock or moved smoothly into it. That sort of sequence of object recognition and guidance of movement repeats itself dozens, perhaps hundreds, of times a day for all of us, in each case operating efficiently and seamlessly thanks to the central processing of a complex sensory input.

CHAPTER

25

Audition

The auditory system detects sound and uses acoustic cues to identify and locate sounds in the environment. The auditory system shares functional and evolutionary similarities with other mechanoreceptive systems, such as the vestibular system and the lateral line system of lower vertebrates. All of these systems use the same type of receptor cell—the hair cell—and all are specialized to detect an external stimulus that eventually causes the stereocilia of the hair cells to be displaced. Unlike other mechanoreceptive systems, the auditory system is sensitive to sound. This chapter explores the characteristics of the auditory system that make it sensitive to sound and that make it capable of localizing a sound source. The generalized mammalian auditory system is emphasized, but examples are also taken from studies of animals with specialized auditory systems, such as those of bats and owls, which have greatly advanced our knowledge of audition.

EXTERNAL AND MIDDLE EAR

The peripheral auditory system is divided into the external, middle, and inner ears (Fig. 25.1). The external ear is composed of the pinna and external auditory canal. These structures convey sound to the middle ear, but not without influencing it. This influence emphasizes and deemphasizes certain sound frequencies, resulting in peaks and notches in the transmitted sound spectrum. Because positions of the peaks and notches depend on the location of the sound source, they provide information about location, even when using only one ear (monaural sound localization). Such information is especially important for determining the elevation of a sound source because spectral peaks and notches are one of the few cues that depend on elevation.

Mechanosensitive organs in lower vertebrates, such as the lateral line of fish, are sensitive to vibrations in aquatic environments. When vertebrates evolved onto land, they faced the problem of converting sound in air to sound in fluid, as the inner ear of vertebrates remains fluid filled. Sound at an air–fluid interface is almost completely reflected back into the air rather than being transmitted into the fluid. The function of the middle ear is to ensure efficient transmission of sound from air into the fluid of the inner ear (reviewed by Geisler, 1998). The middle ear begins at the tympanic membrane (eardrum), continues with the three middle ear ossicles (malleus, incus, and stapes), and ends at the footplate of the stapes, which contacts the inner ear fluids at the oval window of the cochlea (Fig. 25.1). There are several ways in which the middle ear increases the transmission of sound into the inner ear. Most importantly, because the area of the eardrum is larger (by about 35 times) than the area of the stapes footplate, there is a corresponding increase in pressure from the eardrum to the stapes footplate. Additionally, there may be small contributions from a lever action of the ossicles and a buckling motion of the tympanic membrane, both increasing the force applied to the footplate. Together, these mechanisms provide a pressure gain of about 25 to 30 dB in the middle frequencies over what would be achieved by sound striking the oval window directly. This amount of gain means that for middle frequencies, most of the acoustic energy that strikes the eardrum is transmitted through the middle ear. For lower and higher frequencies, however, energy is lost. When sound conduction through the middle ear is compromised, a patient has a conductive hearing loss. One disease that causes a conductive hearing loss is otosclerosis, in which bony growths around the stapes cause it to adhere to surrounding bone and lessen its transmission

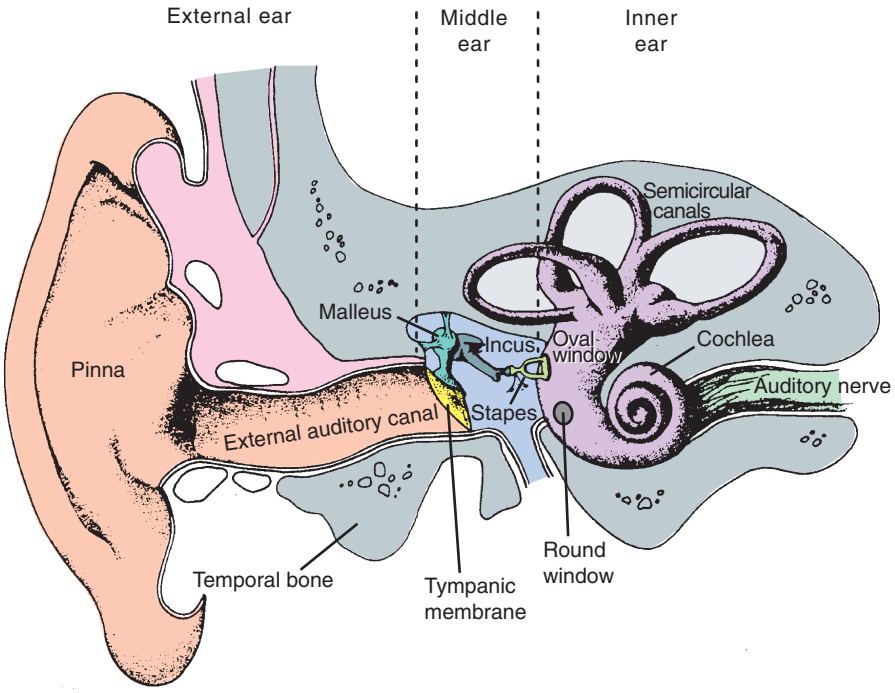

FIGURE 25.1 Drawing of the auditory periphery within the human head. The external ear (pinna and external auditory canal) and the middle ear (tympanic membrane or eardrum, and the three middle ear ossicles: malleus, incus, and stapes) are indicated. Also shown is the inner ear, which includes the cochlea of the auditory system and the semicircular canals of the vestibular system. There are two cochlear windows: oval and round. The oval window is the window through which the stapes conveys sound vibrations to the inner ear fluids. *From Lindsay and Norman (1972).*

of vibration. A surgical procedure called a stapedectomy usually restores hearing by replacing the native stapes with a prosthetic one.

THE COCHLEA

The inner ear is located deep within the head (Fig. 25.1). The inner ear contains the cochlea, which is the sensory end-organ for the auditory system. It also contains the utricle, saccule, and cristae of the three semicircular canals, which are the sensory end-organs for the vestibular system. The word *cochlea* comes from the Greek word *kokhlias*, meaning "snail," as the cochlea is coiled like the shell of a snail. In most species, the long spiraled tube of the cochlea has two to four turns, which are visible in cross section (Fig. 25.2A). The sensory organ, the organ of Corti, contains the receptor cells (hair cells) and supporting cells. The organ of Corti rests on the basilar membrane and is covered by the tectorial membrane (Fig. 25.2B). Hair cells are of two types: inner hair cells and outer hair cells. Their names are derived from the position of the hair cells along the cochlear spiral: inner hair cells are located innermost along the spiral and outer hair cells are located outermost. There is one row of inner hair cells and usually three rows of outer hair cells. In the human cochlea, there are about 3500 inner hair cells and about 14,000 outer hair cells.

Hair Cells Transduce Mechanical Energy Directly into Electrical Energy

Hair cells (Fig. 25.3) are polarized epithelial cells whose major functions are partitioned into apical and basal cellular compartments. The apical end of the cell is specialized for the reception and translation of mechanical energy into receptor currents, whereas the basal end is specialized for the transmission of information to the central nervous system via synaptic contacts with the primary afferent neurons. Stereocilia are modified microvilli, a fraction of a micrometer in width, that project from the cell apex and contain an abundant supply of tightly packed actin filaments, bound by fimbrin, coursing along their length. Depending on which specific organ the hair cells reside in, their lengths range from a fraction (in the bat cochlea) to tens of micrometers (in vestibular organs). The number of stereocilia per hair cell ranges from about 10 to 300. Together the stereocilia from one cell form a "hair bundle" and are bundled together by extracellular filamentous linkages. They taper rapidly as they insert into the hair cell's cuticular plate, an actin-rich apical cytoplasmic

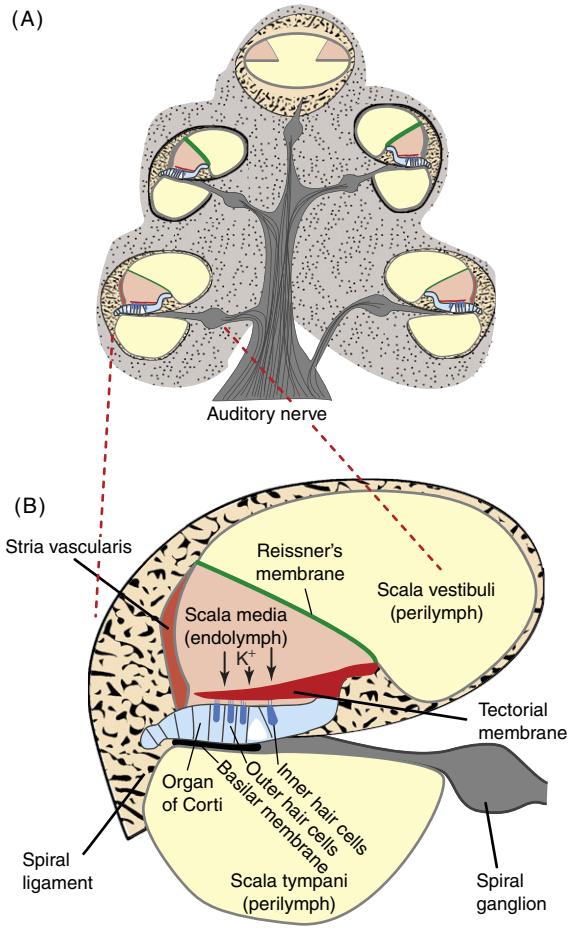

FIGURE 25.2 (A) Cross section through the cochlea. The cross section shows that there are approximately three turns in this human cochlea and that they spiral around a central core (modiolus) that contains the auditory nerve. (B) Cross section through one cochlear turn to illustrate important cell groups (organ of Corti, spiral ligament, stria vascularis, and spiral ganglion) and the main fluid compartments [scala vestibuli, scala media (shaded orange), and scala tympani]. Within the organ of Corti, sensory cells (inner and outer hair cells) are shaded dark blue and are situated between the basilar and tectorial membranes, which move when sound stimulates the cochlea. When these membranes cause motion of the stereocilia of the hair cell, the receptor current, a potassium (K^+) current, flows into the hair cells from the endolymph. The high K^+ concentration and high electrical potential of the endolymph are created by the stria vascularis, and these factors increase the driving force for the receptor current. Supporting cells in the organ of Corti are shaded light blue; these cells form a network that is coupled by gap junctions and may recycle K^+ back to the stria vascularis. Also shown is the spiral ganglion, which contains cell bodies of the auditory nerve fibers.

structure. Because the stereocilia are stiff, rod-like structures, they pivot at their insertion when deflected.

Receptor Potentials Are Evoked by Mechanically Gated Ion Channels within Stereocilia

With the hair bundle in its resting, unperturbed position (Fig. 25.3), a standing inward current exists through a small proportion (10 to 25%) of mechanically activated channels. Because these channels are nonselective for cations, this inward, positively charged flux tends to depolarize the hair cells. In many hair cell sensory systems, including the organ of Corti, the ionic milieu surrounding the hair bundle is richest in potassium (Fig. 25.2B); thus, the major charge carrier for the transduction current is potassium. However, small amounts of calcium are also required to sustain stereociliar channel activity. Displacement of the hair bundle toward the tallest stereocilium increases the proportion of open channels, thereby producing an increase of the inward resting current. The subsequent flow of current across the basolateral membrane produces a depolarizing voltage change, a receptor potential, capable of activating a variety of voltage-dependent conductances in that membrane. Conversely, closure of transduction channels during bundle movement away from the tallest stereociliar row reduces the inward current, effectively hyperpolarizing the basolateral membrane. Several lines of evidence indicate that the flow of transduction current into hair cells occurs near the top of the hair bundle—that is, channels are located near the tips of the stereocilia. Maximal transducer conductance changes up to about 10 nS have been observed. Single channel conductances on the order of 20–200 pS have been either measured or estimated and may increase from apex to base along the tonotopic axis of the cochlea. From such conductance measures, the number of channels per stereocilium has been computed to be one to two.

The relationship between degree of bundle deflection and receptor potential magnitude is neither linear nor symmetric (Fig. 25.4). Bundle displacements in the depolarizing direction produce larger responses than equal displacements in the opposite direction. The displacement–response function is sigmoidal and shifted from its midpoint. Thus, symmetrical sinusoidal deflections of the bundle (as might occur with acoustic stimuli) will produce both sinusoidal (ac) and superimposed depolarizing steady-state (dc) changes in membrane potential. Saturating electrical responses are evoked by deflections as small as 300 nm (Hudspeth & Corey, 1977).

Stereocilia Tip Links May Underlie Transducer Gating

The molecular basis of the hair bundle's response polarity appears to reside in specialized structural attachments at the tips of stereocilia (Pickles, Comis, & Osborne, 1984) (Fig. 25.5). These "tip links" are molecular filaments, comprised of cadhedrin-23 and protocadhedrin 15, that link the top of each stereocilium with a dense membranous plaque on the upper side of the adjacent taller stereocilium, occurring in line with the axis of maximal bundle sensitivity. They are believed to provide the tension required to open transduction channels during bundle deflection, with one end of the filament being anchored and the other pulling on the channel gate located on the shorter stereocilium.

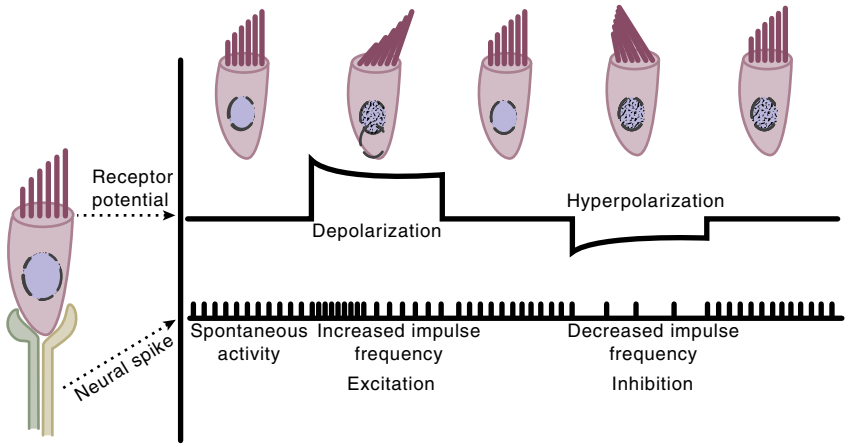

FIGURE 25.3 Illustration of hair cell stimulation, receptor potential response, and auditory nerve fiber discharge. *From Flock (1965).*

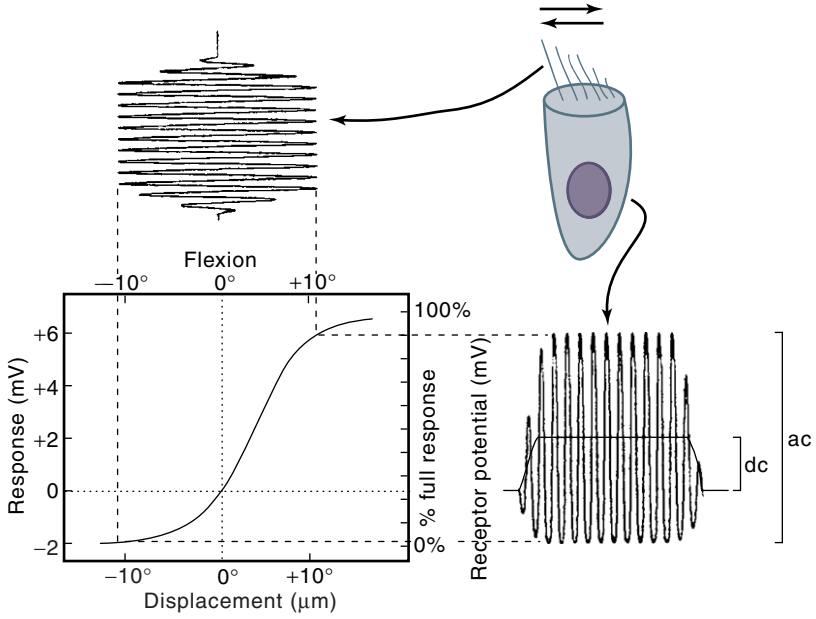

FIGURE 25.4 Sigmoidal input-output function of hair cells. Symmetrical sinusoidal displacement of stereocilia produces an asymmetrical response that includes ac and dc receptor potential components. *Modified from Hudspeth and Corey (1977).*

As the hair bundle tilts during deflection in the excitatory direction, adjacent stereocilia shear against one another, increasing the tension of tip links, thereby increasing the probability that transducer channels will open. When the deflection is in the hyperpolarizing direction, tip link tension slackens and the channels tend to close. In line with tip link or gating spring hypothesis, destruction of the tip links by enzymatic (elastase) or chemical (calcium chelators) treatments can abolish mechanical transduction. In addition, if tip link tension accounts for much of the bundle's stiffness, as expected, bundle compliance varies with the extent of deflection. The deflection versus bundle compliance function is bell shaped, with maximum compliance occurring when half the transduction channels are open. Furthermore, compliance changes are abolished by blocking stereociliar transduction channels with aminoglycoside antibiotics.

Electrical Properties of the Basolateral Membrane Shape Receptor Potentials

The speed of the hair cell transduction process is incredibly fast compared to transduction in other sensory systems, such as vision, olfaction, and the taste modalities of sweet and bitter. The delay between a bundle deflection and the onset of receptor current is estimated to be about 10 μs at 37°C (Corey & Hudspeth, 1983). This rapid response is a consequence of direct mechanical gating of transduction channels, and such speed is essential for auditory hair cells to detect and utilize sound frequencies in the kilohertz (thousand per second) range. Humans can detect sound frequencies up to about 20 kHz, and some mammals, such as bats, can hear above 100 kHz. Although receptor currents may be generated without attenuation

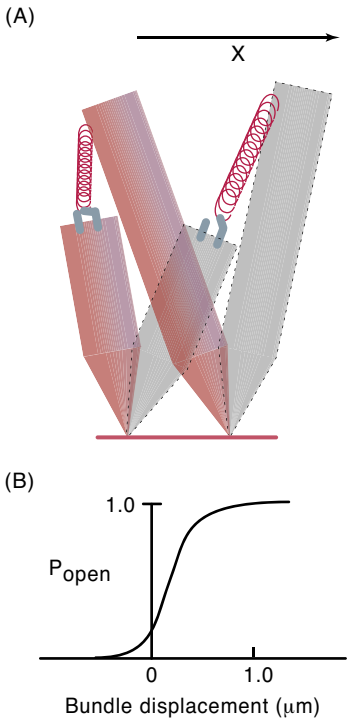

FIGURE 25.5 Gating spring model of hair cell transduction. (A) Tip links connecting channel gate to adjacent taller stereocilium tense during displacement toward the taller stereocilium, thus increasing the probability that the channel will open (B). *From Pickles and Corey (1992).*

across frequency, receptor potentials, which ultimately are responsible for the release of neurotransmitter at the hair cell synapse, are susceptible to the RC filter characteristics of the basolateral membrane. The RC time constant of hair cell membranes ranges from a fraction of a millisecond to a few milliseconds at the resting potential. This translates in the frequency domain to a low-pass filter whose cutoff frequency (fc, the frequency at which the response energy is halved) ranges from tens of hertz to about 1 kHz. This filtering reduces the ac receptor potential in half for every octave increase in frequency above the cutoff. Ultimately, at very high frequencies, ac responses will be negligible, but the dc component will remain unperturbed (Fig. 25.6)—a process termed rectification. The actual cutoff frequency is considered dynamic because receptor potentials themselves may activate voltage-dependent ionic conductances in the basolateral membrane that modify the resistive component of the RC product. In outer hair cells from the organ of Corti, the capacitance of the basolateral membrane is also highly voltage dependent (Santos-Sacchi, 1992), and therefore in this cell type variations in both resistive and capacitive components may influence the membrane filter.

The mammalian organ of Corti rests upon an acellular basilar membrane (Fig. 25.2B) that extends along the coiled cochlea. Cells at the basal end of the organ of Corti have high characteristic frequencies, whereas those at the apex have low ones. Von Bekesy, who won the Nobel Prize in 1968, discovered that different regions of the basilar membrane are tuned to particular frequencies; low-frequency tones cause maximal vibrations of the basilar membrane near the apex, whereas higher-frequency tones cause vibrations more basally. This tuning results from the mechanical characteristics of the basilar membrane, which becomes stiffer and narrower with distance from the apex to the base. As demonstrated in early experiments, the intrinsic frequency selectivity afforded by basilar membrane tuning is not great enough to account for the very selective responses observed in hair cells and auditory nerve fibers. Later experiments demonstrated that active mechanisms are necessary to achieve this high frequency selectivity.

Active Mechanical Properties of the Outer Hair Cells Drive the Mammalian Cochlea Amplifier

Outer hair cells (OHCs) are cylindrically shaped and decrease in resting length by a factor of about four from the apical to the basal ends of the cochlea. When an isolated OHC is stimulated electrically, it responds by altering its length (Brownell, Bader, Bertrand, & de Ribaupierr, 1985). No other auditory cell type responds in this manner. The mechanical response is voltage dependent; depolarizing stimuli induce contractions and hyperpolarizing stimuli induce elongations, with responses as large as 30 nm/mV (Fig. 25.7). This mechanical activity is not akin to any other known form of cellular motility and is governed directly by voltage-dependent, integral membrane protein motors. The motor is the gene product of Prestin (Zheng et al., 2000), one of a family of anion transporter genes (SLC26). OHC electromotility has been demonstrated, *in vitro,* to extend well into the tens of kiloHertz range. *In vivo*, the motor action of OHCs probably is responsible for otoacoustic emissions (Box 25.1).

Through a variety of experimental approaches, OHC motor activity has been shown to be restricted to the lateral membrane of the OHC. As might be expected for a voltage-dependent process that resides within the membrane, a charged voltage sensor must exist, just as voltage-dependent ion channels have voltage sensors. The existence of an OHC motility voltage sensor is confirmed by measuring gating charge movements (capacitive-like currents) under voltage clamp while blocking ionic conductances. These gating currents represent the restricted movement of the charged voltage sensor within the plane of the lateral membrane; increasing voltage will move more charge (thus activating more motors) according to Boltzmann statistics (Fig. 25.8A). Maximum charge moved is about 7500 e/μm^2, and may represent the density of motor molecules in the lateral plasma membrane.

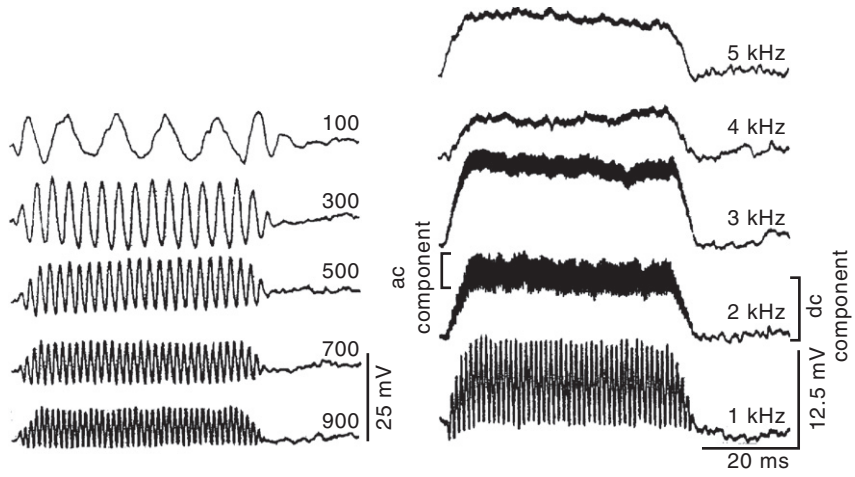

FIGURE 25.6 Receptor potentials from the mammalian inner hair cell in response to acoustic bursts of increasing frequency. Because of the cell's *RC* time constant, the ac component diminishes as frequency increases. However, the dc component remains intact. *From Russell and Sellick (1983).*

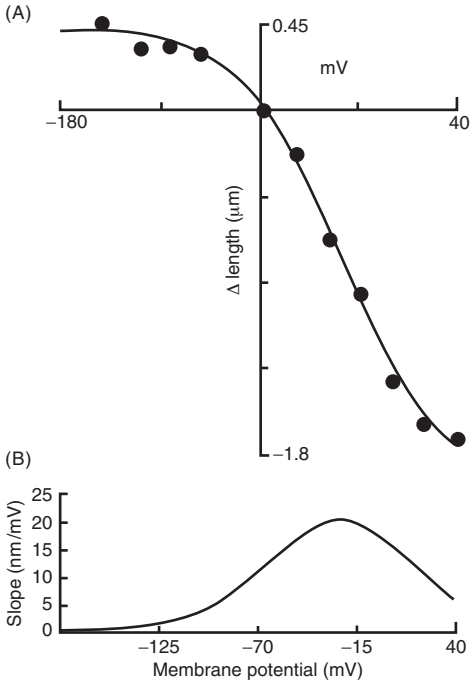

FIGURE 25.7 Mechanical response of mammalian outer hair cell (OHC) under voltage clamp. The OHC changes its length when the cell is held at different membrane potentials (A). The slope of the sigmoidal input-output function defines the cell's sensitivity to membrane potential change (B). *From Santos-Sacchi (1992).*

The slope of the Q/V function is defined as capacitance, and thus the capacitance of the OHC is a bell-shaped function of voltage (Fig. 25.8B). This nonlinear capacitance rides atop the cell's intrinsic linear membrane capacitance of 1 μF/cm^2. Thus, in an OHC of about 70 μm in length, at the point where motile gain is maximum (i.e., where half the motors are activated), the capacitance peaks at about double the cell's linear capacitance. As mentioned earlier, such nonlinear capacitance may have significant effects on membrane-filtering characteristics. Although the mechanical response is voltage dependent and is not evoked by activation of any particular voltage-dependent ionic conductance, the activity of the voltage sensor requires intracellular chloride (Rybalchenko & Santos-Sacchi, 2003), and in intact OHCs a stretch-activated chloride conductance appears crucial for maintaining and modulating motor activity.

Contributions of lateral membrane activity and stereocilia activity, each of which is capable of force production, are likely involved in cochlear amplification. Active mechanical responses of the stereocilia bundle may be driven by calcium influx through calcium-sensitive, mechanically activated stereocilia channels. Indeed, recent evidence suggests that bundle activity, acting through its high pass filter characteristic, can provide for a tuned band pass response of electromotility.

To summarize, OHCs, probably through a mechanical feedback scheme, are required to boost basilar membrane motion and enhance frequency selectivity, a process termed the "cochlear amplifier." In the absence of OHCs or with an impairment of prestin function, either by gene mutation (Dallos et al., 2008) or by reducing OHC chloride levels *in vivo* (Santos-Sacchi, Song, Zheng, & Nuttall, 2006), hearing sensitivity and frequency selectivity are impaired. OHCs are unique because they function as both receptors and effectors, transducing mechanical stimuli via hair bundle displacement and changing length and other mechanical properties in response to the generated receptor potentials. These mechanical events, via an energetic boost to basilar membrane motion, provide an enhanced stimulus to the inner hair cells, which are the cells that provide synapses to the overwhelming majority of auditory nerve afferents.

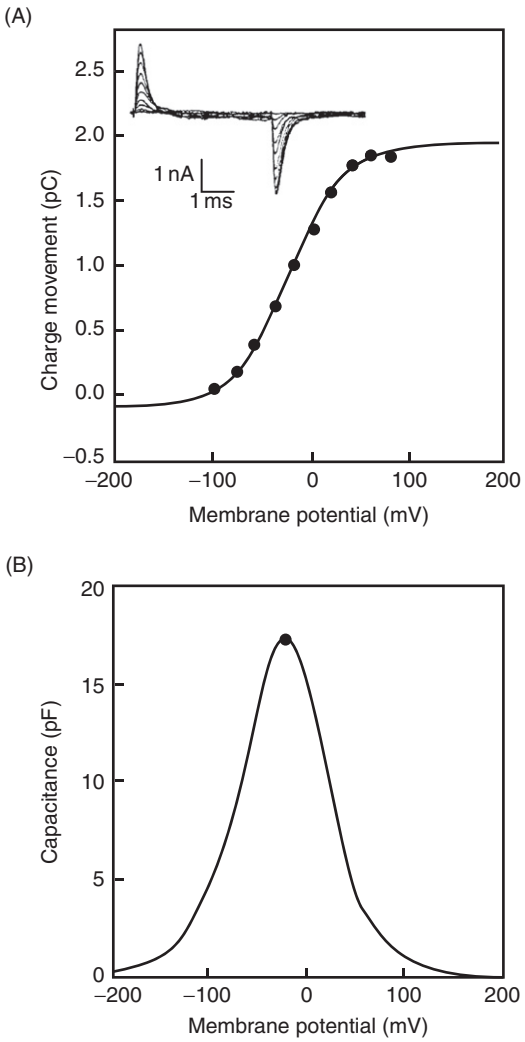

FIGURE 25.8 Gating charge associated with OHC motility voltage sensor. When the membrane potential is stepped with increasingly larger depolarizing voltages from a negative holding potential, nonlinear capacitive currents are generated and are obvious after linear capacitive currents are subtracted (inset). Integrating the onset currents, a measure of the amount of charge moved within the membrane can be obtained (A). The function is sigmoidal and has characteristics similar to the mechanical response. The first derivative of the charge with respect to membrane voltage defines the cell's nonlinear capacitance (B). *From Santos-Sacchi (1991).*

Cochlear Endolymph Increases the Sensitivity of Hearing

An increase in the sensitivity of hair cells is made possible by the unique composition of the inner ear fluids. Within the inner ear, fluids are contained in three compartments known as scalae: scala tympani, scala media, and scala vestibuli (Fig. 25.2B). These scalae extend in parallel along the length of the cochlea from the base to the apex. Scala tympani and scala vestibuli contain perilymph, which is high in Na^+ and low in K^+, similar to other extracellular fluids. Scala media contains endolymph, a specialized fluid with a low concentration of Na^+ and a high concentration of K^+ (about 160 mM). The endolymph is also unusual because it has a positive electrical potential (about 90 mV), observable even in the absence of sound. The endolymph is generated by a highly vascularized tissue in the lateral edge of the cochlea, the stria vascularis (Fig. 25.2B).

The organ of Corti, which contains the hair cells, is located at the junction between endolymph and perilymph (Fig. 25.2B). Stereocilia are surrounded by endolymph, whereas the remainder of the hair cell (basolateral membrane) is surrounded by perilymph. The endolymph increases the sensitivity of the hair cells because it increases the transduction current, a K^+ current that flows from the endolymph into the hair cells (Fig. 25.2B). The endolymph increases this current because (1) the high concentration of K^+ in endolymph forms a concentration gradient that establishes a driving force for K^+ flow into the cells and (2) the positive potential of the endolymph forms a large electrical gradient that is also a driving force for K^+ flow into the hair cells. Once the chemical and electrical properties of the endolymph are established and sound stimulates the cochlea, K^+ flows into the hair cells with little energy expenditure by the hair cells, as K^+ is flowing down its electrochemical gradient. Thus, hair cells do not require a high blood flow that might bring noise to the organ of Corti, interfering with sound reception. In fact, there are only a few blood vessels near the organ of Corti.

Sensorineural Hearing Loss Often Results from Damage to Hair Cells

Sensorineural hearing loss results from damage to hair cells or, less commonly, from damage to auditory nerve fibers (reviewed by Merchant & Nadol, 2010). Hair cells can be destroyed or their hair bundles damaged by intense sounds such as those generated by guns, jet engines, or even earphones operated at high sound levels. Hair cell loss is permanent in the mammalian cochlea, but in the bird cochlea, hair cells are regenerated from nearby supporting cells (Corwin & Cotanche, 1988). Damage from intense sounds can be minimized by (1) decreasing the duration of the sound exposure and (2) decreasing the level of the sound at the tympanic membrane (by wearing protectors such as earguards and earplugs). Hair cells can also be destroyed by chemical agents like aminoglycoside antibiotics (e.g., streptomycin, kanamycin). These agents block the transduction channels directly, but their mechanism of hair cell destruction is independent. In individuals with sensorineural hearing loss, some hearing can be restored with a cochlear implant (Box 25.2).

Summary

Current research on the cochlea is centered on the mechanisms of outer hair cell motility and how this motility

BOX 25.1

OTOACOUSTIC EMISSIONS

In 1978, David Kemp made a surprising discovery: the ear can sometimes *emit* sounds. These "otoacoustic emissions" are now the focus of much interest because basic researchers can use them to study the function of the ear and because clinicians can use them as tests of hearing (reviewed by Shera, 2004). Emissions are almost always so low in level that they are inaudible unless the individual is in an exceptionally quiet environment. Thus, measurement of emissions requires a sensitive, low-noise microphone that is placed in the external ear canal. Many studies indicate that the cochlea (inner ear) is the source of emissions. Within the cochlea, the outer hair cells are likely to be the generators of emissions. After emissions are generated, they travel in reverse of the normal pathway for sound into the inner ear: the emissions propagate from their point of generation along the basilar membrane to the oval window, then through the middle ear via the ossicles, and finally they move the tympanic membrane to result in airborne sound.

There are two main types of emissions—spontaneous and evoked—the latter are evoked in response to an externally presented sound. Spontaneous emissions are detected from the ears of about one-half of normal hearing humans, but these emissions are rare in laboratory animals. They are almost always pure tones. Transient-evoked emissions are evoked by a short sound such as a click and appear several to tens of milliseconds later. These emissions were first called the "cochlear echo," but they are not a real echo because more energy can appear in the emission than was present in the evoking sound. Distortion product-evoked emissions (Fig. 25.9) are evoked by two tones ("primaries" of frequencies f_1 and f_2) and occur at combinations of the primary frequencies (such as at frequency $2f_1–f_2$). The two primary tones each produce traveling waves along the basilar membrane, and a likely point of generation of the emission is where these waves overlap maximally.

Otoacoustic emissions can be used clinically as a screening tool in hearing tests, as subjects with sensory hearing losses greater that 30 dB typically lack emissions. Transient-evoked or distortion product-evoked emissions are used in such tests. Emission-based tests are especially valuable for individuals such as infants who are otherwise hard to test by conventional audiometry. Otoacoustic emissions only rarely are the cause of tinnitus, the sensation of ringing in one's ears. Most individuals who have tinnitus do not have emissions corresponding to the tinnitus. Thus, tinnitus arises by some other mechanism, almost certainly within the nervous system.

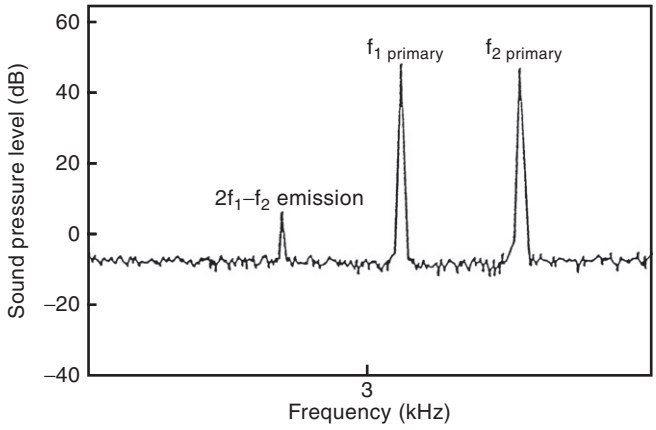

FIGURE 25.9 Distortion-product otoacoustic emission from a human subject measured with a microphone placed in the ear canal. The microphone records the sound pressure of the two primary tones (frequencies f_1 = 3.164 kHz and f_2 = 3.828 kHz, each 50 dB sound pressure level that were used to evoke the emission at $2f_1–f_2$ (2.5 kHz at 12 dB). *From Lonsbury-Martin and Martin (1990).*

contributes to basilar membrane motion. The mechanisms of how sound might use active stereocilia motion remain to be worked out. Substantial interest focuses on the processes and factors involved in hair cell regeneration with the eventual hope that approaches like stem cell implants might encourage restoration of function in the mammalian cochlea. The improvement of cochlear implants is also a very active area of clinical research.

BOX 25.2

COCHLEAR IMPLANTS

The cochlear implant is one of the most successful prostheses used to stimulate the nervous system (Niparko et al., 2000). The cochlear implant can provide partial restoration of hearing for individuals with sensorineural hearing loss. In sensorineural hearing loss, there is usually a partial or complete loss of the sensory cells (hair cells) in the inner ear (cochlea). Hair cells normally transduce the mechanical energy of sound into the electrical energy of receptor potentials. They synapse on primary auditory nerve fibers, which send information to the brain. Hair cells can be damaged irreversibly by intense sound, ototoxic drugs, or the aging process. Once lost, hair cells are not regenerated in mammals. Often, however, individuals with hair cell loss retain a significant complement of auditory nerve fibers. It is these fibers that are stimulated by the cochlear implant.

The cochlear implant consists of a microphone to detect sound, an electronic "processor" that transforms the sound waveform into a code of electrical stimuli, and an array of stimulating electrodes in the cochlea. The electrode array (Fig. 25.10) is inserted through or near the round window into scala tympani where it lies close to the peripheral axons of primary auditory neurons. Usually, the implant consists of more than 20 electrodes that begin in the base and are spaced at intervals along the cochlear spiral. Those electrodes in the most basal regions are positioned to stimulate nerve fibers that originally responded to high frequencies and those in more apical regions are positioned to stimulate fibers that originally responded to lower frequencies.

In some individuals who have received implants, comprehension of speech is possible, even when there are no other cues such as lip reading. These individuals can carry on a normal conversation, even via telephone. In other individuals, however, full speech comprehension is not restored but the implant, together with lip-reading ability, assists with spoken conversation. It also provides for the detection of important sounds such as the ring of a telephone and the approach of a vehicle. Individuals who have become deaf after the acquisition of spoken language have better comprehension than prelingually deafened individuals, almost certainly because of differences in the central nervous system.

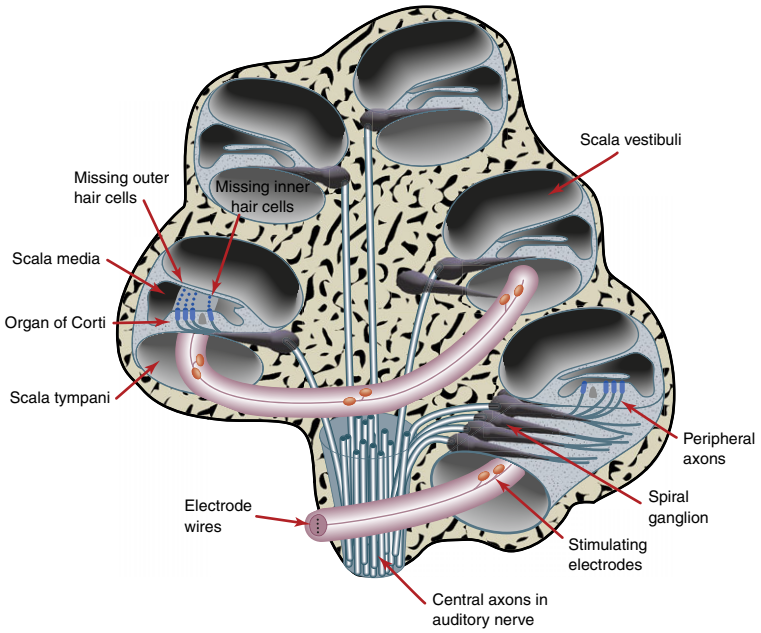

FIGURE 25.10 Drawing of the human cochlea showing cochlear implant electrodes. The electrode array is inserted through the round window of the cochlea into the fluid-filled space called the scala tympani. It stimulates peripheral axons of the spiral ganglion neurons, whose central axons (auditory nerve fibers) send impulses into the brain. In the normal cochlea, frequency is mapped along the cochlear spiral, with the lowest frequencies at the apex of the cochlea (at the top of the figure). The different electrodes of the cochlear implant are designed to stimulate different groups of nerve fibers that originally responded to different frequencies, although because of spatial constraints the implant is not inserted all the way to the cochlear apex. *From Loeb (1985).*

THE AUDITORY NERVE

Hair cells receive their primary afferent innervation from neurons of the spiral ganglion, located in the central core, or modiolus, of the cochlea (Figs. 25.2 and 25.10). These bipolar auditory neurons send peripheral axons to the hair cells and central axons into the brain by way of the auditory nerve, a subdivision of the eighth cranial nerve. Two types of afferent neurons separately innervate the inner and outer hair cells (Fig. 25.11). The first type (the type I neuron) sends processes to contact inner hair cells, almost always contacting a single hair cell, whereas the second type (the type II neuron) sends processes to contact from 5 to 100 outer hair cells. Fibers from type I neurons are relatively large in diameter and myelinated; thus, their information reaches the brain quickly, within a few tenths of a millisecond. Fibers from type II neurons are thin and unmyelinated and transmit information much more slowly. Both types of afferent fibers project centrally into the cochlear nucleus in the brainstem. Interestingly, type I neurons total about 95% of the afferent population (about 30,000 in humans), whereas type II neurons total only about 5%. Thus, outer hair cells, which number over three-quarters of the receptor cell population, are innervated by only a small minority of the afferent neurons. This innervation plan strongly suggests that the functional role for inner hair cells and type I neurons is to serve as the main channel for sound-evoked information flow into the brain.

Responses Are Sharply Tuned to Frequency

Type I auditory nerve fibers respond to sound and transmit these responses to the brain via discrete action potentials (reviewed by Ruggero, 1992; Geisler, 1998). The brain must extract information from these spikes and process this information to eventually form a percept of the stimulus. The information available to the brain via the auditory nerve consists of which nerve fibers are responding and the rate and time pattern of the spikes in each fiber. A fiber's response area is usually plotted as a graph of sound pressure level (SPL) versus frequency with the line showing the threshold contour; such a graph is known as a tuning curve (Fig. 25.12). The lowest point on the tuning curve corresponds to the characteristic frequency (CF). At CF, auditory nerve fibers can respond to sound levels as low as 0 dB in the most sensitive range of hearing. At low sound levels, the tuning curve is impressively narrow, indicating that the fiber responds only to a narrow band of frequencies near CF. This sharply tuned "tip" region (Fig. 25.12) is likely generated by the active motility of the outer hair cells. At high sound levels, the tuning curve becomes much wider, especially for frequencies below CF. This response to a broad range of frequencies likely reflects the passive mechanical characteristics of basilar membrane motion with little contribution from outer hair cells.

The relationship between CF and its point of innervation in a type I fiber has been demonstrated by single unit labeling (Liberman, 1982). The distance to the point of innervation along the length of the cochlea is logarithmically related to fiber CF. Fibers with the lowest CFs innervate the apex of the cochlea, and fibers with progressively higher CFs innervate progressively more basal positions, as expected from the pattern of basilar membrane vibration. This precise mapping of frequency to position is known as tonotopic mapping, and it strongly suggests that frequency is coded via a "place" code.

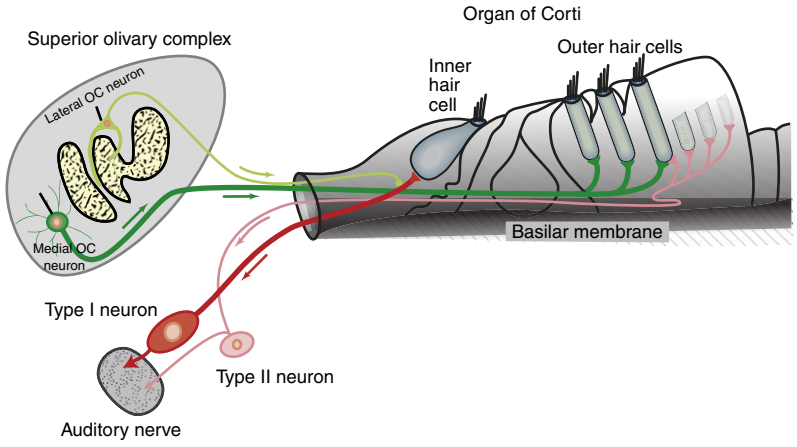

FIGURE 25.11 Innervation patterns of afferent and efferent neurons in the organ of Corti. Afferent innervation is provided by spiral ganglion neurons, which have central axons that form the auditory nerve. There are two types of afferent neurons: (1) type I neurons, which receive synapses from inner hair cells, and (2) type II neurons, which receive synapses from outer hair cells. Efferent innervation is provided by a subgroup of neurons in the superior olivary complex that send axons to the cochlea and are hence called olivocochlear (OC) neurons. There are two types of OC neurons: (1) lateral OC neurons, which innervate type I dendrites near inner hair cells, and (2) medial OC neurons, which innervate outer hair cells. Lateral OC neurons are distributed mainly ipsilateral to the innervated cochlea, whereas medial OC neurons are distributed bilaterally, with approximately two-thirds from the contralateral side (not illustrated) and one-third from the ipsilateral side of the brain. *From Warr et al. (1986).*

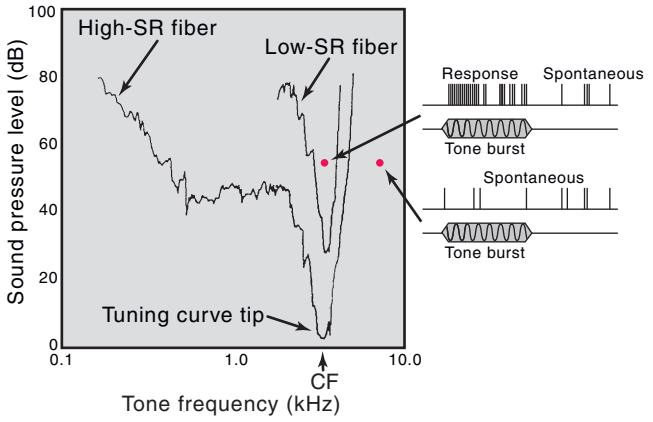

FIGURE 25.12 Tuning curves of two type I auditory nerve fibers. These curves plot the sound pressure level necessary to cause a response as a function of sound frequency. Within the tuning curve, the fiber responds to sound, whereas outside the tuning curve, there is only spontaneous firing (insets at right). The frequency corresponding to the lowest point on the tuning curve is called the characteristic frequency (CF); it is the point of maximal sensitivity. The sharply tuned region near the CF is called the tuning curve tip. The sharp tuning and high sensitivity of this region are generated by the mechanical properties of the outer hair cells. Tuning curves from two fibers are shown, one from a high SR (spontaneous rate) fiber and another from a low SR fiber. As is typical, the high SR fiber has the highest sensitivity. *From Kiang (1984).*

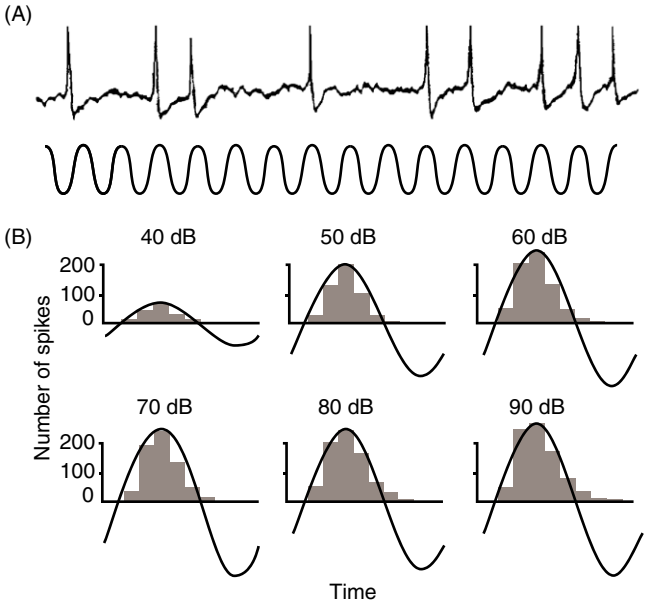

FIGURE 25.13 (A) Preferential firing of an auditory nerve fiber at a certain phase of the sound waveform. This pattern is called "phase locked," although the firing is not on every cycle of the waveform. Stimulus frequency was 0.3 kHz. (B) Histograms that quantify the time of firing plotted within one cycle of the sound waveform for many repeated cycles of the stimulus. Response of the fiber is phase locked at the moderate and high SPLs shown, even on this very fast time scale (time for one period was about 0.9 ms, given the stimulus frequency of 1.1 kHz). (A) *From Evans (1975)*; (B) *From Rose et al. (1971).*

Phase Locking of Responses and Codes for Sound Frequency

Responses of auditory nerve fibers can show time-locked discharges at particular phases within the cycle of the sound waveform, a property known as phase locking (Fig. 25.13). Although locked to a particular phase, there is generally not a spike for every waveform peak. Phase locking in nerve fibers results from the phasic release of neurotransmitter as dictated by the ac receptor potential (Fig. 25.6). Phase locking and the ac receptor potential decrease for frequencies above 1 kHz. At low sound frequencies, phase locking is an important temporal code for sound frequency and the sensation of pitch.

Neural Response Is a Function of Sound Level and Spontaneous Activity

The response of a single auditory nerve fiber increases with sound level until a point at which the rate of the fiber no longer increases and is saturated (Fig. 12.14A, solid line). The dynamic range over which the rate of most fibers increases is generally between 20 and 30 dB. How then can the auditory nerve signal the large range in level of audible sound from 0 to 100 dB? First, it is likely that as the level of a tone increases, more and more fibers that are tuned to other CFs begin to respond, because tuning curves become broader at higher sound levels (Fig. 25.12). Second, auditory nerve fibers vary in their sensitivity to sound, and as sound level is increased, the less sensitive fibers begin to respond. Sensitivity of fibers at a given CF varies by as much as 70 dB. The sensitivity of response is correlated with the rate of spontaneous firing, which is the rate of firing when there is no stimulus or when the stimulus is outside the tuning curve (Fig. 25.12). Spontaneous rates (SRs) vary from one fiber to another over the range of 0 to 100 spikes/s. Although there may be a continuum of SR, three main groups of fibers have been defined (low SR: <0.5 spikes/s; medium SR: 0.5 to 17.5 spikes/s; high SR: >17.5 spikes/s), and these groups predict many physiological and anatomical characteristics of auditory nerve fibers. The high SR fibers have higher sensitivities than medium and low SR fibers (Fig. 25.12). Low and medium SR fibers give off the largest number of terminals in the cochlear nucleus of the brainstem and preferentially innervate certain regions, such as the peripheral cap of small cells, suggesting that information carried by the different SR groups may be processed in somewhat different regions. Low SR fibers may be less sensitive, but they likely play important roles in detecting changes in sounds at high sound levels. Low SR fibers can signal changes at high sound levels because their low sensitivity causes them to respond mostly at higher sound levels and because there is less tendency for their firing rates to saturate.

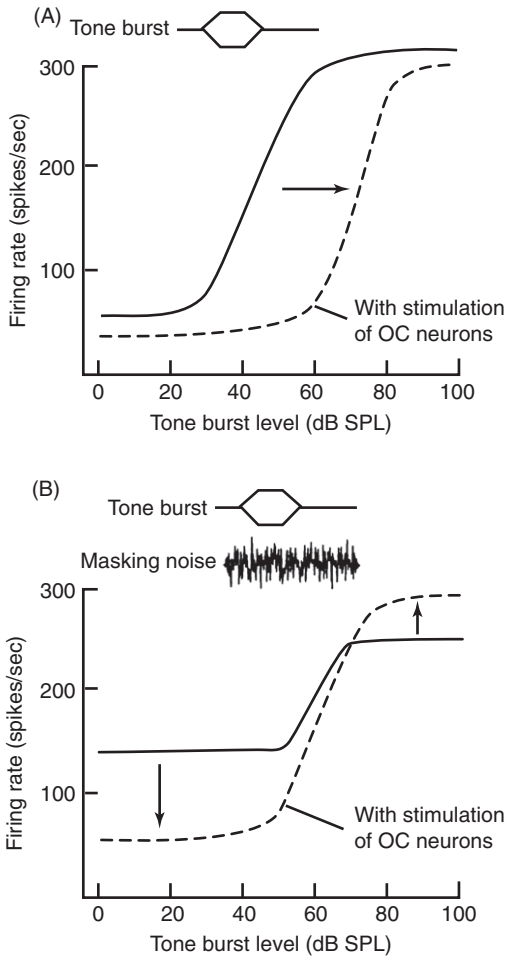

FIGURE 25.14 Rate level function for an auditory nerve fiber in response to tone bursts without (solid lines) and with (dashed lines) electrical stimulation of olivocochlear (OC) neurons. (A) With tone bursts alone, the discharge rate rises with sound level until it reaches a maximum and no longer increases (saturation). Stimulation of the OC neurons shifts the function to the right toward higher tone burst levels (arrow). This shift adjusts the dynamic range of the fiber so that it can signal changes in tone burst level for higher sound levels; this is likely to be an important function of OC neurons. (B) Level function from the same fiber, now for tone bursts accompanied by continuous masking noise (insets at top). At low levels of tone bursts, the fiber has a significant firing rate because it is responding mainly to the noise. Even at high levels of tone bursts, the fiber is still responding to the noise in between tone bursts, which causes adaptation, and the fiber responds less to the tone burst than with tone bursts alone. In this case, stimulation of OC neurons (dashed line) decreases the response to the noise, thus decreasing the rate of the fiber at low levels of tone bursts (left arrow). Because the fiber is responding less to the noise, it is less adapted and has a greater response at high levels of the tone burst (right arrow). The fiber now has a greater ability to signal changes in level of the tone burst; this effect has been called "antimasking" and is likely to be another important function of the OC system. *Adapted from Winslow and Sachs (1987).*

Masking Involves Adaptation and Suppression

The auditory nerve response to one stimulus may be masked, or hidden, by the presence of other stimuli. Masking involves properties of auditory nerve response such as adaptation and two-tone suppression, and possibly refractory properties. In adaptation, firing to a tone burst is high initially and then lessens, or adapts, to a steady state over time (Fig. 25.15). Adaptation probably takes place at the hair cell/nerve fiber synapse, as there is little adaptation in receptor potentials of hair cells for these short times (Fig. 25.6). Because of adaptation to one stimulus, the fiber is less likely to respond to a second stimulus; that is, the first stimulus masks the second stimulus. Masking by continuous noise changes the responses to tone bursts greatly. With tone bursts alone (Fig. 25.14A, solid line), there is a moderate dynamic range and a large difference in firing rate from low to high tone burst levels. With tone bursts in masking noise (Fig. 25.14B, solid line), there is a substantial rate at low tone burst levels because the fiber is now responding to the masking noise. At high tone burst levels, the rate is decreased because the fiber is adapted by the noise and is less likely to respond to the tone burst. Thus, with masking noise, there is much less difference in the rate of the fiber as a function of tone burst level as well as a lower dynamic range: these effects decrease the ability of the fiber to signal changes in the tone burst level.

An additional type of masking, referred to as suppressive masking, involves a phenomenon called two-tone suppression. In two-tone suppression, one tone lowers the response to a second tone even though the first tone may not excite the auditory nerve fiber. Two-tone suppression is present in the motion of the basilar membrane. It may help control the amount of gain provided by the cochlear amplifier, because as stimuli composed of several frequencies increase in sound level, two-tone suppression decreases the response of the nerve fiber and extends its dynamic range. Whether there is adaptive masking or suppressive masking depends on the frequencies and levels of signals relative to the response area of the fiber. Masking is important in the auditory system because many auditory processes, such as speech comprehension, are affected greatly by maskers and because background or masking signals are common in many everyday situations.

Descending Systems to the Hair Cells and Nerve Fibers

The auditory periphery and other hair cell organs receive an efferent innervation from the brainstem (Fig. 25.16). The cochlear efferent neurons have cell bodies in the superior olivary complex and project to the cochlea and hence are called olivocochlear (OC) neurons (reviewed by Ryugo, Popper, & Fay, 2011). There are two groups of OC neurons—medial OC and lateral OC neurons (Fig. 25.11)—named according to the positions of their cell bodies in the superior olive. These olivocochlear fibers

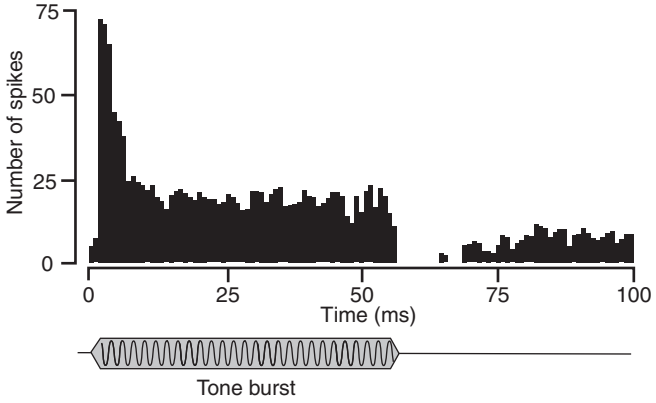

FIGURE 25.15 Poststimulus time (PST) histogram from an auditory nerve fiber in response to a tone burst (outline indicated below). A PST histogram is constructed by repeatedly presenting a stimulus while counting the number of action potentials that fall into bins of time during and after the stimulus. The histogram can be thought of as the probability of firing as a function of time. This function has an initial peak and then a decrease in firing (adaptation) during the burst. After the burst ends, spontaneous firing is lessened but then returns gradually.

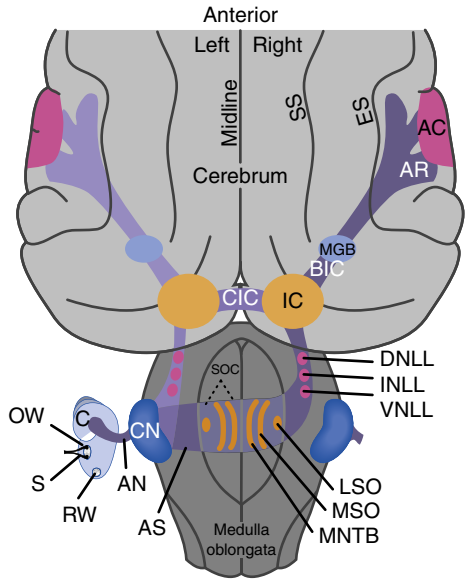

FIGURE 25.16 Simplified schematic of the pathways of the ascending auditory system of a generalized mammal. The pathway begins at the lower left with the cochlea and ends at top right with the auditory cortex. The large band crossing the midline indicates the crossing of the bulk of the pathway below the inferior colliculus. Some ipsilateral pathways and frequent commissural pathways explain the responses of some units at higher centers to ipsilateral sound. AC, auditory cortex; AN, auditory nerve; AR, auditory radiations; BIC, brachium of the inferior colliculus; C, cochlea; CIC, commisure of the inferior colliculus; CN, cochlear nucleus; DNLL, dorsal nucleus of the lateral lemniscus; ES, ectosylvian sulcus; IC, inferior colliculus; INLL, intermediate nucleus of the lateral lemniscus; LSO, lateral superior olive; MGB, medial geniculate body; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; OW, oval window; RW, round window; S, stapes; SOC, superior olivary complex; SS, suprasylvian sulcus; VNLL, ventral nucleus of the lateral lemniscus. *From Kiang and Peake (1988).*

separately innervate the two types of hair cells. Medial OC neurons innervate outer hair cells, whereas lateral OC neurons innervate the inner hair cell region by synapsing on dendrites of type I auditory nerve fibers. Little is known about the lateral OC neurons, as their very thin axons are difficult to study. Medial OC neurons can be activated experimentally by electrical stimulation, which causes them to release the neurotransmitter acetylcholine. At the outer hair cell, acetylcholine acts on a nicotinic receptor that allows Ca^{2+} influx, which then opens Ca^{2+}-activated K^+ channels, allowing K^+ efflux that hyperpolarizes the cell. The hyperpolarization and accompanying decrease in input resistance of the cell probably reduces the electromotility of the outer hair cell, decreases basilar membrane motion, and reduces the responses of inner hair cells and auditory nerve fibers. These decreases shift responses of auditory nerve fibers to higher sound levels (Fig. 25.14A, dashed line). This shift means that sound levels that previously saturated the discharge rates are now within the increasing portion of the rate level curve of the fiber, so the fiber can now signal changes in sound level at higher sound levels. Thus, one function of medial OC neurons may be to control the gain of the cochlear amplifier to shift the dynamic range of hearing.

Another function of medial OC neurons may be to reduce the effects of masking noise on the responses of auditory nerve fibers. Decreases in responses by maskers can occur by adaptation and suppression. The effect of OC stimulation on masked responses to tone bursts can be to *enhance* the response (Fig. 25.14B, dashed line). Responses at low tone burst levels are decreased because the response of the fiber to the noise is decreased (left arrow on Fig. 25.14B); responses at high tone burst levels are increased because there is less noise-induced adaptation and a greater response to the tone bursts (right arrow on Fig. 25.14B). The fiber now has a greater ability to signal changes in level of the tone burst; this effect has been called "antimasking" and may be an important function of the OC system. A third function of medial OC neurons may be to protect hair cells in the cochlea from damage due to intense sounds via their large synaptic endings on outer hair cells. Additional protection from damage is afforded by two muscles of the middle ear, whose contractions decrease sound transmission through the middle ear.

Summary

Although the function of type I auditory nerve fibers is fairly well understood, we do not yet know how afferent fibers of the outer hair cells, the type II fibers, function in the hearing process. Future experiments will provide insight into the roles played by different spontaneous rate groups of type I auditory nerve fibers. More work is

needed to identify the mechanisms used to prevent the degradation of signals by masking noise. These mechanisms could potentially be applied clinically in the design of hearing aids and cochlear implants.

CENTRAL NERVOUS SYSTEM

Auditory Pathways Are Tonotopically Organized

The auditory nerve projects tonotopically into the cochlear nucleus, which in turn projects to the other auditory nuclei of the brainstem: the superior olivary complex, nuclei of the lateral lemniscus, and inferior colliculus (Fig. 25.16). The finding of tonotopic mappings in central auditory nuclei supports the theory of a place code for sound frequency (reviewed by Ehret & Romand, 1997; Popper & Fay, 1992; Webster et al., 1992). This is especially true in higher nuclei because here neurons have a decreased ability to phase lock to the sound waveform, and thus a temporal code does not seem to be as robust. In most auditory nuclei there are not large overrepresentations of certain frequencies, although, as noted later, a given nucleus may be more devoted to low frequencies (e.g., medial superior olive) or to high frequencies (e.g., lateral superior olive). An important exception is the case of echolocating bats that use a constant frequency in their echolocating pulse; in these species, there is an over-representation of one of the constant frequencies. This over-representation begins in the cochlea and is preserved in the cortex (e.g., Fig. 25.23C). In these bats much cortical area is devoted to the constant frequency, analogous to the large somatosensory cortical areas devoted to important areas such as the hands and face.

Under certain conditions, tonotopic mappings have been shown to be capable of plastic changes (Robertson & Irvine, 1989; reviewed by Parks, Rubel, & Fay, 2004). After peripheral hearing loss, tonotopic mapping of the auditory cortex is altered such that a region that originally processed frequencies within the hearing loss begins to respond to adjacent frequencies. For instance, when the cochlea is damaged so that it no longer responds to high frequencies, the high frequency portion of the cortex does not stay unresponsive, but over time becomes responsive to middle frequencies where hearing is still normal. Plasticity is of interest to humans because of a common condition called presbycusis, which is hearing loss with advanced age. Presbycusis generally begins with a loss at high frequencies and spreads to lower frequencies with advancing age. While presbycusis and other forms of hearing loss are caused by peripheral changes, they may result in plastic changes in the central pathways that change the way sound is processed in the brain.

Units Are Classified by Their Responses to Sound

Classification by PST Histograms

The cochlear nucleus is the auditory center that is understood best at the cellular level (reviewed by Rhode & Greenberg, 1992). Cochlear nucleus neurons have been well classified both anatomically and physiologically, and structure–function correlations can be made between these classifications. Physiologically, cochlear nucleus neurons process their inputs from the auditory nerve to form new output patterns. These patterns may be used to classify units on the basis of the shape of the poststimulus time (PST) histogram, which plots the spike pattern of the unit as a function of time for short-duration tone bursts. Unit types are called "pauser," "onset," "primary-like with notch," "chopper," and "primary-like" (Fig. 25.17). A correspondence has been established between these unit types and anatomical cell types of the cochlear nucleus. The correspondence was first suggested by the regional distributions of unit and cell types; for example, there is a region of the cochlear nucleus in which one finds mostly "octopus" cells and from which mostly onset units are recorded. Direct correspondence has been made by single-unit labeling, in which a single unit is first classified physiologically according to PST type and subsequently injected with a neural tracer (e.g., horseradish peroxidase) that fills the neuron and its processes. The anatomical cell type can then be determined from postexperiment histology. These types of experiments are difficult and low yielding, but they firmly establish the structure–function correspondences, at least for neurons large enough to record and label *in vivo.* For instance, a major cell type in the ventral subdivision of the cochlear nucleus, the "spherical bushy" cell, has a "primary-like" response pattern (Fig. 25.17).

Use of PST histograms is helpful not only in classifying units but also reveals functional properties of the neurons. Let us consider the example of primary-like units. The primary-like pattern reveals that the spherical bushy cell has faithfully preserved the temporal properties of the auditory nerve fiber response and implies that these units receive endbulbs from nerve fibers (see Box 25.3). In contrast, other types of cochlear nucleus neurons alter the spike patterns of the auditory nerve fibers and presumably have distinct functions. For instance, onset units respond mainly at the onset of a short tone burst (Fig. 25.17). One subclass of onset units can increase its response over a large range of SPL and might be involved in signaling sound level. Relative to mammals, tests of such hypotheses are easier in birds, where there is much more regional segregation of neurons by anatomical and physiological type in the cochlear nucleus. In birds, bushy cells are segregated in one region (nucleus magnocellularis), whereas other cell types,

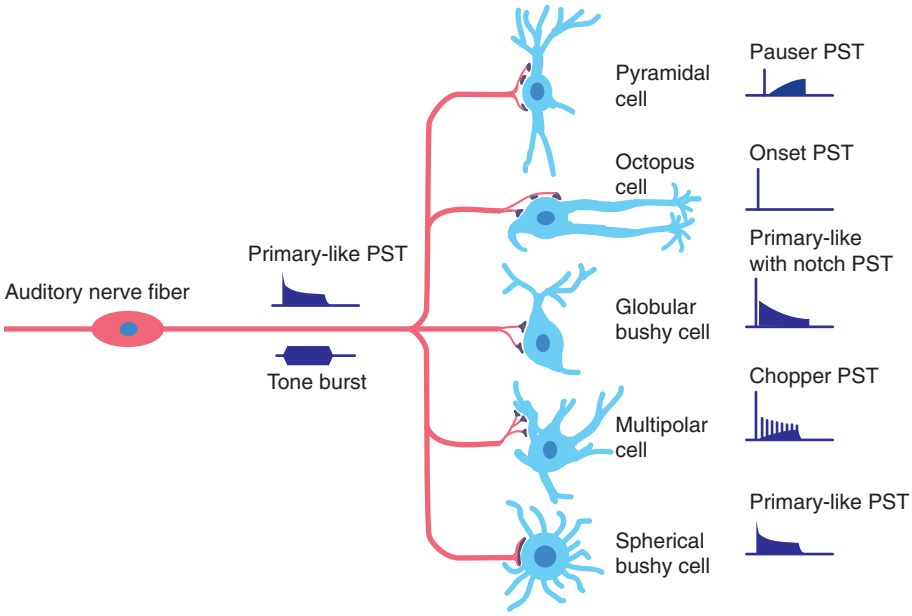

FIGURE 25.17 Schematic of the main anatomical cell types of the cochlear nucleus and their corresponding poststimulus time (PST) histograms. (Left) An auditory nerve fiber is shown with its typical response, a primary-like PST histogram (shown in Fig. 25.15). (Center) The auditory nerve fiber divides to innervate the main cochlear nucleus cell types. (Right) PST histograms corresponding to these cell types are shown. In their PST histograms, pauser units fire an initial spike and then have a distinct pause before a slow resumption of activity. Onset units fire mainly at the tone burst onset. Primary-like units get their name from the similarity of their PSTs to those of primary auditory nerve fibers, but the primary-like with notch type additionally has a brief notch following the initial peak. Chopper units have regular interspike intervals that result in regular peaks in the PST. Most of these patterns are very different from the primary-like PST and irregular interspike intervals of the auditory nerve fibers. For histograms, the sound stimulus is typically a 25-ms tone burst with frequency at the CF of the neuron and sound level at 30 dB above threshold. *From Kiang (1975).*

such as multipolar cells, are confined to a second region (nucleus angularis). The bushy cells in nucleus magnocellularis have excellent phase locking, but a poor dynamic range of response when sound level is increased. Multipolar neurons in nucleus angularis have complementary properties: poor phase locking, but excellent dynamic ranges. Overall, these results suggest that in the auditory system of diverse animal species there are separate neural pathways for time coding versus sound level coding as well as for other types of coding. Thus, the cochlear nucleus is the level where parallel pathways in the auditory system begin.

Classification by Response Map

Another important way to classify neurons in the cochlear nucleus, as well as throughout the auditory nervous system, is by the response map of a neuron (Fig. 25.19). Response maps are plotted on graphs of sound level versus frequency; like tuning curves, these maps show areas of excitation, but they additionally show areas of inhibition. They are especially valuable where inhibitory influences play a role in shaping responses, such as in the dorsal subdivision of the cochlear nucleus, the inferior colliculus, and at higher stages of the auditory system. In the dorsal cochlear nucleus, five response types have been defined (Fig. 25.19). Type I neurons have excitatory tuning curves similar to those of the auditory nerve (Fig. 25.12) and have no inhibitory areas. Other response types have progressively larger inhibitory areas; for example, type IV neurons have only a small excitatory area near CF and a narrow, knife-sharp excitatory area above CF, with the rest of their area dominated by inhibition. This inhibition is generated by inhibitory circuits within the dorsal cochlear nucleus, most likely from type II neurons. Type IV neurons correspond to the main projection neurons of the dorsal cochlear nucleus, the pyramidal neurons, whereas type II neurons are likely to be inhibitory interneurons. One hypothesis for the functional role of type IV neurons is that their sharp borders between excitatory and inhibitory areas serve to detect the spectral notches that result from the acoustic characteristics of the external ear, especially the pinna. These notches could be used for sound localization, as their frequencies depend on sound source location. The notches also depend on position of the pinna; in fact, type IV neurons receive input from brainstem somatosensory nuclei that may inform the type IV neurons about the position of the animal's moveable pinna. Animals that lack a moveable pinna, such as humans and cetaceans (whales and porpoises), have a dorsal cochlear nucleus that differs greatly from that of other mammals by being unlayered and possibly lacking in several cell types (granule and cartwheel cells).

BOX 25.3

GIANT SYNAPTIC TERMINALS: ENDBULBS AND CALYCES

The largest synaptic terminals in the brain are contained in the central auditory pathway. There are two types of these giant synaptic terminals: (1) endbulbs of Held, which are found in the ventral cochlear nucleus (Fig. 25.18A), and (2) calyceal endings, which are found in the medial nucleus of the trapezoid body. Calyces are so large that it is possible to use patch electrodes to record and clamp the presynaptic terminal while simultaneously doing the same with their postsynaptic target in *in vitro* preparations (Forsythe, 1994). This type of study has given insight into presynaptic and postsynaptic regulation of transmitter release at this glutamatergic synapse.

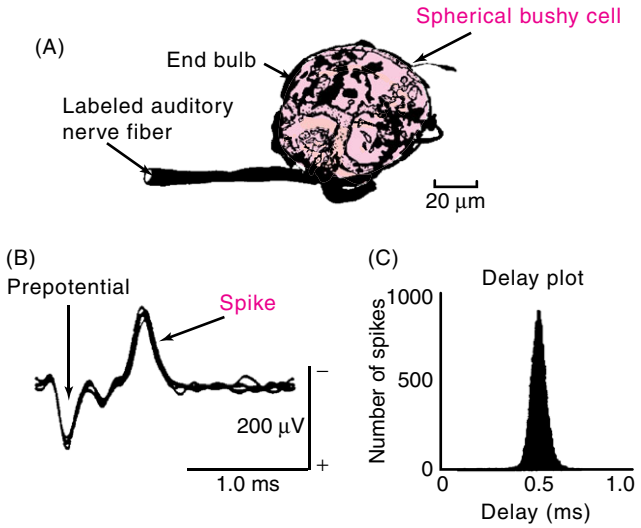

FIGURE 25.18 (A) Drawing of a labeled auditory nerve fiber forming an endbulb of Held that completely envelops a spherical bushy cell in the anteroventral cochlear nucleus. *From Rouiller et al. (1986).* (B) Superimposed waveforms recorded by an extracellular metal electrode in the anteroventral cochlear nucleus. The endbulb is such a large synaptic ending that it generates a prepotential, which is followed after a synaptic delay by the spike from the bushy cell. *From Pfeiffer (1966).* (C) Histogram of the delay time between prepotential and spike. This represents the synaptic delay between endbulb and bushy cell. The delay of this synapse has an exceptionally low jitter in time. *From Molnar and Pfeiffer (1968).*

Endbulbs and calyces enable secure transmission of information to their postsynaptic neurons. Endbulbs of Held are formed by primary auditory nerve fibers; each nerve fiber forms one or sometimes two endbulbs. The endbulbs contact and completely encircle their postsynaptic target, the spherical bushy cells of the cochlear nucleus (Fig. 25.18A). The endbulb probably forms hundreds of synapses directly onto the soma of the spherical bushy cell. In single-unit recordings near bushy cells, an extracellular microelectrode records a complex waveform that differs from recordings in other regions of the brain (Fig. 25.18B). The waveform consists of a prepotential followed about 0.5 ms later by a spike. The prepotential is likely from the presynaptic endbulb and the spike is from the postsynaptic bushy cell. The delay between the two events has a low jitter, or variability, in time (Fig. 25.18C).

The large influence of the endbulb would, for most neurons, last many milliseconds so that two closely spaced presynaptic spikes would produce only one postsynaptic spike or a second spike that was delayed, thus smearing in time the pattern of input spikes. However, the bushy cell membrane potential recovers quickly because its membrane contains specialized K^+ channels that allow the cell to repolarize after firing an impulse so it is "reset" and ready to fire again (Manis & Marx, 1991). The overall effect of endbulb–bushy cell specializations are to replicate the spike pattern of the auditory nerve fiber, producing a PST histogram and phase-locking pattern like that of an auditory nerve fiber. These characteristics are important because the end-bulb–bushy cell synapse is the only central synapse in the pathway to the medial superior olivary nucleus, a nucleus where timing information from the two ears is compared in order to localize sound sources (Fig. 25.21A).

Classification by Laterality of Response: The Response to the Contralateral versus Ipsilateral Ear

A final important way to classify neurons is by their laterality of response, which is defined as whether the neuron responds to the contralateral or ipsilateral ear and whether the response is excitatory or inhibitory (reviewed by Irvine, 1986). Many neurons in central auditory nuclei above the cochlear nucleus are binaural and can be influenced by sound presented to either ear. A predominant pattern, however, is for the neuron to be excited by sound in the contralateral ear (the side opposite to where the neuron is located). The influence of the ipsilateral ear can be excitatory, inhibitory, or mixed. The contralateral

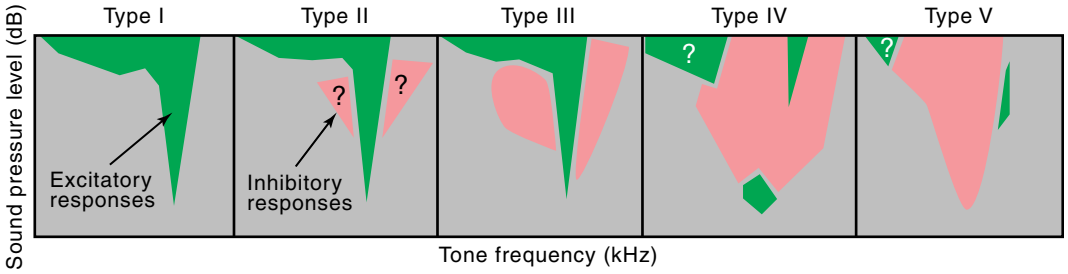

FIGURE 25.19 Unit classification by "response map." Shown are response areas for the five response types (types I–V) typically found in the cochlear nucleus. Response types are distinguished by the positions of their response areas: excitatory (green shading) and inhibitory (pink shading). Question marks show variable or uncertain areas. Type I neurons have excitatory response areas similar to the tuning curves of auditory nerve fibers. Type II neurons have similar excitatory areas and are inferred to have inhibitory flanking areas because they have little response to broadband signals like noise. Type III neurons have similar excitatory areas and definite inhibitory areas on either side. Type IV neurons have a small excitatory area at low levels (near the characteristic frequency), as well as a knife-sharp excitatory area at higher frequencies. Inhibition dominates much of the remainder of their response area. Type V neurons are similar to type IV neurons but lack a low-level excitatory area. *From Young (1984).*

response results from the fact that many central auditory pathways cross to the opposite side of the brain (Fig. 25.16). There are also uncrossed pathways; these pathways generate the response to the ipsilateral ear. Despite an influence of the ipsilateral ear, lesion studies indicate the functional importance of excitation from the contralateral ear. For instance, damage to the inferior colliculus or auditory cortex on one side of the brain decreases the ability to localize sound sources within the spatial hemifield on the opposite side of the body. Thus, as in other sensory and in motor systems, one side of the brain is primarily concerned with function on the opposite side of the body.

The Auditory Brainstem Uses Binaural Cues to Determine Sound Location

An important function of the auditory system is to determine the location of sound sources in space. Binaural sound localization occurs when cues from both ears are used to locate sounds (reviewed by Wightman & Kistler, 1993). This is the most accurate type of localization for determining the azimuthal position of a sound source. Binaural localization uses two cues: interaural time differences (ITDs) and interaural level differences (ILDs) (Fig. 25.20). ITDs result because sound reaches the ear closest to the source sooner than the ear farther from the source (Fig. 25.20A). ITDs are a good cue for localization because they depend greatly on the azimuth of the source. For ongoing sounds, such as pure tones, they can be translated into phase differences in the sound waveforms at the two ears. These phase differences are useful at low frequencies, but become ambiguous for high frequencies (above about 1.5 kHz in humans) because by the time sound reaches the ear away from the source, the waveform has repeated by a cycle or more. The decline in phase locking for frequencies above 1 kHz is a second reason that phase differences are less important for localizing sounds at high frequencies.

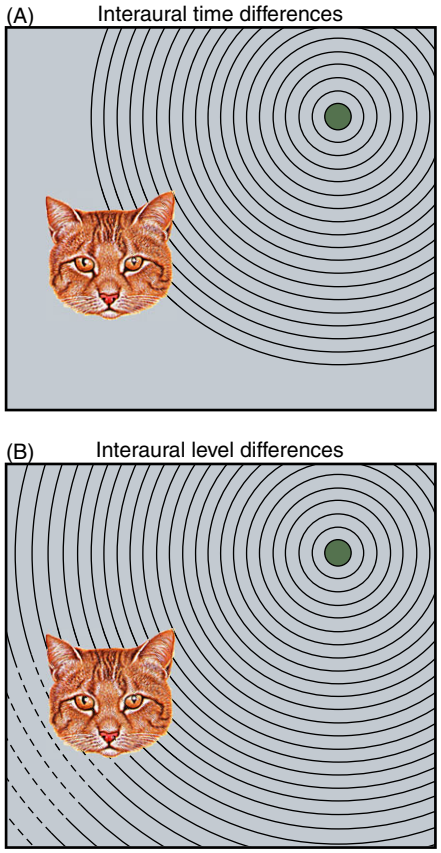

FIGURE 25.20 The two cues for binaural localization of sound. A sound source is shown as a solid dot to the right of the animal's head and sound waves are shown as concentric lines. (A) Interaural time differences result from the longer time it takes sound to travel from the source to the ear away from the source. (B) Interaural level differences result from the head forming a "sound shadow," reducing the level of sound at the ear away from the source.

Interaural level differences (ILDs) result when the head forms a "sound shadow," reducing the level of sound at the ear away from the source (Fig. 25.20B). ILDs vary greatly with sound-source azimuth, but due to the directional

characteristics of sound, ILDs are significant only at high frequencies and are much smaller at low frequencies. Thus, for sound localization at low frequencies (<1 kHz), ITDs are the major cues, but for localization at high frequencies (>3 kHz), ILDs are the major cues. For human performance using pure tones, the accuracy of azimuthal localization is good at low frequencies and at high frequencies, but somewhat less accurate at middle frequencies, perhaps because the cues are more ambiguous in this range. In psychophysical experiments in humans under optimal conditions, the minimum discriminable angle for localization of a sound source approaches one degree of azimuth. The physical cues corresponding to this angle are about 10 μs in ITD or 1 dB in ILD. When experiments are conducted with headphones to manipulate the ITDs and ILDs, such small interaural differences are indeed discriminable in human subjects.

Mechanisms of Interaural Time Sensitivity

The auditory pathway has more brainstem nuclei than other sensory pathways, and much of this processing is devoted to determining the location of a sound source. Two neural circuits that provide sensitivity to ITD or ILD are within the superior olivary complex (Fig. 25.21; Irvine, 1986; Yin & Chan, 1990). The neural mechanisms that generate sensitivity to ITDs are impressive given the small sizes of the differences. For instance, the central nervous system must be able to detect ITDs of 10 μs by comparing spikes coming in from the neural channels of the two sides that differ in time by 10 μs. However, 10 μs is less than the rise time of neural spikes, making the incoming spikes almost identical. The neural circuit that is sensitive to ITDs in the mammal is the medial superior olive (MSO) and its inputs (Fig. 25.21A); a similar circuit is present in birds in nucleus laminaris. The MSO inputs are from primary-like units (spherical bushy cells) of the left and right cochlear nuclei. These inputs preserve the phase-locking and timing characteristics of the auditory nerve because of the low jitter in the endbulb/bushy cell synapse (see Box 25.3). For a low frequency sound with an ITD, phase-locked spikes from one side will have a time difference relative to the other side. Phase-locked spikes will repeat this time difference many times during the waveforms of a continuous sound. Neural delay lines that "make up" for this time difference are formed by axons for both contralateral and ipsilateral inputs, in the model originally proposed by Lloyd Jeffress (Fig. 25.21A). An axon forms a delay line simply because it takes time for an impulse to travel along the axon. Within the MSO, neurons respond best when they receive coincident input from the two sides; thus a neuron in the middle of the drawing of the MSO in Figure 25.21A would respond best if the delays were about equal. A neuron at the bottom of the drawing has a long contralateral axonal delay that makes up for stimuli coming in later from the ipsilateral side. Thus, this neuron would respond best if the sound to the contralateral ear were leading, which occurs for a sound source located on the contralateral side (Fig. 25.21B). Medial superior olive neurons are thus tuned to a particular ITD and respond less to other ITDs. The Jeffress model has recently been challenged: new data in small mammals demonstrates that the best delays are outside the physiological range for the size of the animal's head and the neural inhibition in the MSO is not explained in the Jeffress model (Brand, Behrend, Marquardt, McAlpine, & Grothe, 2002). As mentioned earlier, ITDs are most important for sound localization at low frequencies and the MSO has a tonotopic organization that is composed predominantly of neurons with low characteristic frequencies.

Mechanisms of Interaural Level Sensitivity

A second neural circuit in the brainstem, within the lateral superior olive (LSO), generates responses that are sensitive to ILDs (Fig. 25.21C). Input to the LSO from the ipsilateral side is excitatory by way of spherical bushy cells of the cochlear nucleus. Input from the contralateral side is inhibitory. This input originates from globular bushy cells of the cochlear nucleus and synapses by way of giant calyceal endings on neurons in the medial nucleus of the trapezoid body (MNTB; Fig. 25.21C). Most of the neurons in the medial nucleus of the trapezoid body are inhibitory and use the neurotransmitter glycine, which is a common inhibitory transmitter throughout the auditory brainstem. These inhibitory neurons then project to the LSO. Because of these inputs, LSO neurons compare the difference in levels of the sound at the two ears: they are excited when sound in the ipsilateral ear is of higher level, but are inhibited when sound in the contralateral ear is of higher level (Fig. 25.21D). When the sound is of equal level in the two ears, the strong contralateral inhibition usually dominates and there is little response. These neurons are thus excited by sound sources located on the ipsilateral side of the head. As the lateral superior olive projects further centrally, this ipsilateral-side response is transformed to a contralateral-side response by crossing to the inferior colliculus on the opposite side. (There is also an uncrossed projection, but it is inhibitory.) As mentioned earlier, ILDs are most important for sound localization at high frequencies and the LSO has a tonotopic organization that is composed predominantly of neurons with high characteristic frequencies.

Inferior Colliculus

Ascending input from lower brainstem centers converges at the inferior colliculus, which is a synaptic station for almost all ascending neurons. The inferior colliculus consists of several subdivisions, the best studied of which is the large, tonotopically organized central nucleus. In the central nucleus, direct input from the cochlear nucleus interacts with binaurally responsive input from the MSO

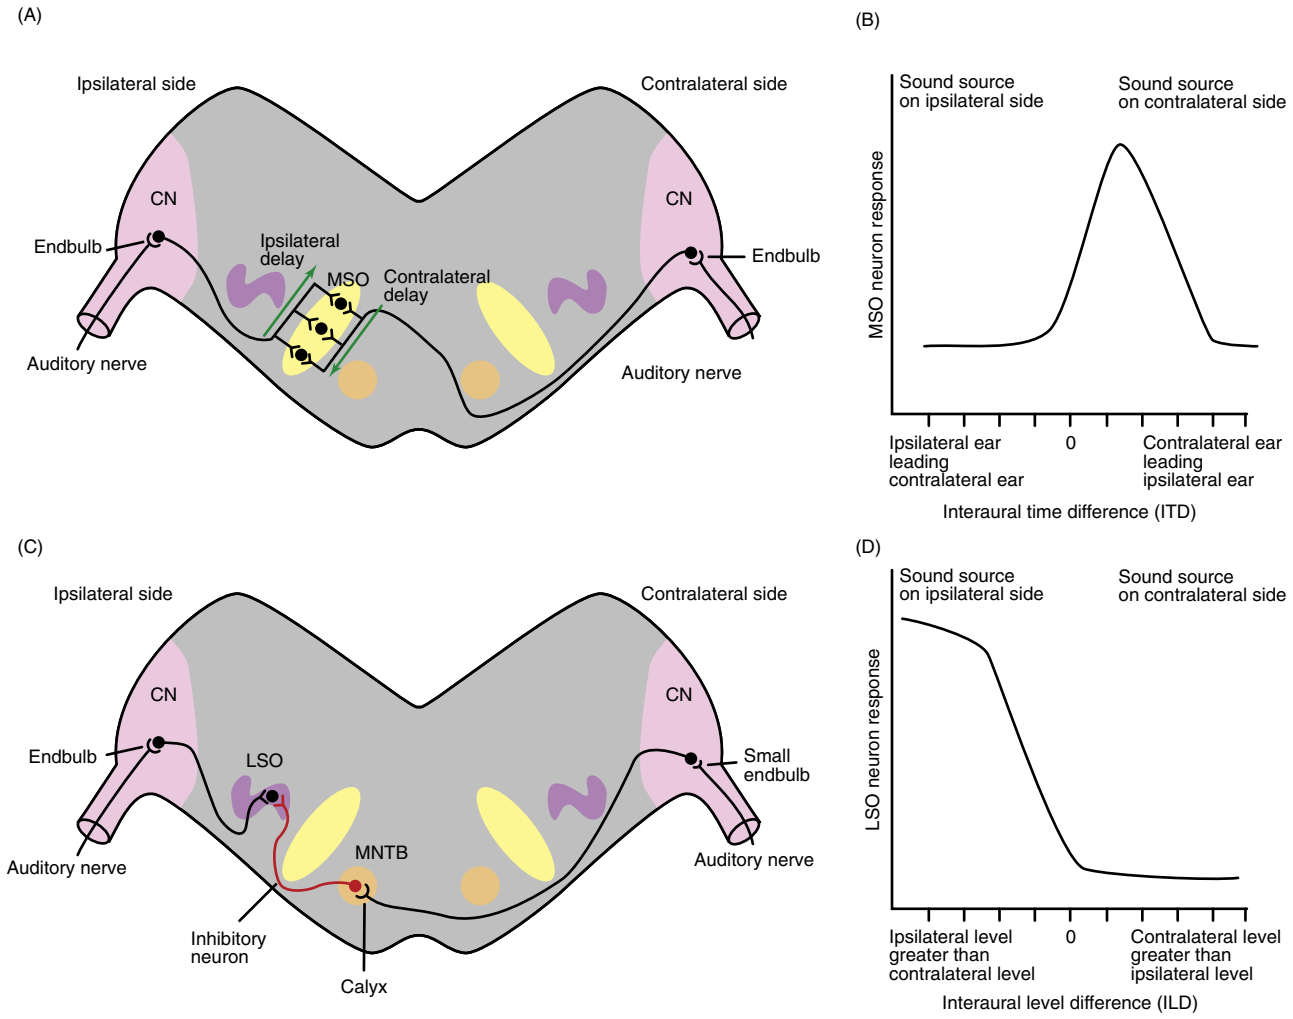

FIGURE 25.21 Innervation schematics and responses of two circuits in the lower brainstem that are important in binaural sound localization. Neuronal cell bodies are shown as dots, and fiber pathways are shown as lines; positions of large synaptic terminals (endbulbs and calyces) are indicated. (A) Circuit of the medial superior olive (MSO), which is sensitive to interaural time differences (ITD). Input to the cochlear nucleus (CN) from the auditory nerve terminates at the large endbulbs of Held that synapse onto spherical bushy cells (see Fig. 25.18A). Bushy cells project bilaterally such that a single MSO receives input from both sides. Bushy cell inputs form delay lines such that ITD is mapped along the MSO. Data suggest that the delay line is oriented rostrocaudally and that only contralateral inputs are delayed. (B) Response of an MSO neuron as a function of ITD. Neurons within the MSO respond when spikes from their two inputs arrive at the same time. The response plotted is of a neuron in the lower part of the MSO drawn in part A; there is a large response when the ipsilateral input lags so that early contralateral input has time to proceed down the axonal delay line to reach the neuron at the same time as the lagging ipsilateral input. This type of lagging ipsilateral input would be produced by a sound source located in the hemifield of space contralateral to the MSO where the recording is made. (C) Circuit of the lateral superior olive (LSO), which is sensitive to interaural level differences (ILD). Excitatory input arises from the ipsilateral CN. Inhibitory input (red line) from the contralateral side is through the medial nucleus of the trapezoid body (MNTB), a nucleus of inhibitory neurons. The large synaptic ending in the MNTB is called a calyx (similar to the endbulb pictured in Fig. 25.18). (D) Response of an LSO neuron as a function of ILD. There is a large response when sound is of higher level on the ipsilateral side and no response when sound is of higher level on the contralateral side. Thus, a response is produced by a sound source located in the ipsilateral hemifield.

and LSO. Low CF input (including that from the MSO) projects to the dorsolateral part of the colliculus and high CF input (including that from the LSO) projects to the ventromedial part. Many low CF collicular neurons are thus sensitive to ITDs like their MSO inputs, whereas many high CF collicular neurons are sensitive to ILDs like their LSO inputs. Interestingly, large lesions of the superior olivary complex do not completely disrupt ILD sensitivity in the colliculus; this is evidence that ILD sensitivity is created anew at levels above the LSO. ILD sensitivity may be created in part by the dorsal nucleus of the lateral lemniscus, a nucleus within the lateral lemniscus that sends a large inhibitory projection to the colliculus. ILD sensitivity may also be created anew by inhibitory mechanisms within the colliculus. Additional circuits for the generation of ITD sensitivity have not been identified,

thus the colliculus appears to be sensitive to ITD because of its inputs from the MSO.

An important question is whether the colliculus uses its inputs to form a "space map"—a mapping of sound source location to position within the brain. Such a mapping has not been reported in the mammalian inferior colliculus, but a mapping exists in the deep layers of the superior colliculus, where it is in register with a mapping of the visual field. These deep layers of the superior colliculus have sensorimotor functions concerning orientation movements of the head, eyes, and pinnae. Another auditory space map has been observed in the barn owl, which hunts for prey in darkness using acoustic cues (reviewed by Cohen & Knudsen, 1999). In the owl, the mapping has been observed within a nucleus homologous to the external nucleus of the inferior colliculus (nucleus mesencephalicus lateralis dorsalis). Here, spatial receptive fields of neurons are narrow in both azimuth and elevation and are arranged such that there is a mapping of sound source location within the brain. This mapping demonstrates that space maps do exist, but they do not appear to be a common feature of the auditory system of nonspecialized mammals.

The Medial Geniculate and Auditory Cortex Are the Highest Stages of the Auditory Pathway

The medial geniculate and auditory cortex contain a number of subdivisions that have clear tonotopic organization (reviewed by Clarey, Barone, & Imig, 1992; de Ribaupierre, 1997). For instance, in the cortex of the cat, there are four fields that have clear tonotopic mappings (fields AI, A, P, VP) (Fig. 25.22). The tonotopic axis of field AI runs from high frequencies rostrally to low frequencies caudally; other adjacent fields (such as A) have mirror-image tonotopy (Fig. 25.22B). The major ascending pathway that connects tonotopic areas at the highest levels of the pathway begins in the central nucleus of the inferior colliculus, forms synapses in the laminated ventral division of the geniculate and then continues to most of the tonotopic cortical fields. Other parallel pathways exist that connect regions with less tonotopic organization. One of these pathways begins in the dorsal cortex of the colliculus, forms synapses in the dorsal division of the medial geniculate and projects mainly to cortical field AII. Another, a polysensory pathway, begins in the external and dorsal nuclei of the colliculus and projects via the medial division of the geniculate to almost all the auditory cortical fields.

In general, the physiology of tonotopic areas has been explored most extensively. Units from the tonotopic areas, such as the ventral division of the geniculate and cortical field AI, tend to have short latencies and sharply tuned tuning curves. Neurons in areas with less obvious tonotopy tend to have longer latencies, broader tuning curves, and

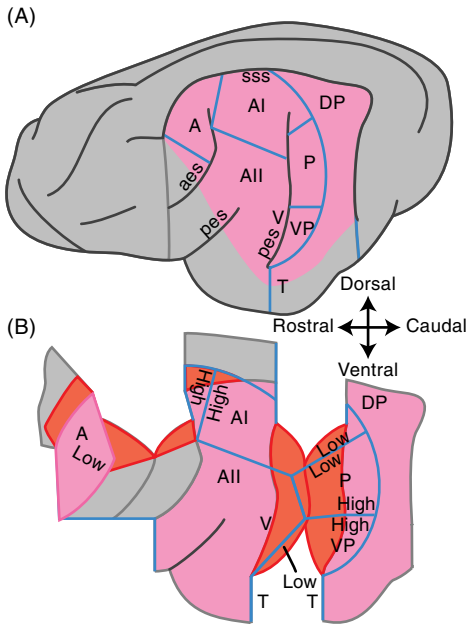

FIGURE 25.22 Auditory cortical fields in the temporal cortex of the cat. (A) Lateral view. (B) Lateral view that is "unfolded" to show the parts of the fields that are normally hidden within the sulci (orange shading), as well as the high- and low-frequency limits of the tonotopic fields. The four tonotopic fields are the anterior (A), primary (AI), posterior (P), and ventroposterior (VP). Positions of the lowest and highest CFs in these fields are indicated in B. Note that at the boundaries of the tonotopic fields, the direction of tonotopy is reversed so that adjacent fields have "mirror-image" tonotopy. Other cortical fields have less rigidly organized or little tonotopy. These fields are secondary (All), ventral (V), temporal (T), and dorsoposterior (DP). Also indicated are suprasylvian sulcus (sss) and anterior and posterior ectosylvian sulci (aes, pes). *From Imig and Reale (1980).*

responses that can habituate or stop responding after multiple presentations of the stimulus, especially in anesthetized preparations. In humans, the primary auditory cortex is located on Heschl's gyrus, which is on the superior surface of the temporal lobe. Sound-evoked activation is seen in this region with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

The medial geniculate exerts its influence on ascending information, but it does so with extensive influence from the cortex. The geniculate receives a large number of projections from the auditory cortex: it probably receives more input from cortex than from lower centers. One large projection is from the tonotopic cortical fields AI and A to the tonotopic ventral division of the medial geniculate. Apparently, however, the geniculate mediates important functions that do not require the cortex. For example, fear conditioning is a behavior that can be established by pairing a sound with a painful electric shock in rats. After conditioning is established, conditioned responses such as an increase in blood pressure can be elicited by sound alone. Lesions of the auditory pathway up to and including the geniculate have a large effect on such conditioning;

however, lesions of the auditory cortex do not produce large alterations (LeDoux, Sakaguichi, & Reis, 1984). Pathways directly from the geniculate to the amygdala mediate such conditioned responses. Cortical neuron responses are also changed by conditioning; for example, the pairing of an acoustic stimulus with a noxious stimulus greatly alters the response of cortical neurons. Such observations indicate that responses at these high levels of the auditory pathway are context dependent.

Cortical Fields and Sound Localization

Physiological and behavioral studies suggest a role for cortical field AI in sound localization. In AI, many neurons are sensitive to the spatial position of a sound source. As expected from the fact that auditory pathways are predominantly crossed, a large number of cortical neurons respond to sound sources centered on the contralateral side. Behaviorally, sound localization performance is decreased by lesions of AI, the posterior auditory field (a tonotopic field just caudal to the primary auditory field), and an area near the anterior ectosylvian sulcus (Malhotra & Lomber, 2006). Furthermore, the deficit is frequency specific: if the lesion is in areas of AI tuned to certain frequencies, the deficit is observed only for those frequencies (Jenkins & Merzenich, 1984).

Coding of Complex Signals in the Cortex

Animals emit a variety of vocal signals that make possible a wide range of behaviors. Studies in echolocating bats demonstrate specialized cortical fields and responses (see Box 25.4). Cortical neurons show selectivity to complex sounds such as species-specific calls over what would be predicted from their pure tone frequency selectivity (Rauschecker, Tian, & Hauser, 1995). For instance, a neuron that responds well to a particular type of call does not usually respond as well to the call played backward in time even though it has an identical frequency content. Similar results in response to speech stimuli have been

BOX 25.4

BAT ECHOLOCATION

Bats offer unique opportunities for researchers studying the auditory system (rev. by Popper and Fay, 1995). Echolocating bats emit high-frequency pulses of sound and use the return echoes to locate and capture their flying insect prey. These pulses are above the upper frequency limit of human hearing. They were discovered in the 1940s by Donald Griffin, who was then an undergraduate student at Harvard University. The echolocation performance of the bat is impressive: bats are adept enough to find a mosquito above a golf course at night. Indeed, Griffin demonstrated that bats can avoid wires as thin as 0.3 mm diameter while flying in a darkened room.

There are more than 800 species of echolocating bats, all within the suborder Microchiroptera. One of the best-studied bats is the mustached bat, *Pteronotus parnellii*. It emits echolocating pulses that have an initial part of constant frequency, followed by a part of decreasing frequency (frequency modulated). This bat is thus called a CF-FM bat (Fig. 25.23B). Some other species of bats emit only the FM portion and are called FM bats. Bats use differences between the emitted pulse and the returned echo to locate targets. Relative to the pulse, the returned echo is delayed because of the sound's round-trip travel time from the bat to the target. The delay between the pulse and echo can thus be used as a measure of target range. The echo is changed in frequency, or Doppler-shifted, if the bat is moving relative to the reflecting surface. Bats that are moving toward a reflecting surface will have an echo that is Doppler-shifted toward higher frequency. Most background surfaces will be Doppler shifted about the same. However, targets that are moving differently from the background will generate different Doppler shifts. For instance, a moth with moving wings will reflect an echo with a moving Doppler shift that is quite different from the stationary background. Such differences are presumably used by the CF-FM bat to locate moving targets. Insects are not always passive in the face of such predatory behavior. For instance, some moths have good ultrasonic hearing and take evasive flight maneuvers when exposed to a bat's pulse.

Research on the auditory system of bats has been greatly aided by knowledge of the "relevant" stimulus, since much of the time the bat hears an emitted pulse followed a short time later by an echo. Pioneering work by Nobuo Suga has demonstrated that the auditory cortex of the mustached bat contains many specialized areas (Fig. 25.23C). One large area (DSCF area) is devoted to processing the Doppler-shifted echo for the strongest harmonic of the pulse, near 60 kHz. Within the DSCF area, there is a mapping of neuronal best level for a response as well as the best or characteristic frequency. In other cortical regions, there are neurons whose response properties cause them to detect various features of the pulse and echo. For instance, neurons in the FM-FM region respond preferentially to two FM pulses separated by a specific delay. The best delays for these neurons range from 0.4 to 18 ms, which would correspond to target ranges of 7 to 310 cm. Furthermore, these best delays are mapped along

BOX 25.4 (*cont'd*)

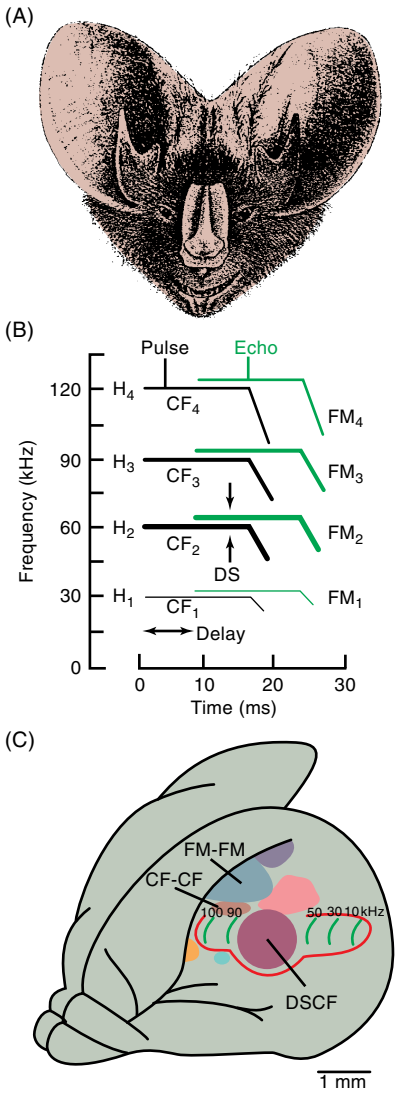

FIGURE 25.23 (A) Close-up view of an echolocating bat, *Megaderma lyra*. Like many echolocating bats, this bat has an enlarged nose leaf that probably focuses the echolocating pulse ahead. Also like many echolocating bats, this bat has enlarged external ears that make the bat more sensitive to echoes coming from ahead. *From Griffin (1958).* (B) Schematic of emitted pulse and returned echo of the mustached bat, *Pteronotus parnellii*. The emitted pulse consists of four harmonics (H_1–H_4), the strongest of which is H_2 at about 60 kHz. Each harmonic has an initial part of constant frequency (CF) and a later part of changing frequency (frequency modulation, FM). The echoes are returned after a travel time that causes a delay relative to the pulse. Additionally, if the target is moving relative to the bat, the echo is returned with a Doppler shift (DS) in frequency. (C) Dorsolateral view of the auditory cortex of the mustached bat showing several of the areas specialized for processing the echolocation signals. The primary auditory cortex, AI, is delineated by a red line and its isofrequency contours are indicated in kHz. It contains a region called the Doppler-shifted CF region (DSCF), which is a greatly expanded region devoted to the most prominent component of the Doppler-shifted echo (60 to 63 kHz). Other shaded regions contain neurons that are combination sensitive and respond to combinations of the pulse and echo, often at certain delays. Neurons that respond to pulse/echo CF portions are in the CF/CF region. Those that respond to pulse/echo FM portions are in the FM/FM region. *From Fitzpatrick et al. (1993).*

cortical distance. Work on the bat cortex has resulted in specific hypotheses about the function of most of their auditory cortical fields. Our state of knowledge of the cortical fields in other animals is by contrast much more primitive.

found in recordings of units from auditory areas in the superior temporal gyrus of human patients undergoing surgery for epilepsy.

Human speech is an especially complex acoustical signal. Language is processed in perisylvian cortex including Wernicke's area, which is close to auditory cortex and can be considered an auditory association area (see Chapter 49). Imaging studies demonstrate the processing of such complex acoustic stimuli in areas near primary auditory cortical fields. Further studies will be very useful in showing more specifically the distinct functions of the auditory fields and how they work together to process sound stimuli.

Summary

Much about the central auditory pathways remains to be explored. Although these pathways are mapped tonotopically, whether there are other mappings in orthogonal dimensions is unknown. Much current research is focused on the plasticity of central auditory responses with auditory experience and after hearing loss and whether this plasticity is generally present at the many subcortical auditory centers. The fact that there are descending systems at many levels of the pathways is known, but research is necessary to show how these systems alter the processing of auditory information.

CHAPTER

26

Vision

OVERVIEW

Vision is the most studied and perhaps the best understood topic in sensory neuroscience. This chapter is concerned primarily with vision in mammals and focuses on the pathway in the visual system that has to do with perception: from the retina to the lateral geniculate nucleus of the thalamus (LGN) and on to the multiple areas of visual cortex. Other regions of the brain that receive visual input (such as the superior colliculus) are dealt with briefly in this chapter and more extensively in the chapter on eye movements (see Chapter 32).

Studying vision provides the opportunity to explore the brain at many different levels, from the physical and biochemical mechanisms of phototransduction to the boundary between psychology and physiology (Chapter 44). At each of these levels, the visual system has evolved to solve a number of difficult problems. In terms of the physical stimulus, vision operates over extremely wide ranges of illumination. The visual system detects single photons in the dark but can also see clearly in bright sunlight, when the retina is bombarded with over 10^{14} photons per second. At a much higher level of complexity, ensembles of neurons in the cerebral cortex are able to solve extremely difficult problems, such as extracting the three-dimensional motion of an object from two-dimensional retinal images.

At every moment, the visual system is confronted with the vast amount of information present in visual scenes. The complex circuitry of the retina has evolved so that much of this information is extensively processed and relayed to the rest of the central nervous system, both efficiently and with great fidelity. Vision, however, has not evolved to treat all of this information equally; instead, it appears to be best suited to extract the sort of information that may be useful to animals, including humans, in a natural environment. Vision allows animals to navigate in the world; to judge the speed and distance of objects; and to identify food, members of other species, and familiar or unfamiliar members of the same species.

In many animals, primates in particular, more of the brain is devoted to vision than to any other sensory function. This is perhaps because of the extreme complexity of the task required of vision: to classify and to interpret the wide range of visual stimuli in the physical world. At the highest levels of processing, the cerebral cortex extracts from the world the diverse qualities experienced as visual perception: from motion, color, texture, and depth to the grouping of objects, defined by the combination of simple features.

The Receptive Field Is the Fundamental Concept in Visual Physiology

The strategies that the brain uses to solve the problems of vision can be understood at a very intuitive level. The most useful concept to aid this intuition is that of the *receptive field*, which is the cornerstone of visual physiology. As defined by H. K. Hartline in 1938 (Ratliff, 1974, p. 167), a visual receptive field is the "region of the retina which must be illuminated in order to obtain a response in any given fiber." In this case, "fiber" refers to the axon of a retinal neuron, but any visual neuron, from a photoreceptor to a visual cortical neuron, has a receptive field. The definition was later extended to include not only the region of the retina that excited a neuron, but also the specific properties of the stimulus that evoked the strongest response. Visual neurons can respond preferentially to the turning on or turning off of a light stimulus—termed *on-and-off* responses—or to more complex features, such as color or the direction of motion. Any of these preferences can be expressed as attributes of the receptive field.

SENSORY SYSTEMS DETECT CONTRAST OR CHANGE

In the 1930s and 1940s, Hartline developed the concept of the receptive field with studies of the axons of individual neurons that project from the lateral eye of the horseshoe crab *(Limulus)* and from the frog's eye (Ratliff, 1974). The lateral eye of the *Limulus* is a compound eye made up of about 300 *ommatidia* arranged in a roughly hexagonal array. Each ommatidium contains optical elements, photoreceptors, and a single neuron whose axon joins the optic nerve. Hartline found that when an isolated ommatidium was illuminated, the firing rate of its axon increased. More surprisingly, the firing of the same axon was decreased by a light stimulus in any adjacent ommatidium. This form of antagonistic behavior, known as *lateral inhibition,* serves to enhance responses to edges while reducing responses to constant surfaces. Without it, visual neurons would be just as sensitive to a featureless stimulus, such as a clean white wall, as to stimuli defined by edges, such as a white square on a black wall. Similar spatially antagonistic visual responses were found in mammals, as first demonstrated by Kuffler (1953) in the retina of the cat (Box 26.1; Fig. 26.3).

Lateral inhibition represents the classic example of a general principle: most neurons in sensory systems are best adapted for detecting changes in the external environment. This principle can be explained in behavioral terms. As a rule, it is change that has the greatest significance for an animal—for example, the edge of an extended object or a static object beginning to move. This principle can also be explained in terms of information processing. Given a world that is filled with constants—with uniform objects, with objects that move only rarely—it is most efficient to respond only to changes.

Several types of visual responses can be discussed in terms of the detection of change, or of *contrast:* defined as the fractional difference in luminance between two

BOX 26.1

KUFFLER'S STUDY OF CENTER-SURROUND RETINAL GANGLION CELLS

The classic experiments that Kuffler (1953) performed on retinal ganglion cells have formed the foundations for much of the subsequent physiological analysis of the mammalian visual system. Even beyond the study of vision, they represent a model for understanding the neurobiology of sensory systems. These experiments were performed *in vivo* in anesthetized cats. The first step in this sort of experiment is the careful placement of a fine microelectrode close to a single neuron so that action potentials can be recorded extracellularly. An oscilloscope trace of the firing pattern of this neuron is important, but the sound of action potentials on an audio monitor is even more critical. This immediate feedback allows the researcher to search for visual stimuli that excite or inhibit the neuron. Kuffler's first finding was that there were two categories of ganglion cells, as Hartline had seen in the retina of the frog. The cells were either *on,* i.e., excited by light increment, or *off*—that is, excited by light decrement.

One of Kuffler's most important contributions was the careful mapping of lateral interactions in the retina, or what he termed the *center-surround* structure of the receptive field. When an *on* ganglion cell was being studied, a small light spot placed in the center of its receptive field would cause an immediate increase in firing rate of the cell (Fig. 26.3B, top). The center of the receptive field of an *on* ganglion cell was defined as all positions where the small spot evoked an *on* excitatory response. When the same spot was placed just beyond the center, in the region termed the *surround*, the neuron decreased its firing rate (Fig. 26.3B, bottom). Kuffler mapped the spatial extent of the regions that evoked excitation or inhibition simply by listening to the responses to spots flashed at many different locations. Alternatively, Kuffler studied receptive fields by searching for an optimal stimulus—one that increased the firing of a ganglion cell most effectively. The strongest stimulus for an *on* center cell was a spot of light that filled the receptive field center entirely (Fig. 26.3C). Similarly, the most effective inhibitory stimulus was a bright annulus shown to the surround alone. Following such strong inhibition, the cell had an excitatory response when the stimulus was turned off (Fig. 26.3D). Finally, Kuffler studied interactions between receptive field subregions. A large bright stimulus that covered both center and surround was found to evoke a much weaker response than a smaller spot confined to the center; the surround inhibition weakened or altogether eliminated the central excitation (Fig. 26.3E).

Kuffler's early experiments, along with those of Hartline, established the technical and conceptual foundations for the field of visual physiology. Almost all subsequent work in this field can be seen as falling into the three broad categories of experiments, exemplified by Kuffler's 1953 study: (1) the mapping of responses with isolated, suboptimal stimuli, (2) the search for an optimal stimulus, and (3) the study of interactions between responses evoked by two or more stimuli.

R. Clay Reid

stimuli. There are several forms of contrast. The first is spatial contrast, the detection of which is enhanced by neurons in the retina that have lateral inhibition (center-surround organization, see Box 26.1). Next, there is temporal contrast, or change over time. Starting in the retina, visual neurons are affected very little by slow changes in illumination but are extremely sensitive to more rapid changes. Finally, there is motion, which is distinguished by characteristic changes in a stimulus over both space and time. Many neurons in the visual system are excited selectively by objects that have a certain rate or direction of motion. In summary, contrast sensitivity can take on at least three forms: sensitivity to spatial variations in a stimulus (spatial contrast), sensitivity to changes over time (temporal contrast), and sensitivity to changes in both space and time (motion).

Receptive Fields Encode Increasingly High-Order Features of the Visual World

From the photoreceptors to the multiple visual cortical areas, the visual system is hierarchical. One level provides input to the next in a feedforward progression, although lateral interactions and feedback are almost always present as well. As a general rule, receptive fields at successive stages of processing (from photoreceptors, bipolar cells, ganglion cells, and geniculate neurons, through neurons in multiple visual cortical areas) encode increasingly high-level features of the visual stimulus. The outer segment of a photoreceptor, which contains the visual pigment, is influenced only by a small point in visual space. It is therefore almost entirely insensitive to the spatial structure of a stimulus. At the opposite extreme, neurons in the inferior parietal region of visual cortex seem to respond best when the animal is viewing a specific face (see Chapter 50).

These two extremes of visual responses illustrate the visual system's dual task: to maintain generality—the ability to respond to any stimulus—while also being able to represent specific, environmentally important classes of stimuli. High-level neurons classify visual stimuli by integrating information that is present in the earlier stages of processing, but also by ignoring information that is independent of that classification. For instance, motion-sensitive neurons in area MT of the cerebral cortex (see later) are exquisitely sensitive to the direction and rate of motion of an object, but very poor at distinguishing the object's color or its position. This lack of localization is quite common in high-level neurons: receptive fields become larger as the features they represent become increasingly complex. Thus, for instance, neurons that respond to faces typically have receptive fields that cover most of visual space. For these cells, large receptive fields have a distinct advantage: the preferred stimulus can be identified no matter where it is located on the retina.

Summary

The mammalian visual system is a complex, hierarchical system that can be studied from a number of different viewpoints. This chapter concentrates on the physiology of visual neurons, which is based on the study of receptive fields. Originally, receptive fields were defined as the area of the retina that could evoke responses in a visual neuron. The concept has evolved to include the stimulus attributes that lead to a neural response, such as color, motion, or even the complex features of a specific physical object. Within the hierarchy of the visual system—from retina to the multiple areas of the visual cortex—neurons are selective for increasingly complex or high-order features.

THE EYE AND THE RETINA

The Optics of the Eye Project an Inverted Visual Image on the Retina

The study of vision begins with the eye (Fig. 26.1), whose refractive properties are determined by the curvature of the cornea and the lens behind it. These optical elements act to focus an inverted image on the retina, where the first stages of neural visual processing take place. The curvature of the cornea is fixed, but the curvature of the lens is adjusted by smooth muscles that flatten

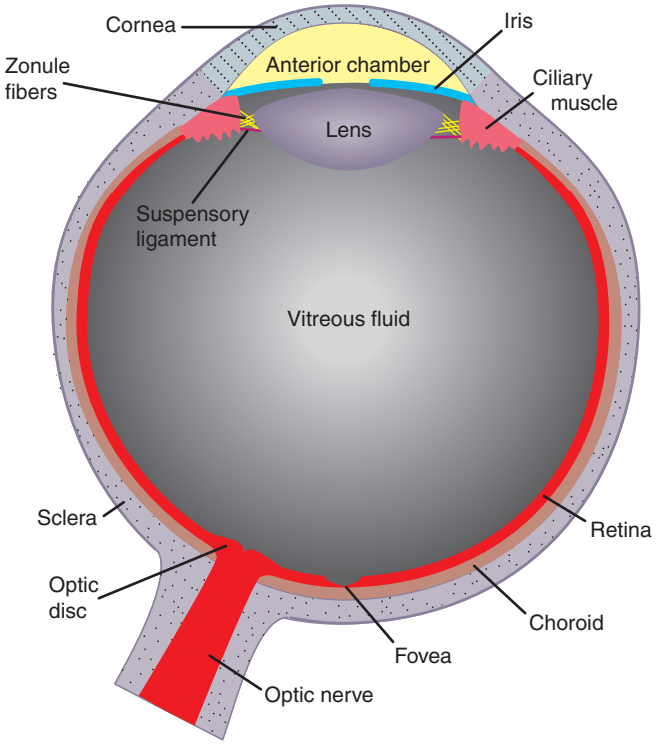

FIGURE 26.1 Schematic diagram of the human eye.

the lens when they relax, thus bringing more distant objects into focus. The amount of light that reaches the retina is controlled by the iris, whose aperture is the pupil. The iris, which is situated between the cornea and the lens in the *anterior chamber* of the eye, contracts at high light levels, and expands in the dark.

The Retina Is a Three-Layered Structure with Five Types of Neurons

The anatomy of the retina has an almost crystalline beauty, a beauty that is enhanced by the clear relationships between form and function (Dowling, 1997). It is composed of five principal layers: three layers of cell bodies separated by two layers of neural processes, dendrites and axons (Fig. 26.2). The vertebrate retina is oriented within the eye so that light must travel through the entire thickness of the neuropil to reach the photoreceptors.

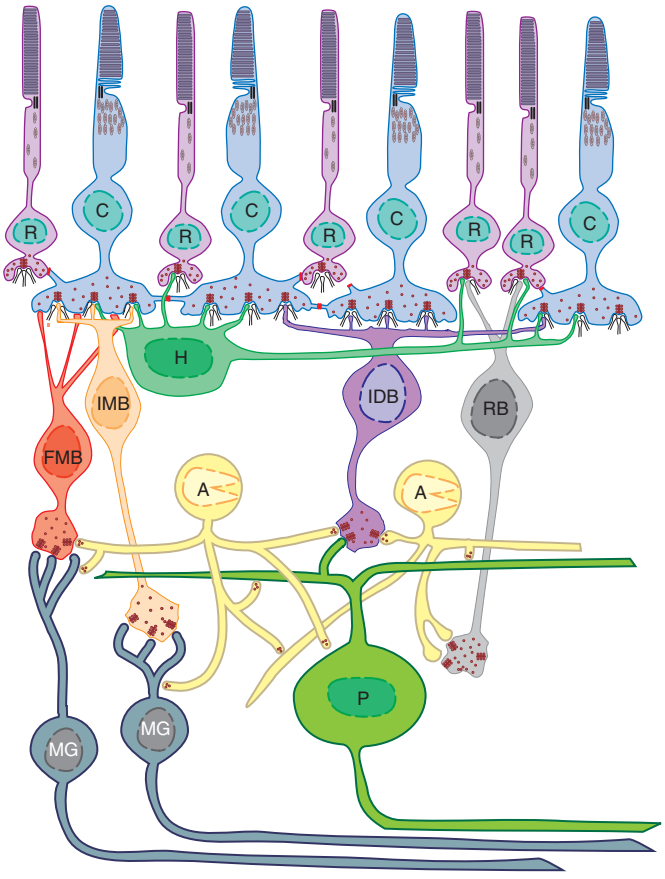

FIGURE 26.2 Summary diagram of the cell types and connections in the primate retina. R, rod; C, cone; H, horizontal cell; FMB, flat midget bipolar; IMB, invaginating midget bipolar; IDB, invaginating diffuse bipolar; RB, rod bipolar; A, amacrine cell; P, parasol cell (also confusingly called an M cell because of its thalamic targets, see text for details); MG, midget ganglion cell (also confusingly called a P cell). *Adapted from Dowling (1997).*

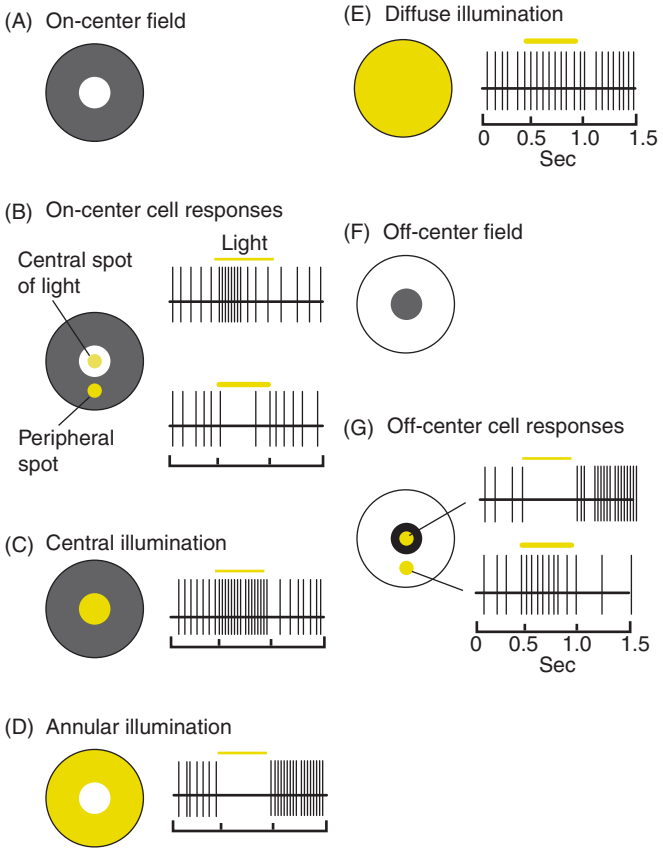

FIGURE 26.3 Visual responses of *on*-center (white) and *off*-center (dark gray) retinal ganglion cells. Visual stimuli are indicated in yellow, and the responses to these stimuli are shown to the right. See text for details.

Of the three cell layers, the first is farthest from the center of the eye and is thus called the *outer nuclear layer*. It contains the cell bodies of the photoreceptors, the rods, and the cones. The next cell layer is the *inner nuclear layer*, which contains the cell bodies of the interneurons of the retina, both excitatory and inhibitory. These include horizontal cells, bipolar cells, and amacrine cells. Finally, the *ganglion cell layer* is home to the retinal neurons whose axons form the optic nerve, the sole pathway from the retina to the rest of the central nervous system. Interposed between the cell body layers are two layers of cell processes: *inner* and *outer plexiform layers*. The two plexiform layers are the sites of all interactions between the neurons of the retina.

The retina is one of the few circuits in the nervous system simple enough that cell types and connections can be learned without great effort. This is made even easier, since the role of each of the five cell types can be placed within a simple functional scheme. The two main attributes of the output of the retina—the point-to-point representation of the visual image and the spatially antagonistic center-surround interactions in the receptive field

(see Box 26.1)—can be understood in terms of the anatomy. The direct pathway, photoreceptor → bipolar cell → ganglion cell, is the substrate for the center of the receptive field of the ganglion cell and thus for its spatial resolution. Lateral interactions in the retina, most notably the center-surround antagonism, or lateral inhibition, are mediated by horizontal cells and amacrine cells.

Photoreceptors Are Hyperpolarized by Light

The two major types of photoreceptors in the vertebrate eye are the rods and cones (Fig. 26.2). Both types of photoreceptor have an outer segment that contains the molecular machinery for phototransduction, an inner segment that contains densely packed mitochondria, a cell body that contains the nucleus and other important organelles, and a terminal process that releases neurotransmitter. Although rods and cones were once viewed as the only cells in the vertebrate eye to transduce light energy into an electrical response, recent work shows that phototransduction also takes place in melanopsin-containing ganglion cells that likely convey nonspatial information about light levels to regions of the brain involved with circadian rhythms (Berson, 2003).

Rods and cones work together to allow the visual system to operate over a wide range of luminance conditions. Under scotopic conditions when luminance levels are very low (e.g., starlight), only the rods are active. As luminance levels increase to mesopic conditions (e.g., moonlight), both the rods and cones contribute to vision. As luminance levels increase further yet, to photopic conditions (e.g., sunlight), rod responses saturate and only the cones contribute to vision. Because the center of our retina (the fovea) contains very few if any rods, we have a foveal blind spot under very dim conditions. Consequently, a dim star will disappear when we move our eyes to look at it directly.

Phototransduction occurs when photons of light are absorbed by photopigments located in the outer segments of photoreceptors. Photopigments have an organic, light absorbing component (11-*cis* retinal) and a protein component (opsin). The opsin determines the wavelength specificity of the photopigment and has the ability to interact with G proteins. Rods contain a single photopigment, rhodopsin, while cones contain one of three cone opsins (the relationship between these opsins and color vision is discussed below). Once a photon is absorbed, a cascade of events occurs that ultimately affects the membrane potential of the photoreceptor. This cascade begins with the activation of the G protein (transducin) that then activates a phosphodiesterase that hydrolyzes cGMP and reduces the intracellular concentration of cGMP. Because the outer membrane of a photoreceptor contains many cGMP-gated cation channels, a decrease in the intracellular concentration of cGMP will cause the photoreceptor to hyperpolarize. In this way, light increments lead to hyperpolarization and a reduction in neurotransmitter release, while light decrements lead to depolarization and an increase in transmitter release. Importantly, photoreceptors do not produce action potentials, but rather have graded potentials that are modulated around a mean level.

Bipolar Cells Can Be Hyperpolarized or Depolarized by Light

Similar to photoreceptors, bipolar cells generate graded potentials rather than action potentials. Bipolar cells are divided into two broad classes, termed *on* and *off* bipolars, that respond to light stimuli with depolarization and hyperpolarization, respectively. *On* bipolars are also known as *invaginating bipolars*, and *off* bipolars are known as *flat bipolars* because of the shape of the synaptic contacts they receive from photoreceptors (Fig. 26.2). Because all photoreceptors use glutamate as their neurotransmitter, these opposite responses require that *on* and *off* bipolar cells respond to the same neurotransmitter in opposite ways (Wu, 1994). Glutamate, typically an excitatory transmitter, is inhibitory for *on* bipolars. It acts by closing a cGMP-gated sodium channel, similar to that seen in photoreceptors. The depolarization of *on* bipolars by light results not from excitation, but from the removal of inhibition, which occurs when photoreceptors are hyperpolarized by light. *Off* bipolars are excited by glutamate via more typical kainate receptors (named for the pharmacological agent that selectively activates them; see Chapter 9). When these cells are inhibited by light, the inhibition is in fact due to the removal of tonic excitation, which again occurs when the photoreceptors are hyperpolarized.

The functional importance of the *on* and the *off* pathways can best be understood in terms of contrast. From the bipolar cells onward—that is, once *on* and *off* pathways have been established—visual neurons respond best to spatial and temporal contrast rather than to absolute light levels. Objects in the world are visible by the light they reflect; their borders are discerned usually because of different degrees of reflectance, which leads to contrast (changes in illumination, except for shadows, tend to be much more gradual). Because the visual system is adapted for seeing objects that can be either brighter or darker than their backgrounds, it is not too surprising that it is equally sensitive to positive and negative contrast steps.

Most ganglion cells, the output cells of the retina, receive their main excitatory input from bipolar cells. Thus, these ganglion cells also have either *on* or *off* responses in the center of their receptive fields, according to which class of bipolar cells provide their input (see Box 26.1). Other ganglion cells, known as *on-off* cells, respond to both light onset and to light offset. These latter cells receive input from both classes of bipolar cells. Many of these cells respond preferentially to stimuli moving in a particular direction of motion.

Horizontal and Amacrine Cells Mediate Lateral Interactions in the Retina

There is a complex three-way synaptic relationship among the terminals of the photoreceptors, the processes of horizontal cells, and the dendrites of bipolar cells (Fig. 26.2). Horizontal cells are inhibitory (GABAergic), and, as the name implies, they contact photoreceptors over a much larger horizontal extent of retina than bipolar cells. Thus, because they are the only neurons that sample over a sufficiently large area in the outer plexiform layer, horizontal cells are thought to be responsible for the antagonistic surround seen in the receptive fields of bipolar cells.

The second family of lateral interneurons in the retina, the amacrine cells (literally, cells with no axons), is a diverse class of cells that exhibits a wide range of morphologies. As is true of horizontal cells, all processing takes place on the dendrites of amacrine cells (in the inner plexiform layer), which contain both pre- and postsynaptic elements (Fig. 26.2). Most amacrine cells use GABA, glycine, or both acetylcholine and GABA as neurotransmitters, but it is thought that virtually every transmitter found in the brain is used by some amacrine cell. The functions of most of these diverse subclasses remain poorly understood. In addition to a possible role in the creation of the antagonistic surround, it has been proposed that some amacrine cells are responsible for the nonlinear responses in Y cells of the cat (see Box 26.2; Fig. 26.3) or for the direction selectivity of certain classes of ganglion cells identified in the rabbit and rodent retina.

BOX 26.2

QUANTITATIVE METHODS IN THE STUDY OF VISUAL NEURONS CLASSIFICATION OF RETINAL GANGLION CELLS

Although neuroscientists have learned a tremendous amount about the visual system using the tools developed by Kuffler, researchers have been following a parallel line of studies of the visual system by asking different sorts of questions with the aid of more quantitative methods. In Kuffler's experiments and, most notably, many of Hubel and Wiesel's (see later), easily produced stimuli (such as spots, edges, and bars) were used to stimulate visual neurons. Action potentials were detected primarily with an oscilloscope and audio monitor. In the more quantitative studies of visual physiology, stimuli are shown primarily on video monitors and data are recorded with computers. The quantitative study of visual physiology constitutes a large field, which stems from the work of Hartline, Ratliff, Campbell, Barlow, and others (see Ratliff, 1974). Analysis of the receptive fields of retinal ganglion cells in the cat performed by Enroth-Cugell and Robson (1966) represents an early and influential example of this line of research.

Stimuli used by Enroth-Cugell and Robson, and in many studies that followed theirs, consisted of *gratings*: light and dark bands whose luminance varied in a sinusoidal fashion across a screen. Gratings were not designed to be the most effective stimuli for visual neurons. The broad goal of this sort of experiment is to study not just what makes neurons respond best, but to study how they would respond to *any* stimulus and to probe what mechanisms they use to produce these responses. The analytical framework that goes along with these experiments is called *systems theory*, the study of input-output (or stimulus-response) systems. *Linear systems*, those that simply add up all of their inputs to produce an output, constitute an important part of this theory.

Enroth-Cugell and Robson used a simple test of linearity in their study of retinal ganglion cells in the cat. A grating was presented at different positions (called phases), and the responses to its introduction and removal were recorded. Two questions were addressed for each cell studied: (1) If a certain phase (whose bars were arranged white, black, and white; as in Fig. 26.4, 0°) excited the cell, did the opposite grating (black, white, and black; Fig. 26.4, 180°) inhibit it? (2) More importantly, were there null positions for the grating that evoked no response, as excitation and inhibition were perfectly balanced (Fig. 26.4, 90 and 270°)?

One class of ganglion cells, called X *cells*, passed these tests for linear spatial summation (Fig. 26.4, left). A second class of cells, *Y cells*, behaved differently. Like X cells, these cells also had a center-surround receptive field when mapped with spots and annuli. When studied with two opposite gratings, however, the responses evoked were not equal and opposite. Instead, the introduction and removal of the gratings at all positions resulted in two peaks of excitation, and no null position could be found (Fig. 26.4, right).

The use of systems theory and quantitative techniques in the study of the visual system has had a number of notable successes. It has helped in the classification of different families of visual neurons, such as X and Y cells. Further, it has been used to elucidate some of the mechanisms responsible for the responses of visual neurons (such as directionally selective cells). Perhaps most importantly, along with a large body of psychophysical experiments that employ the same stimuli, it has helped create a common framework in which the responses of neurons can be related to perception.

R. Clay Reid

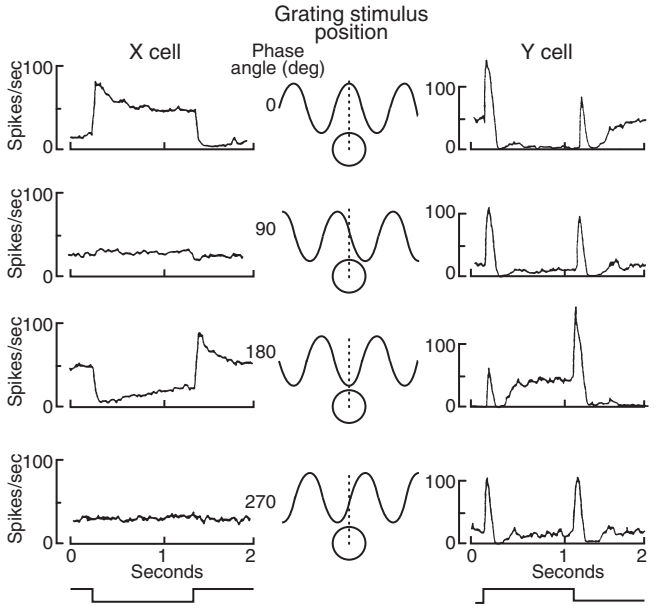

FIGURE 26.4 Visual responses of X and Y cells to contrast-reversing sine-wave gratings at different spatial phases (different positions, indicated schematically in the middle column). Visual responses, in spikes per second, are shown as poststimulus time histograms synchronized to the repetitive stimulus. Upward deflection of the lowest trace indicates introduction of the grating pattern (contrast on), and downward deflection indicates removal of the pattern (contrast off, but no change in mean luminance). *Adapted from Enroth-Cugell and Robson (1966).*

Retinal Ganglion Cells Provide the Output of the Retina

Visual information leaves the eye via the optic nerve, which is composed of the axons of all of the different classes of ganglion cells. The optic nerve begins at the *optic disc* (Fig. 26.1). Because there are no photoreceptors at the optic disc, this circular region constitutes a blind spot in the retina. The routing of ganglion cell axons to different parts of the brain provides a number of interesting problems for developmental neurobiology (Chapters 15, 16, and 21). The routing of axons is both macroscopic—different types of ganglion cells project to different regions of the brain—and microscopic: within any given target region, axons are sorted out in a precise manner. In each of two principal targets of retinal axons, the superior colliculus and lateral geniculate nucleus of the thalamus (LGN), a topographical map of visual space is created in which spatial relations are maintained between neighboring neurons.

This chapter is concerned primarily with the classes of retinal ganglion cells that project to LGN neurons, which in turn project to the primary visual (striate) cortex. Although cells in the LGN are more than mere relays of information from the retina, their receptive fields are quite similar to those of their ganglion cell inputs. The following discussion of retinal receptive fields, therefore, can serve equally well to describe receptive fields in the LGN.

Parallel Pathways Are Composed of Distinct Classes of Retinal Ganglion Cells in the Cat

Kuffler found that retinal ganglion cells in the cat have a stereotyped center-surround organization. Similar cells (both *on* and *off*) were found at every position across the entire retina. Researchers later discovered, however, that there are in fact several different functional classes of ganglion cells, each with distinct response properties. Although different cell classes have been found in different species, in none is the retina composed of a single mosaic of identical cells. The fact that there are multiple types of output from the retina has had a profound effect on the study of visual processing in the brain. The degree to which these *parallel pathways* (Livingstone & Hubel, 1984; Merigan & Maunsell, 1994; Sincich & Horton, 2005) are combined or kept separate has been a major theme in the study of central visual pathways, particularly the visual cortex.

The idea that there are parallel sensory pathways into the brain is not new. At the beginning of the nineteenth century, both Bell and Müller argued for what Müller termed the "specific energy of nerves." This term is a precursor of the idea that axon sensory neurons are "labeled lines," each of which conveys distinct signals to the brain. A surprisingly modern version of this idea was given in 1860 by Helmholtz in the *Handbook of Physiological Optics* (2000), in which he expressed Thomas Young's theory of color vision (1807) in the following manner: "The eye is provided with three distinct sets of nervous fibers. Stimulation of the first excites the sensation of red, stimulation of the second the sensation of green, and stimulation of the third the sensation of violet."

In one of the earlier studies using a quantitative approach to receptive field mapping (see Box 26.2), Enroth-Cugell and Robson (1966) found that cat retinal ganglion cells could be classified into two categories: X and Y (more categories have been found subsequently). This classification was based on a simple criterion: did ganglion cells simply add together all of their excitatory and inhibitory inputs (linear summation), or were the interactions between inputs more complicated (nonlinear summation)? The linear/nonlinear distinction between X and Y cells (see Box 26.2; Fig. 26.4) may seem fairly abstract, but these cells turned out to be different in a number of other ways. Most notably, Y cell receptive fields are, on average, three times larger than those of neighboring X cells. X cells are therefore far more numerous, because many more X cell receptive fields are needed to effectively tile, or cover, the retina. One view is that the large, nonlinear receptive fields of Y cells make them well suited to

detect change, at the cost of their ability to signal the exact location or nature of the stimulus; similarly, X cells are better at localizing more specific stimulus features, but less sensitive in detecting change.

Primate Ganglion Cells Project to Three Subdivisions of the Lateral Geniculate Nucleus: Parvocellular, Magnocellular, and Koniocellular

Primates have a number of different classes of retinal ganglion cells, each with distinct cellular morphology, projection patterns, and visual response properties. This discussion focuses on ganglion cells that project to the lateral geniculate nucleus (LGN). There are many differences among primate species (nocturnal versus diurnal, Old World versus New World); this section concentrates on the macaque—a diurnal, Old World primate. The macaque visual system has been studied extensively with anatomical, physiological, and behavioral methods. Most importantly, macaque vision is very similar to human vision.

The most numerous class of ganglion cells in the macaque retina are sometimes referred to as P *cells*, so called because they project to the dorsal-most layers of the LGN, the *parvocellular layers* (small cells; Fig. 26.7). M cells, which project to the two ventral layers of the LGN, the *magnocellular layers* (large cells), constitute a second class of retinal neurons. P and M cells have distinct morphologies (Fig. 26.2). P cells (also known as *beta* cells or, in the central retina, midget ganglion cells) have very small dendritic fields. M cells (also known as *alpha* cells or parasol cells) have much larger dendritic fields. Finally, members of a third class of retinal cells project to the *intercalated layers*, located between the parvocellular and magnocellular layers. These intercalated layers are also termed *koniocellular* (dust-like, or tiny cells). There are roughly 1,000,000 P cells in the retina and parvocellular neurons in the LGN; there are 100,000 M and magnocellular neurons. Although the intercalated layers appear quite sparse and thin in standard histological sections (Fig. 26.7), there are as many intercalated cells as there are magnocellular cells. Due to their size and location, intercalated cells have been difficult to study and little is known about them in the macaque. Therefore the following section discusses only the functional properties of P and M pathways.

P and M Pathways Have Different Response Properties

As noted earlier, the receptive field properties of the LGN relay cells match closely those of their retinal afferents, but the two parallel pathways, P → parvocellular and M → magnocellular, are quite different. Five main characteristics distinguish the responses of P cells and M cells. (1) P cell receptive fields are smaller than M cell receptive fields at the same retinal position. (2) M cell axons conduct impulses faster than P cell axons. (3) The responses of P cells to a prolonged visual stimulus, particularly a color stimulus, can be very sustained, whereas M cells tend to respond more transiently. (4) Most P cells

BOX 26.3

INHERITED AND ACQUIRED DEFECTS OF COLOR VISION: RETINAL AND CORTICAL MECHANISMS

Inherited defects of color vision have been studied for over 200 years, originally with psychophysical methods but more recently with the tools of molecular genetics. Normal color vision is *trichromatic* (literally, three colored) because there are three different classes of cone photoreceptors. In the most common form of color vision defect, there are three pigments, but one of them is abnormal, or anomalous. More severe defects are found in *dichromats*, who lack a single cone type entirely. The current terminology for the three types of dichromacy was proposed by von Kries in 1897: *protanopia* (literally, the first type of blindness, or "red-blindness"), *deuteranopia* (second type, or "green-blindness"), and *tritanopia* (third type, or "blue-blindness"). While dichromats are unable to make certain color distinctions, only the very rare *monochromats*—people with one cone type or only rods—are truly color blind.

The genetics of red-green defects have long been known to be X linked: they are inherited from the mother and are fairly common in men, but they are uncommon in women.

Because of the overlap in cone pigments, inherited color vision defects are not as simple as terms such as "red blindness" might suggest. In broad terms, protanopes and deuteranopes are unable to make specific discriminations along the red-green axis. Depending on the defect, they are unable to distinguish certain reds and greens from gray or from each other. Tritanopes are unable to discriminate between colors with and without a short wavelength component, such as between gray and certain shades of violet or yellow.

BOX 26.4

VISION IN MICE

The choice of species is always of great importance in attacking any biological problem. This chapter has concentrated on the macaque monkey because its visual system is very similar to that of humans. But vision has been an important topic in neuroscience for the past 50 years, not merely because we wish to understand how humans see but because it is also a tractable system for addressing many fundamental topics, from development through neural coding. Although traditionally neglected in visual neuroscience, the mouse is quickly becoming one of the most studied species (Chalupa & Williams, 2008), as it is in much of neuroscience.

The rodent visual system has many homologies with the primate visual system (and most other mammals), but there are several clear differences. Most obviously, while mice are certainly not proverbially blind, they have far lower acuity than primates. Humans can discern features as small as 1 minute of arc, but mice are barely able to make discriminations at the scale of 1 degree, 60 times larger. The past decade has told us that there is a great richness of visual processing in the mouse retina, thalamus, and visual cortex, and we can learn a great deal from studying mouse vision. For instance, although we have long known that the visual world is analyzed in parallel by numerous different classes of ganglion cells, it is likely that we will soon have a definitive list of ganglion cells in the mouse. With mouse lines that target single classes of cells, there has been a spate of recent discoveries about ganglion cells, such as a previously neglected class, identified with a transgenic marking method, that respond preferentially to upward motion (Kim et al., 2008). The visual cortex of rodents has many similarities with other species—with orientation-selective neurons, such as simple cells. However, it also has one fundamental difference with most other species in that it has no map for stimulus orientation, a characteristic found also in rats and other rodents (Ohki et al., 2005; Fig. 26.14A). There are also at least nine higher-order visual areas, which have the added benefit that they are all on the cortical surface (Wang & Burkhalter, 2007; Fig. 26.14B), so they can all be imaged with optical techniques. Although there will be no exact homologies between these areas and the extrastriate regions found in primates, they offer a rich opportunity to study classical problems, such as cortical arealization and hierarchical processing, with all of the modern tools of molecular genetics and *in vivo* imaging.

R. Clay Reid

are sensitive to the color of a stimulus; M cells are not. (5) M cells are much more sensitive than P cells to low-contrast, black-and-white stimuli. These last two differences, which have strong implications for the functional role of these pathways, are discussed next.

Color-Selective Responses in the P Pathway Are Derived from Antagonistic Inputs from L and M Cones

Color vision depends on the distinct sensitivities of the three classes of cone photoreceptors to different wavelengths of light (see Box 26.3; the rods are active only under low light levels and are not involved in color vision). Although fine distinctions can be made between different wavelengths, it is important to emphasize that each of the light-sensitive pigments in the three cone classes is sensitive to a broad range of wavelengths. The spectral sensitivities of these pigments overlap considerably. Consequently, the names sometimes used for these pigments—red, green, and blue sensitive—are inaccurate. For instance, the "red" pigment is most sensitive to light whose wavelength is 564 nm, or yellow, although it is more sensitive than the other pigments to red light. A more accurate terminology, one that identifies the relative sensitivities of the three cone absorption spectra, is usually employed: long, middle, and short wavelength sensitive (or L, M, and S).

Because green light will excite both long and middle wavelength cones, the color green can be distinguished only by the fact that it excites middle wavelength cones more strongly than it excites long wavelength cones. This distinction can be made by neurons that are sensitive to the difference between the signals from two cone classes, or neurons that are *color opponent*. In the retina and LGN, there are two categories of color-opponent cells: red-green and blue-yellow (yellow is made of the sum of long and middle wavelength cone signals; Dacey, 2000). The most numerous color-opponent neurons in the primate retina are red-green opponent P cells. These cells receive antagonistic input from long and middle wavelength-sensitive (L and M) cones.

Near the fovea, the center of the retina, a P cell receives input from only one bipolar cell. This *midget bipolar* in turn receives input from a single cone (Fig. 26.2). This arrangement ensures not only that the center of the ganglion cell's receptive field is as small as possible, but also that the center receives input from only one cone type: L or M. Classically, the antagonistic surround of these P cells (or their counterparts in the LGN) has been thought to be dominated by the other main cone class, M or L, respectively (Wiesel &

Hubel, 1966), although the nature of the surround in red-green P cells has been somewhat controversial (Dacey, 2000).

M Cells Are Highly Sensitive to Contrast

Because of their marked color sensitivity and small receptive fields, P cells have long been thought to be involved with the ability to make color discriminations and to see the finest details. When tested with black-and-white stimuli, however, P cells responded to low contrast very poorly compared to M cells. In a study that used the quantitative methodology similar to Enroth-Cugell and Robson's (see Box 26.2), Kaplan and Shapley (1986) measured the responses of P and M cells to sine-wave gratings of various contrasts (Fig. 26.5). Perceptually, stimuli can be detected that have less than 1% contrast (i.e., 1% luminance deviation from the mean). Kaplan and Shapley (1986) found that M cells often responded well to contrasts of less than 5% and that they gave their strongest responses at contrasts as low as 20%. P cells tended to respond poorly to contrasts below 10%, a stimulus that is quite salient, and rarely reached their strongest responses below 64%. From this, Kaplan and Shapley concluded that the ability to see low contrasts is due primarily to the M cell system.

The relatively poor sensitivity of P cells to low-contrast stimuli is not well understood, but it may be partially the result of two factors: receptive-field centers receive input from a very small region of the retina, and the inputs from different cone classes are subtracted from each other rather than added together. Whatever the reason, the poor performance of the P pathway in detecting low contrast implies an important role for M cells in the detection of the form of objects (which is robust at low contrasts), in addition to their role in the motion pathway (discussed later).

Summary

The retina, part of the central nervous system, is a self-contained neuronal circuit whose anatomy and physiology have been studied in great detail. There are five types of cells in the retina. Photoreceptors, bipolar cells, and ganglion cells constitute the direct, feed-forward pathway. Horizontal cells and amacrine cells subserve lateral interactions within the retina. Photoreceptors are all hyperpolarized by light, but bipolar cells can be either hyperpolarized (*off* cells) or depolarized by light (*on* cells). There is a great variety of retinal ganglion cells, but most have an antagonistic center-surround organization. In the primate, the two best studied classes of ganglion cells are P cells and M cells, which project to the parvocellular and magnocellular layers of the LGN, respectively. P cells have small receptive fields, are sensitive to the color of a stimulus, and are relatively insensitive to low contrasts. M cells have larger receptive fields, are insensitive to color, and are very sensitive to low contrasts.

THE RETINOGENICULOCORTICAL PATHWAY

Visual Information Is Relayed to the Cortex via the Lateral Geniculate Nucleus

In mammals with forward-facing eyes, such as most carnivores and the primates, retinal axons are routed so that visual information from the same points in space coming from the two eyes can be combined. From both eyes, ganglion cells whose receptive fields are in one half of the visual field project to the opposite cerebral

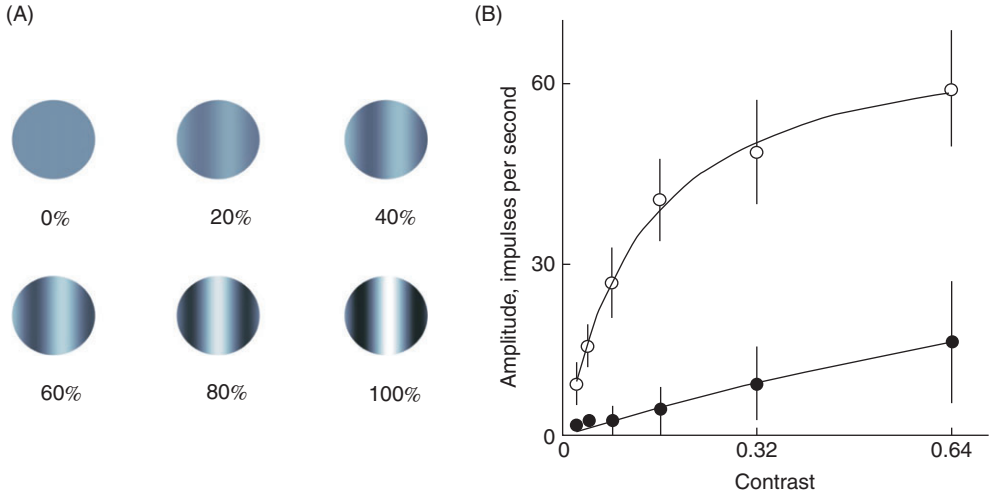

FIGURE 26.5 Relationship between stimulus contrast and the visual responses of magnocellular and parvocellular neurons in the macaque. (A) Examples of sinusoidal gratings with different levels of luminance contrast. (B) Average contrast response functions of P (•) and M (○) cells measured in spikes per second. P cells respond poorly to low contrasts and do not saturate at high contrasts. M cells respond better to low contrasts, but saturate by 20 to 30%. B: *From Kaplan and Shapley (1986).*

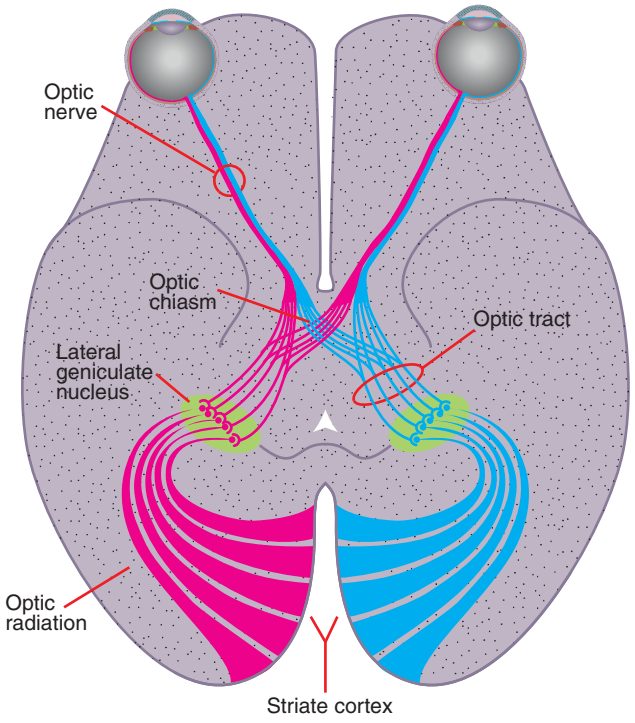

FIGURE 26.6 The retino-geniculo-cortical pathway in the human. Optic nerve axons from the nasal retina cross at the optic chiasm and join axons from the temporal retina of the other eye. Together, these contralateral and ipsilateral axons make up the optic tract, which projects to the LGN. Each of the six layers of the LGN receives input from only one eye. Axons from the LGN make up the optic radiations, which project to the striate cortex. *Adapted from Polyak (1941).*

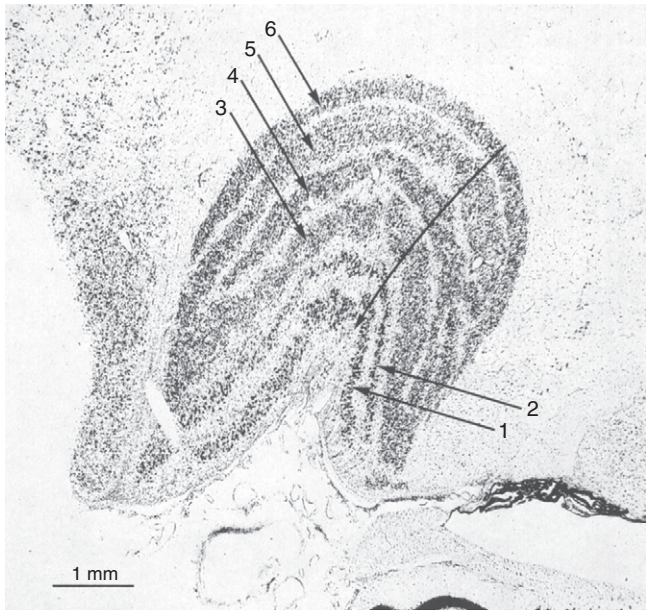

FIGURE 26.7 The six-layered LGN of the macaque monkey. The top four parvocellular layers (6, 5, 4, and 3) receive input from the ispilateral and contralateral eye in the order of contra, ipsi, contra, and ipsi. The bottom two magnocellular layers (2 and 1) receive ipsi and contra input, respectively. In between these principal layers are intercalated or koniocellular layers. The arrow from layer 6 to 1 indicates organization of the precisely aligned retino-topic maps of the six layers. The receptive fields of neurons found along this line are located at the same position in visual space. *From Hubel and Wiesel (1977).*

hemisphere (Fig. 26.6). This cross-routing occurs at the optic chiasm (from the Greek letter *chi*, χ). Here, axons from the medial (nasal, or nearer the nose) half of one retina cross over to join the axons from the lateral (temporal, or nearer the temples) half of the other retina. In other words, the temporal retina projects to the *ipsilateral* (same-side) hemisphere and the nasal retina projects to the *contralateral* (opposite-side) hemisphere. Unlike somatic sensation, which is entirely crossed (see Chapter 24), only half of the retinal axons cross. Like somatic sensation, however, the crossing of retinal axons results in each half of the external visual field being represented in the opposite cerebral hemisphere.

The LGN Is a Layered Structure That Receives Segregated Input from the Two Eyes

As they leave the optic chiasm, retinal axons from the two eyes travel together in the optic tract, which terminates in the LGN (Fig. 26.6). The LGN is composed of layers, each of which receives input from only one eye, although the number varies between species. In the macaque, the six principal layers contain most of the relay cells to primary visual cortex (Fig. 26.7). The four parvocellular layers are found dorsally. They receive P cell input from the contra-lateral and ipsilateral eye in the order of contra, ipsi, contra, and ipsi. The magnocellular layers are found more ventrally. They receive M cell input in the order of ipsi and contra. Interposed between these principal layers are the intercalated layers, populated by koniocellular neurons.

In the cat, the LGN has only two principal layers, called A and A1, which receive input from the contralateral and ipsilateral retinas, respectively. The neurons are again quite similar to either the retinal X cells or the Y cells that innervate them.

The Primary Visual Cortex in the Cat Is an Example of a Functional Hierarchy

Cat primary visual cortex (area 17) is perhaps the best understood neocortical area in any species. The first studies of Hubel and Wiesel (1962) form the foundation of this understanding. Hubel and Wiesel found cells whose responses differed dramatically from those in the retina and thalamus. Many of these cells could be excited by stimuli presented to either eye. The primary visual cortex thus represents the first level of the visual system at which binocular interactions could form a substrate for depth perception. Most strikingly, Hubel and Wiesel found that

the vast majority of cortical cells respond best to elongated stimuli at a specific orientation and give no response at the orthogonal orientation. This is in sharp contrast to cells in the retina and LGN, which are not selective for orientation.

Hubel and Wiesel described two broad classes of neurons in area 17: *simple cells* and *complex cells*. The receptive fields of simple cells were segmented into oriented *on-and-off* subregions (Figs. 26.8C and 26.8D) and were therefore most sensitive to similarly oriented stimuli. In these receptive field subregions, responses were evoked by turning a light stimulus *on* or *off*, but not by both. Given these well-defined *on-and-off* subregions in simple cells, Hubel and Wiesel suggested a straightforward hierarchical model to explain orientation selectivity: neurons in the lateral geniculate nucleus whose receptive fields are arranged in a row could all converge to excite a specific simple cell (Fig. 26.8E). Although this model has generated much controversy over the ensuing years, many of its elements have been demonstrated directly (Ferster, Chung, & Wheat, 1996; Reid & Alonso, 1995).

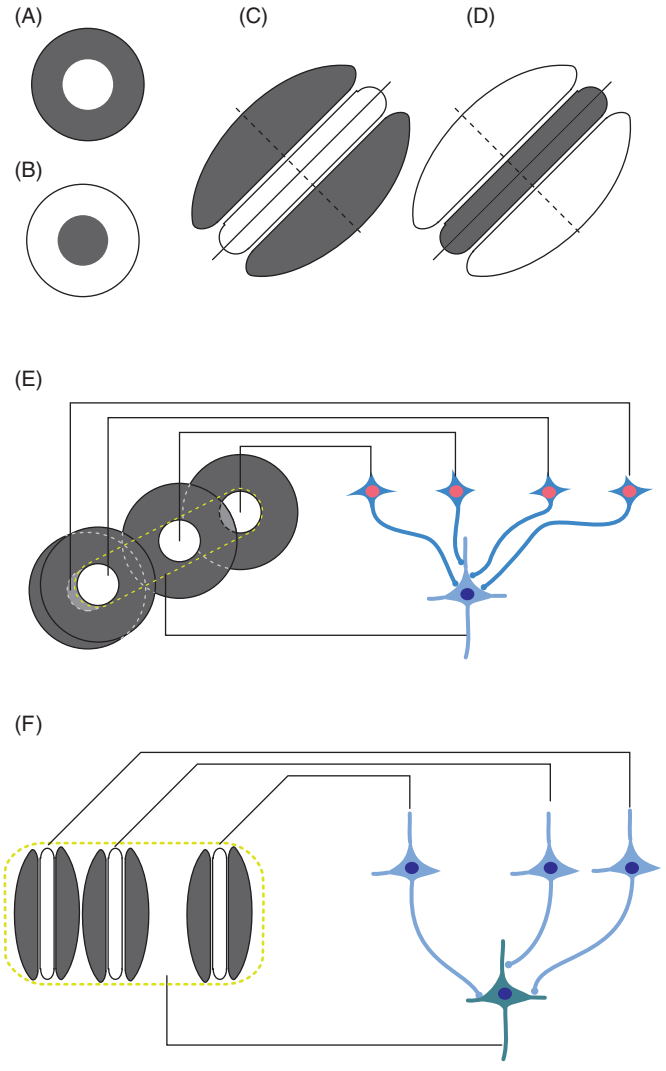

FIGURE 26.8 Hubel and Wiesel's original models of visual cortical hierarchy. (A and B) Receptive field maps of center-surround receptive fields in LGN. White: *on* responses; dark gray: *off* responses. (C and D) Receptive field maps of simple cells. (E) Model of convergent input from LGN neurons onto the cortical simple cell. (F) Model of convergent input from simple cells onto complex cells. *Adapted from Hubel and Wiesel (1962).*

The second class of cortical neurons, complex cells, also responded best to oriented stimuli, but their receptive fields were not elongated along a preferred orientation, nor were they divided into distinct *on-and-off* subregions. It would therefore be difficult to imagine how the responses of these neurons could be constructed directly from the center/surround receptive fields in the thalamus. Given the properties of simple cells, Hubel and Wiesel proposed a hierarchical scheme. Complex cells receive their orientation selectivity from convergent input from simple cells whose receptive fields have the same orientation preference, but have slightly different spatial locations (Fig. 26.8F).

This original model is hierarchical or serial; information flows from one level to the next in a well-defined series. In contrast to this hierarchical model of cortical processing, it has also been proposed that each region of the cerebral cortex is made up of several different streams of information that are all processed in parallel. As with most dichotomies, elements of both hierarchical and parallel processing have been found in the visual cortex of all mammals studied. For simplicity, an outline of the organization of visual cortex in the cat is discussed here in terms of a hierarchical model. Parallel processing will be illustrated with the example of a primate visual cortex.

The hierarchical scheme has received support from several correlations between anatomy and physiology of area 17. In broad terms, simple cells are more common in the layers of cortex that receive direct input from the thalamus (layer 4 and, to a lesser extent, layer 6). Complex cells are found more frequently in layers that are more distant from the thalamic input in layers 2 + 3, which receive input primarily from layer 4, and in layer 5, which receives most of its input from layers 2 + 3 (Gilbert & Wiesel, 1985; Fig. 26.9).

In terms of their probable function in perception, the receptive fields of complex cells furnish an early example of what was meant in the introduction by a higher order representation. Complex cells convey information about orientation to later stages of processing, but that information has been combined and generalized. A simple cell responds to an oriented stimulus of a specific configuration and a specific location; in particular, it has separate *on-and-off* subregions. A complex cell also responds to stimuli at one orientation, but the receptive field is not segregated into *on-and-off* subregions. Instead, it can respond to a light or dark stimulus of the correct orientation, independent of the exact location of the stimulus

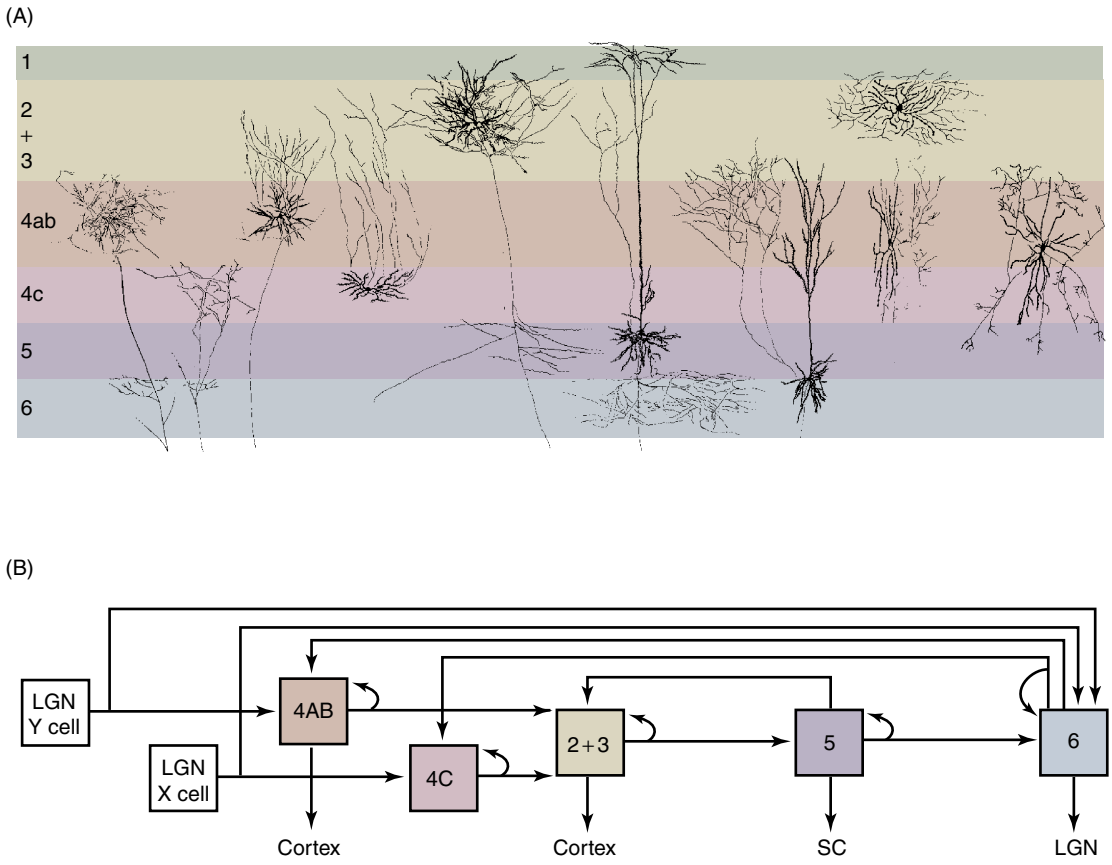

FIGURE 26.9 Circuitry of cat cortical area 17. (A) Morphology of individual cells stained with horseradish peroxidase. Thick lines: dendrites; thin lines: axons. (B) Schematic diagram of connections. Most thalamic (LGN) input is concentrated in layer 4 and, to a lesser degree, in layer 6. Y cells tend to project more superficially in layer 4 than X cells (note that sublayers 4ab and 4c are not strictly analogous to 4A, 4B, and 4C in the macaque). There is a fairly strict hierarchical pathway from layers 4 → 2 + 3 → 5 → 6 with feedback connections from 5 → 2 + 3 and 6 → 4. There are also many lateral connections between neurons within the same layer. *Adapted from Gilbert and Wiesel (1985).*

within the receptive field. This sort of generalization is a recurrent theme in the cortical processing of visual information.

Several Parallel Streams Are Found in the Macaque Primary Visual Cortex

In the macaque primary visual cortex (V1, or striate cortex), a hierarchical organization is certainly present, but it is also clearly composed of several parallel streams. As discussed earlier, at least three types of inputs to visual cortex (parvocellular, magnocellular, and koniocellular) are first segregated within the LGN. Each class of neurons projects to a specific subdivision of primary visual cortex. Most thalamic afferents terminate in layer 4C, which is split into two divisions. 4Cα receives its input from magnocellular neurons and 4Cβ from parvocellular neurons. Intercalated, or koniocellular, geniculate neurons project to layers 2 + 3, specifically to regions known as "blobs" (discussed later) that stain densely for the enzyme cytochrome oxidase (Livingstone & Hubel, 1984).

Thus, visual information from functionally and anatomically distinct M and P retinal neurons are kept separate through the LGN and at least up to the cortical neurons that receive direct thalamic input. The degree to which these pathways—as well as the more poorly understood koniocellular pathway—are kept separate within visual cortex remains an area of active research (Fig. 26.13).

Functional Architecture Can Be Seen in the Columnar Structure of the Visual Cortex

So far, the physiology of the visual cortex has been considered in terms of individual neurons and their response properties. Another major contribution of Hubel and Wiesel was their demonstration that cells with similar receptive field properties tend to be found near each other in the cortex. Further, they found that physiological response properties, such as orientation selectivity, are organized in an orderly fashion across the cortical surface. They termed the relationship between anatomy and physiology the *functional architecture* of visual cortex.

Hubel and Wiesel's key observation in this arena was that when an electrode is advanced through the cortex perpendicular to its surface, all neurons encountered have similar response properties. If a cell near the surface has a specific orientation and is dominated by input from one eye, then cells below it share these preferences. This finding is consistent with the idea, proposed by Lorente de Nó, that the fundamental unit in cortical architecture is a vertically oriented *column* of neurons. It is interesting to note that rodent cortex deviates from this organizational plan, as neurons preferring the same orientation are not clustered together in a columnar fashion (Fig. 26.14A). Hubel and Wiesel proposed that a cortical column is both a physiological and an anatomical unit, as had Mountcastle in his study of somatosensory cortex (see Chapter 24). A second observation was that the property of orientation preference varies smoothly over the cortical surface. If an electrode takes a tangential path through the cortex through many different columns, the orientation preference generally changes in a steady clockwise or counterclockwise progression, although occasionally there are discontinuous jumps (Fig. 26.10A).

In addition to orientation, at least two other parameters are mapped smoothly across the cortical surface. Cells in the visual cortex receive inputs from the two eyes in varying proportion, a property that Hubel and Wiesel termed *ocular dominance.* In tangential micro-electrode penetrations, cells are found that are dominated first by input from one eye and then the other. This provides evidence for *ocular dominance columns,* which have subsequently been demonstrated anatomically as well as physiologically. Second, prior to Hubel and Wiesel's work, a precise map of visual space across the surface of the cortex had been demonstrated. For any cortical column, receptive fields are all located at roughly the same position on the retina. Nearby columns represent nearby points in visual space in a precise and orderly arrangement. The position of a stimulus on the retina is termed its *retinotopy*; thus, a region of the brain (such as the superior colliculus, LGN, or the visual cortex) that maintains the relations between adjacent retinal regions is said to have a *retinotopic map.*

Given the existence of multiple functional maps, the obvious question is: How do these maps relate to each other? This question has been answered most definitively for the relationship between retinotopy and ocular dominance. Layer 4 in the primate is ideal for studying this question, as the receptive fields are quite small and the borders between ocular dominance columns are well defined. By making long, tangential penetrations through layer 4 of the striate cortex, Hubel and Wiesel found a precise interdigitating map from each eye. When eye dominance shifts, the receptive field location shifts to a point corresponding to the middle of the previous ocular dominance column (Fig. 26.10B). Thus, there is a 50% overlap in the spatial locations represented by adjacent ocular dominance columns. In this manner, a complete representation of space is attained for both eyes while ensuring that cells that respond to overlapping points in visual space are always nearby within the cortex.

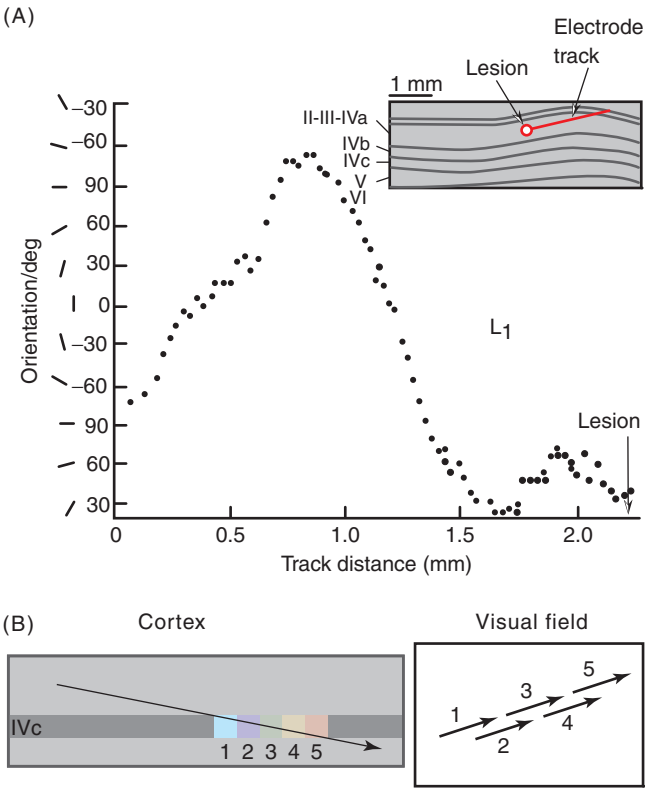

FIGURE 26.10 Two aspects of the functional architecture of the macaque primary visual cortex. (A) Graph of the preferred orientation of neurons encountered in a long microelectrode penetration through layers 2 + 3 (inset). There was a steady, slow progression of preferred orientations, although there were a few positions where the orientations changed more abruptly. (B) Schematic diagram of an electrode penetration through layer 4C (left) and the retinotopic positions of receptive fields (right). Numbers (1–5) indicate regions dominated by input from alternating eyes. At the border between ocular dominance columns (e.g., instance between 1 and 2), the location of receptive fields jumps back to a point represented near the middle of the previous ocular dominance column. There is a complete representation of visual space in columns dominated by each eye (1, 3, 5 or 2, 4) and these representations are spatially interleaved. *Adapted from Hubel and Wiesel (1977).*

Ocular Dominance and Orientation Columns Can Be Revealed with Optical Imaging

The technique of optical imaging has proven extremely useful in the study of the functional architecture of the visual cortex. Optical imaging allows direct visualization of the relative activity of small cortical ensembles rather than relying on inferences made from single unit studies (Blasdel & Salama, 1986; Grinvald, Lieke, Frostig, Gilbert, & Wiesel, 1986). The technique uses dyes that change their optical properties with neural activity. Even if no dyes are used, brain activity can be mapped with

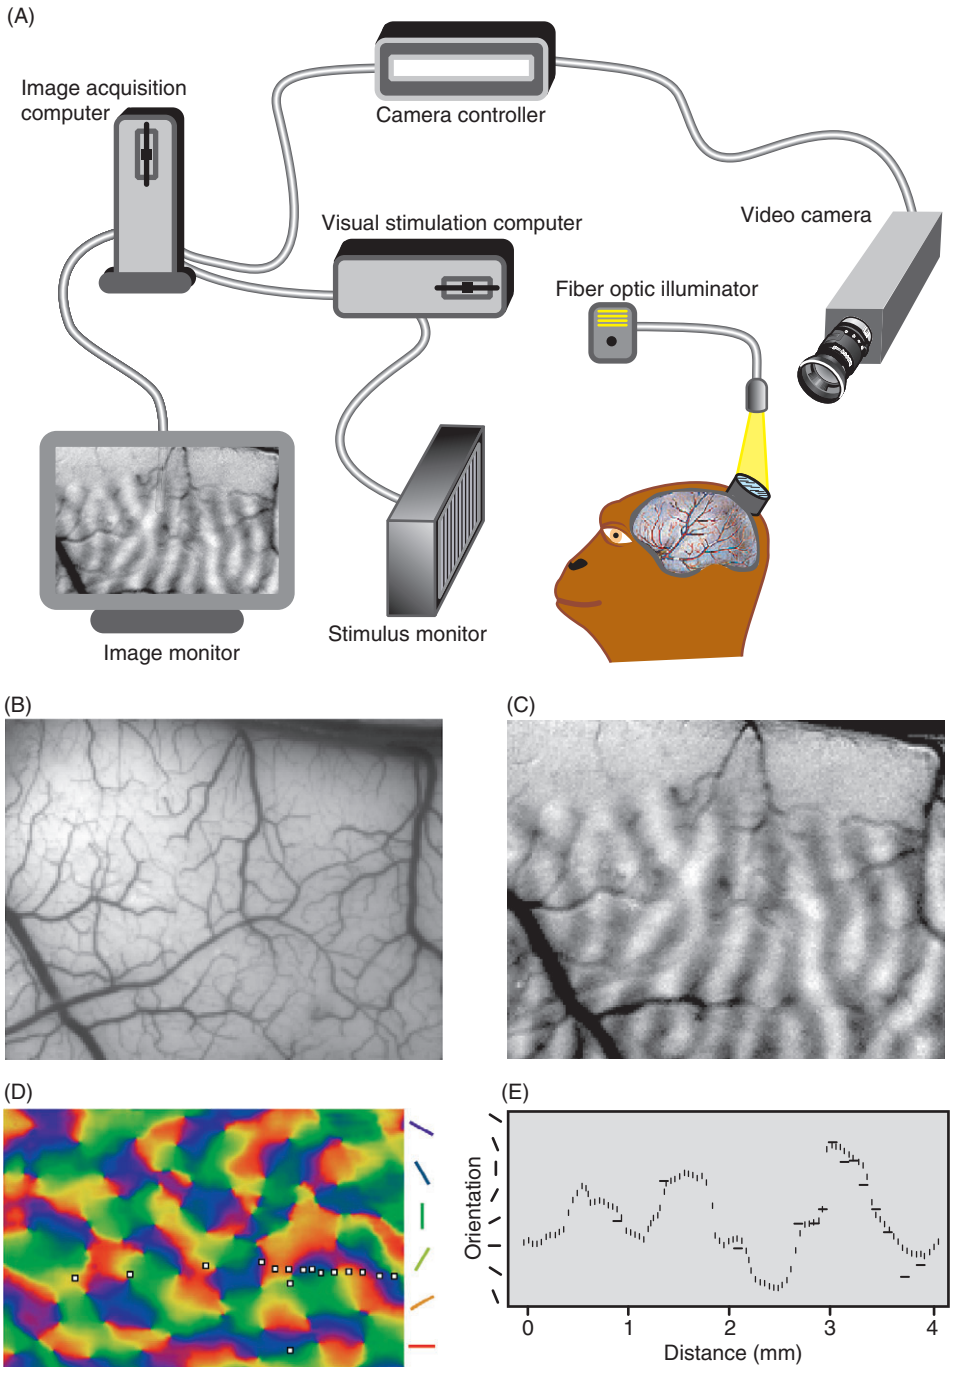

FIGURE 26.11 Optical imaging of functional architecture in the primate visual cortex. (A) Schematic diagram of the experimental setup for optical imaging. Digitized images of a region of visual cortex (as in B) are taken with a CCD camera while the anesthetized, paralyzed animal is viewing a visual stimulus. These images are stored on a second computer for further analysis. (B) Individual image (9 by 6 mm) of a region of V1 and a portion of V2 taken with a special filter so that blood vessels stand out. (C) Ocular dominance map. Images of the brain during right-eye stimulation were subtracted digitally from images taken during left-eye stimulation. (D) Orientation map. Images of the brain were taken during stimulation at 12 different angles. The orientation of stimuli that produced the strongest signal at each pixel is color coded, as indicated to the right. The key at the right gives the correspondence between color and the optimal orientation. (E) Comparison of the preferred orientation of single neurons with the optical image. At each of the locations indicated by squares in D, single neurons were recorded with microelectrodes. The preferred orientations of the neurons (dashes) were compared with the preferred orientations measured in the optical image, sampled along the line connecting the recording sites (dots). A: *Adapted from Grinvald et al. (1988)*; B and C: *Adapted from Ts'o, Frostig, Lieke, and Grinvalid (1990)*; D and E: *Adapted from Blasdel and Salama (1986)*.

an intrinsic signal, caused primarily by changes in blood flow and blood oxygenation.

A typical optical imaging experiment works as follows (Fig. 26.11A). First, a series of digitized images is taken of a region of visual cortex (Fig. 26.11B) while the animal is presented with visual stimuli through the left eye. Next, a similar series is captured during right eye stimulation. When the right eye images are subtracted digitally from the left eye images, a striking picture is created that reveals the functional architecture of ocular dominance (Fig. 26.11C). Previously, anatomical methods had been used to produce maps of ocular dominance, and these maps appear similar to those found with optical imaging, but an important feature of optical imaging is that multiple images can be obtained from the same region of the cortex. For instance, in addition to ocular dominance, maps of the preferred orientation can also be made. A useful way to present these data is in terms of a color code, in which each color represents a different preferred orientation (Fig. 26.11D). The orientation columns revealed by

optical imaging were consistent with earlier microelectrode studies (compare Fig. 26.11E with Fig. 26.10A), but the images for the first time gave a detailed picture of the layout of orientation across the cortical surface. Details of these orientation maps—and their relationships with ocular dominance—were entirely new and had not been demonstrated with previous techniques.

Cytochrome Oxidase Staining Reveals Blobs and Stripes in Cortical Areas V1 and V2

In the primate, there is a fourth feature of the functional architecture of visual cortex in addition to retinotopy, orientation, and ocular dominance columns. When stained for the enzyme cytochrome oxidase (a metabolic enzyme whose presence indicates high activity), histological sections of V1 revealed a regular pattern of patches, or blobs (Fig. 26.12). In layers 2+3, these blobs were reported to contain neurons whose receptive fields are color selective, poorly oriented, and monocular (Livingstone & Hubel, 1984).

In V2, the second visual area in the cerebral cortex (see later), cytochrome oxidase staining reveals regions of high and low activity arranged in parallel stripes (thick, thin, and pale stripes; Fig. 26.12, along the top). The anatomical connections between V1 and V2 are strongly constrained by the subdivisions revealed by cytochrome oxidase staining. In an early view, V1 neurons in the blobs projected to the thin stripes of V2, neurons in the interblobs projected to the pale stripes, and neurons in layer 4B projected to the thick stripes (Livingstone & Hubel, 1984). More recently, this organizational scheme has been revised and simplified such that V1 neurons in blob (or patch) columns, including underlying regions of layer 4B, project to the thin stripes of V2, while neurons in the interblob (interpatch) columns, again including underlying regions of layer 4B, project to both the pale stripes and thick stripes (Sincich & Horton, 2005). One of the reasons it is important to understand the anatomical relationship between V1 and V2 is that neurons in the thick, thin, and pale stripes of V2 give rise to projections that appear selective for either the dorsal or ventral streams of visual processing in extrastriate cortex (described below), whereby neurons in the thick stripes provide input to the dorsal stream and neurons in the thin and pale stripes provide input to the ventral stream.

Many Extrastriate Visual Areas Perform Different Functions

In early studies of the cytoarchitecture of cerebral cortex, the visual cortex was divided into three areas according to Brodmann's classification: areas 17, 18, and 19. These divisions were based on differences in cell cytoarchitecture, or differences in the size, morphology, and distributions of cells within the six cortical laminae. Area 17 is primary visual cortex, or striate cortex, so named because of a heavily myelinated sublamina within layer 4 (4Cα), prominently visible as a stripe in transverse section. Areas 18 and 19 were known simply as the visual association cortex. An assumption behind these designations was that areas defined by anatomical criteria would ultimately prove to be functionally specialized.

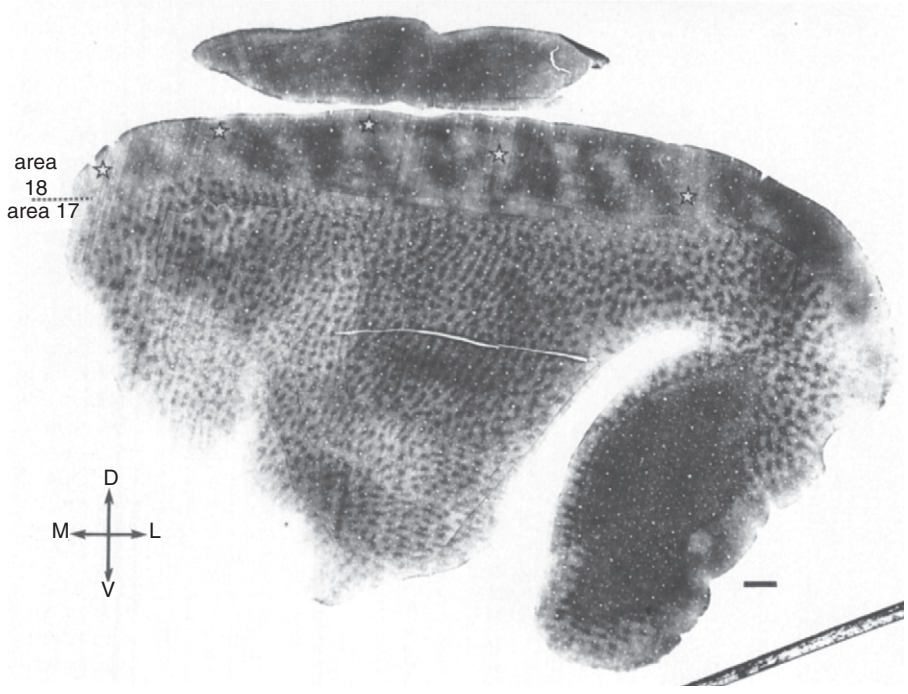

FIGURE 26.12 Macaque visual cortex stained for the metabolic enzyme cytochrome oxidase. A tangential section through layers 2 + 3 of V1 (below) and V2 (above) is shown. In V1, blobs are seen in a regular array with a spacing of 400 μm. In V2, there are cytochrome oxidase-rich stripes with much coarser spacing. The distinction between thick and thin stripes (see text) is seen less readily in the macaque than in the owl monkey. Scale bar: 1 mm. *From Livingstone and Hubel (1984).*

The demonstration of multiple visual cortical areas has been one of the important discoveries of the past quarter century in the field of sensory neurobiology. A vast expanse of cerebral cortex—greater than 50% of the total in many primate species—is involved primarily or exclusively in the processing of visual information. The extrastriate cortex now includes areas 18 and 19, as well as large regions of the temporal and parietal lobes (see Fig. 26.13 for a diagram of the four main regions of cerebral cortex: occipital, parietal, temporal, and frontal). It is composed of some 30 subdivisions that can be distinguished by their physiology, cytoarchitecture, histochemistry, and/or connections with other areas (Felleman & Van Essen, 1991). Each of these extrastriate visual areas is thought to make unique functional contributions to visual perception and visually guided behavior. Higher-order cortical areas are also present in rodents (Fig. 26.14B); however, the number of cortical areas serving vision in rodents is substantially less in comparison to primates.

As a testament to the increasing complexity of the field, the naming of visual areas (Fig. 26.13) has progressed from the use of simple labels—V1 through V4—to the use of more complex terms specifying anatomical location of each new area, such as MT (medial temporal, or V5), MST (medial superior temporal), or IT (inferotemporal, itself made up of several distinct areas).

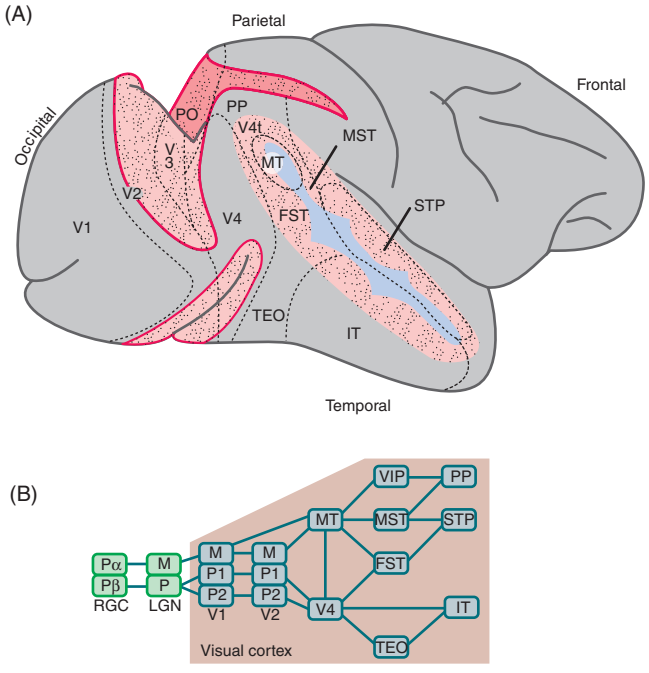

FIGURE 26.13 Extrastriate cortical regions. (A) Lateral view of the macaque brain, with the sulci partially opened to expose the areas within them. Shown are the rough outlines of the main visual areas, which take up all of the occipital cortex and much of the parietal and temporal cortex. (B) Partial diagram of the connections between visual areas. Emphasis is placed on the hierarchical organization of the connections and on the partially segregated P parvocellular and M magnocellular pathways. *Adapted from Albright (1993).*

The dual themes of parallel and hierarchical processing are central to the understanding of the extrastriate cortex. Figure 26.13 is a vastly simplified version of a wiring diagram between visual areas (Felleman & Van Essen, 1991). Several criteria have been used to define new visual cortical areas. First, extrastriate regions have retinotopic maps of the visual world that can be demonstrated by physiological recordings. Second, a clear hierarchy between many cortical areas can be demonstrated anatomically. There is a stereotyped pattern of projections from one visual area to the next. Where strong connections between two areas exist, these connections tend to be bidirectional. The feedforward and feedback connections are distinguished by the layers that send and receive the connections. In such a manner, a clear hierarchy can be traced, for instance, along the pathway V1 → V2 → V3 → MT → MST (with several shortcuts, such as V1 → MT).

While physiological studies of cortical areas revealed profound differences between them, a series of studies by Ungerleider and Mishkin (1982) uncovered a higher-order dichotomy between two types of processing in the extrastriate cortex. Using behavioral analyses of animals with anatomically defined cortical lesions, Ungerleider and Mishkin found a strong dissociation between the types of deficits exhibited by animals with lesions in either their parietal cortex or their temporal cortex (see Fig. 26.13). Animals with temporal lesions were often much worse at recognizing objects visually, although lower-level visual function, such as acuity, was not appreciably lessened. Parietal lesions led to little or no deficit in object recognition, but visuospatial tasks, such as visually guided behavior, were impaired profoundly. From these studies and the growing body of physiological evidence, two distinct streams were postulated: a *temporal* or *ventral stream* devoted to object recognition and a *parietal* or *dorsal stream* devoted to action or spatial tasks. Ungerleider and Mishkin termed these the "what" and "where" pathways.

The ventral stream, V1 → V2 → V3 → V4 → IT …, is discussed elsewhere (Chapter 44). This chapter considers only the dorsal stream, V1 → V2 → MT → MST…. The dorsal stream is dominated by magnocellular cells and the ventral stream by parvocellular cells, although the segregation is far from strict (Merigan & Maunsell, 1994).

In the Parietal Cortex, Neurons Are Selective for Higher Order Motion Cues

MT, or V5, is perhaps the best understood of the extrastriate visual areas. It has held particular interest ever since it was discovered in 1971 (Allman & Kaas, 1971; Dubner & Zeki, 1971), primarily because it was the first area found that was strongly dominated by one visual

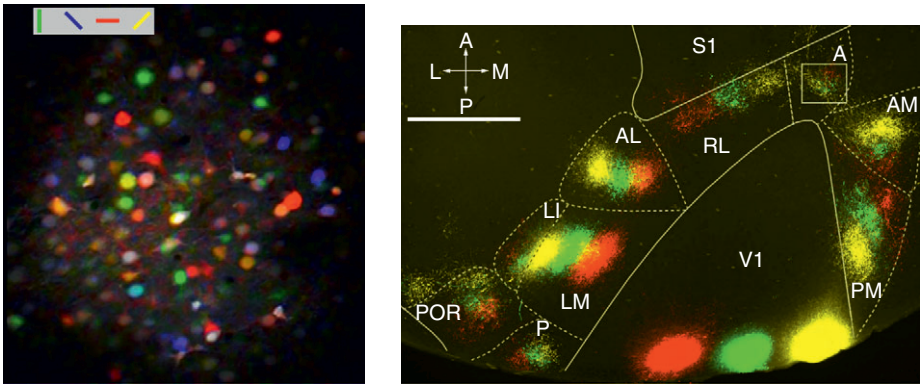

FIGURE 26.14 Rodent visual cortex. (A) Orientation-selective neurons in rat visual cortex (as well as mice) are not organized into columns, but instead are positioned randomly in V1. Individual neurons were stained with an activity-sensitive indicator and imaged *in vivo* with two-photon microscopy, a form of fluorescence imaging that can easily resolve single neurons in the living brain. Neurons were imaged during visual stimulation and their preferred orientations are indicated with a color code, as in Fig. 26.12C (legend serves also as 100 μm scale bar). (B) Anatomical image of primary visual cortex (V1) and nine distinct higher visual areas in the mouse. Higher visual areas are named according to their anatomical positions, such as posteromedial (AM) or anterolateral (AL); S1 is primary somatosensory cortex. Three different colors of fluorescent tracers were injected in V1, so that axons from V1 to each of the higher visual areas could be visualized. Axons from the three distinct injection sites project to distinct regions within each of the higher areas, which indicates that the retinotopic map of visual space is maintained in all of the visual areas. Scale bar: 1 mm. Legend: **A**nterior, **P**osterior, **L**ateral, **M**edial. A: *Adapted from Ohki, Chung, Ch'ng, Kara, and Reid (2005)*; B: *Adapted from Ma and Burkhalter (2007).*

function. Fully 95% of the neurons in MT are highly selective for the direction of motion of a stimulus (Dubner & Zeki, 1971). In V1, a significant fraction of neurons are selective for the direction of motion, but the optimal speed may vary depending on the spatial structure of the object that is moving. In MT, speed tuning is less dependent on other stimulus attributes. Receptive fields of individual neurons in MT integrate motion information over large regions of visual space and are qualitatively less selective than neurons in the primary visual cortex. This generalization of motion signals can be achieved in a simple manner, such as by adding together inputs over space or, in a complex manner, by combining two component motions in different directions into a single coherent motion. Of even greater interest, neurons in MT (and, to a greater extent, those in MST) appear to be sensitive to more complex aspects of visual motion, such as the motion of extended objects rather than isolated features (Albright, 1993).

The range of stimuli that a given MT neuron can respond to is impressively broad—the attributes, or form cues, that define a figure can be luminance, texture, or relative motion—but the preferred direction and speed are always the same for that neuron (Albright, 1993). This is an extreme example of what were termed high-order responses in the introduction to this chapter. Neurons at lower levels in the visual system are sensitive to isolated and specific features in visual scenes. Higher visual areas respond to very specific attributes, but these attributes are increasingly remote from the physical stimulus. Instead, they represent increasingly complex concepts, such as the motion of an extended object or the identity of a face.

Summary

The lateral geniculate nucleus of the thalamus is a layered structure that receives segregated input from the two eyes and projects to the primary visual cortex (V1). Geniculate neurons have center-surround receptive fields that are similar to those of their retinal inputs. In contrast, most neurons in the primary visual cortex are sensitive to the orientation of a stimulus. In mammalian species, there are elements of both hierarchical and parallel processing in the primary visual cortex. This section has emphasized that the visual cortical circuit in the cat can be seen as a functional hierarchy that transforms geniculate input into simple and then complex receptive fields. In the macaque monkey the focus has been on the parallel pathways that are kept relatively separate in the striate and extrastriate cortex.

The visual cortex has an orderly functional architecture. Neurons within a cortical column have similar receptive field attributes, such as orientation selectivity, ocular dominance, and receptive field location. Each of these receptive field attributes varies smoothly over the cortical surface. The organization of ocular dominance columns and orientation columns across the cortical surface can be visualized with optical imaging.

Finally, in the macaque monkey, there are more than 30 extrastriate visual cortical regions, each of which performs different functions. These extrastriate regions can be divided into two pathways: the ventral stream, devoted to form recognition, and the dorsal stream, devoted to action or to spatial tasks. Areas in each stream form a

functional and anatomical hierarchy. Neurons in successive visual areas respond to increasingly high-order or abstract features of the visual world.

CHAPTER

27

Fundamentals of Motor Systems

"All mankind can do is to move things … whether whispering a syllable or felling a forest."—Sherrington

This quote is a reminder of the basic fact that all interactions with the surrounding world are through the actions of the motor system. When a human baby is born, it is a sweet but very immature survival machine, with a limited behavioral repertoire. It is able to breathe and has searching and sucking reflexes so that it can be fed from the mother's breast. It can swallow, vomit, and process food, and it can cry for attention if something is wrong. A baby also has a variety of protective reflexes that mediate coughing, sneezing, and touch avoidance. These different patterns of motor behavior are thus available at birth and are due to innate motor programs (Fig. 27.1).

During roughly the first 15 years of life, the motor system continues to develop through maturation of neuronal circuitry and by learning through different motor activities. Playing represents an important element both in children and in young mammals such as kittens and pups. During the first year of life, the human infant matures progressively. It can balance its head at 2 to 3 months, is able to sit at around 6 to 7 months, and can stand with support at approximately 9 to 12 months. The coordination of different types of posture, such as standing, is a complex motor task to master, with hundreds of different muscles taking part in a coordinated fashion. Sensory information contributes importantly, in particular from the vestibular apparatus, eyes, muscle, and skin receptors located at the soles of the feet. This development represents to a large degree a maturation process following a given sequence but with individual variability among different children. When the postural system has evolved to a sufficient degree, a child is able to start walking, which requires that the body posture is maintained while the points of support are changing by the alternating movements of the two legs. In common language the child is said to "learn" to walk, but in reality a progressive maturation of the nervous system is taking place. Identical twins start to walk essentially at the same time, even if one has been subjected to training and the other has not. At this point the motor pattern is still very immature. Proper walking coordination followed by running appears later, and the basic motor pattern actually continues to develop until puberty. The fine details of the motor pattern are adapted to the surrounding world, but also to modification by will. The basic motor coordination underlying reaching and the fine control of hands and fingers undergo a similar characteristic maturation process over many years.

While the newborn human infant is comparatively immature, other mammals, such as horses and deer, represent another extreme. The gnu, an African buffalo-like antelope, needs to run away in order to survive attacks of predators such as lions. The young calf of the gnu can stand and run directly after birth and has been reported to be able to gallop ahead 10 minutes after delivery, tracking the running mother (Fig. 27.2). Clearly the neural networks underlying locomotion, equilibrium control, and steering must be sufficiently mature and available at birth, needing minimal calibration. This is astounding. A similar range of maturity is present in birds. To get out of the egg, a chick makes coordinated hatching movements to open up the eggshell to subsequently lift off the top of the egg and to stand up to walk away on two legs following the mother hen and start picking at food grains. Most birds are more immature when hatching, but after a few weeks, they leave the nest flying rather successfully, for the first time in their life, and thus without any previous experience.

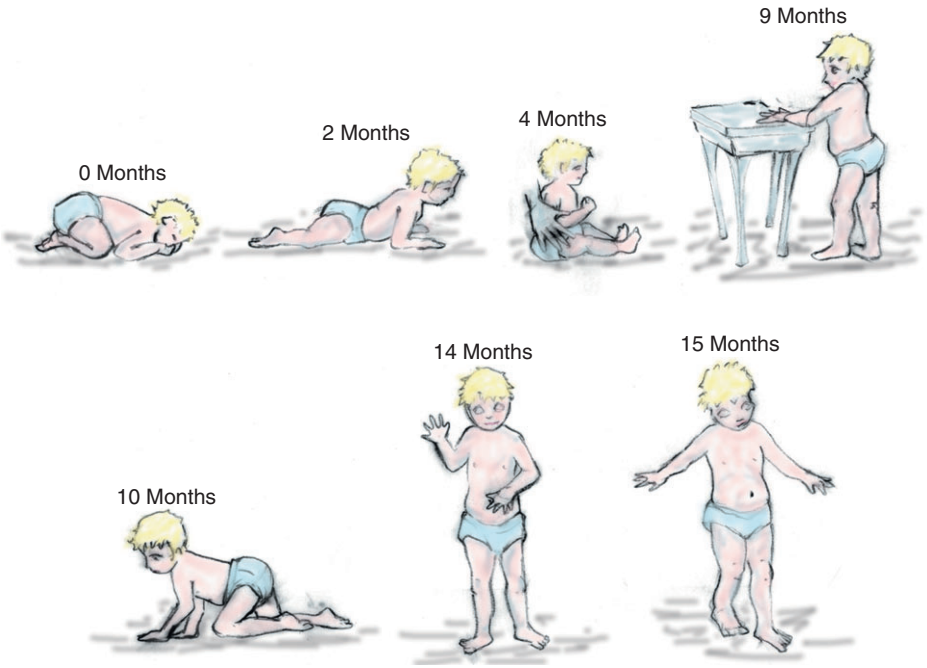

FIGURE 27.1 Motor development of the infant and young child. The pattern of maturation of the motor system follows a characteristic evolution. Two months after birth a child can lift its head, at 4 months it sits with support, and subsequently it is able to stand with support; later it crawls, stands without support, and finally walks independently. The approximate time at which a child is able to perform these different motor tasks is indicated above each figure. The variability in the maturation process is substantial. *Modified from M. M. Shirley.*

FIGURE 27.2 Some animals are comparatively mature when they are born. Ten minutes after the calf of the gnu, a buffalo-like antelope, is born, it is able to track its mother in a gallop. This means that the postural and locomotor systems are sufficiently mature to allow the young calf to generate these complex patterns of motor coordination at birth. There is little time to calibrate the motor system after birth and obviously no time for learning. *Courtesy of Erik Tallmark.*

In addition to the basic motor skills such as standing, walking, and chewing, humans also develop skilled motor coordination, allowing delicate hand and finger movements to be used in handwriting or playing an instrument or utilizing the air flow and shape of the oral cavity to produce sound as in speech or singing. The neural substrates allowing learning and execution of these complex motor sequences are expressed genetically and are characteristic of our species. What is learned, however, such as which language one speaks or the type of letters one writes, is obviously a function of the cultural environment.

BASIC COMPONENTS OF THE MOTOR SYSTEM

Motoneurons and Motor Units

The motoneurons that control different muscles are located in different motor nuclei along the spinal cord and in the brainstem. Each motoneuron sends its axon to one muscle and innervates a limited number of muscle fibers. A motoneuron with its muscle fibers is referred to as a motor unit. The muscle fibers of each motor unit have similar contractile properties and metabolic profile. The muscle fibers in different muscles are composed of three main types specialized for different demands, such as a continuous effort as in long-distance running (slow motor units) or fast explosive movements, such as lifting a heavy object [fast motor units (two subtypes)].

Motoneurons are activated by interneurons of different motor programs or reflex centers and by descending tracts from the forebrain and the brainstem. Thus motoneurons supplying different muscles can be activated with great precision by these different sources that together determine the degree of activation, as well as the exact timing of the motoneurons of a given muscle.

Sensory Receptors Are Important in Movement Control

Signals from sensory receptors are used by the motor system in a number of ways.

1. Sensory signals can trigger behaviorally meaningful motor acts such as withdrawal, coughing, or swallowing reflexes.

2. Sensory receptors may contribute to the control of an ongoing motor pattern and influence the switch from one phase of movement to another. For instance, in the case of breathing, sensory signals from lung volume receptors control when inspiration is terminated. In walking, sensory signals related to hip position and load on the limb help regulate the duration of the support and swing phases of the step cycle and correct for perturbations.
3. Sensory signals may also be more specific and influence only the level of activity of one muscle or a group of close synergists. Muscle receptors play a particularly important role in this context. They are of two types: Golgi tendon organs that sense the degree of contraction in a muscle (located in series with the muscle fibers at their insertion into the tendon), and muscle spindles that signal the length of a muscle (located in parallel to the muscle fibers), as well as the speed of changes in length. Moreover, the sensitivity of muscle spindles can be regulated actively through a separate set of small motoneurons, referred to as γ-motoneurons (in contrast to the larger α-motoneurons that control muscle contraction). These two muscle receptors have fast conducting afferent axons that provide rapid feedback to the spinal cord and take part in the autoregulation of the motor output to a given muscle. Fast muscle spindle afferents provide direct monosynaptic excitation to the α-motoneurons that control the muscle in which the muscle spindle is located. Thus, lengthening a muscle will lead to excitation of its motoneurons, counteracting the lengthening. This stretch reflex thus involves negative feedback. This reflex arc also provides the basis of the muscle contraction elicited by a brief tendon tap, which is used as a clinical test to investigate whether responsiveness of the motoneuronal pool is normal (the tendon reflex) (Fig. 27.3).
4. Sensory signals from a number of different receptor systems help detect and counteract any disturbance of body posture during standing or maintenance of another body position. Skin and muscle receptors and receptors signaling joint position, as well as vestibular receptors and vision, contribute to different aspects of the dynamic and static control of body position.
5. When an object is held by the fingers, skin receptors at the contact points at the fingertips play an important role. If the object tends to slip, the skin receptors become activated and signal rapidly to the nervous system that there is a need for extra muscle force.
6. A great variety of sensory signals provide information about the position of different parts of the body in relation to each other and to the external world. Such information is critical when initiating a voluntary movement. For example, to move a hand toward a given object, it is important to know the initial position of the arm and the hand in space. Depending on whether the hand is located to the left or the right of the object, different types of motor commands must be given to bring the hand to the target. Sensory information about the initial position of the hand (or any other body part) in relation to the rest of the body, as well as the target for the movement, is thus important for eliciting an effective neural command signal.

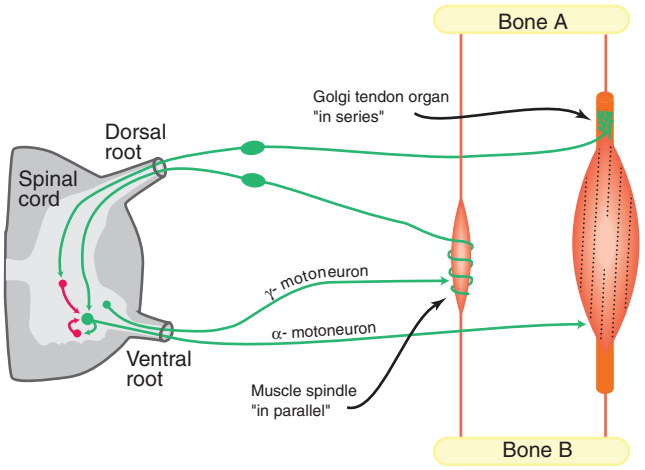

FIGURE 27.3 Feedback from muscle receptors to motoneurons: the stretch reflex. In a muscle connected between two bones, the Golgi tendon organ is located at the transition between muscle and tendon. It senses any active tension produced by the muscle fibers being in series between muscle and tendon. The muscle spindle is located in parallel with the muscle fibers. It signals the muscle length and dynamic changes in muscle length. Both the muscle spindle and the Golgi tendon organ have fast-conducting afferent nerve fibers in the range of ~100 m/s. The muscle spindle activates α-motoneurons directly, which causes the muscle fibers to contract. The sensitivity of the muscle spindle can be actively regulated by γ-motoneurons, which are more slowly conducting. The muscle spindle provides negative feedback. If the muscle with its muscle spindle is lengthened, the afferent activity from the muscle spindle increases, exciting the α-motoneurons and leading to an increased muscle contraction, which in turn counteracts the lengthening. This is called the stretch reflex. The Golgi tendon organ provides force feedback. The more the muscle contracts, the more the Golgi tendon organ and its afferent are activated. In the diagram the intercalated interneuron between afferent nerve fiber and motoneuron is inhibitory. Thus increased muscle force leads to inhibition of the α-motoneuron, which results in a decrease of muscle force. The efficacy of length and force feedback can be regulated independently in the spinal cord and via γ-motoneurons. Thus their respective contributions can vary considerably between different patterns of motor behavior.

To summarize, the sensory contribution to motor control is very important in many different contexts. If sensory control is incapacitated, motor performance will in most cases be degraded. Without sensory information in different forms, movements can usually still be executed, but as a rule with much less perfection.

Feedback and Feed Forward Control

If a perturbation occurs when an object is held in the hand, or when standing in a moving bus, it will be detected by different sensory receptors. This sensory signal will be fed back to the nervous system and be used to counteract the perturbation rapidly. This represents feedback control that is a correction of the actual perturbation after it has occurred. A limiting factor for the efficacy of feedback control in biological systems is the delay involved. A sensory afferent signal must first be elicited in the receptors concerned. It then has to be conducted to the central nervous system and be processed there to determine the proper response. The correction signal must subsequently be sent back to the appropriate muscle(s) and make the muscle fibers build up the contractile force required. In large animals, including humans, the delays involved can be substantial, and during fast movement sequences there may be little or no time for feedback corrections. In less demanding, more static situations, such as standing, sensory feedback is of critical importance.

In many cases a perturbation is anticipated before it is initiated, and correction begins before it has actually occurred. This type of proactive control is often called feed forward control in contrast to feedback. Such anticipatory control mechanisms are often automatic and involuntary, and are part of an inherent control strategy. For example, when standing on two legs and planning to lift up one leg to stand on the other, the body position begins to shift over to the supporting leg before the other leg is lifted. The projection of the center of gravity will fall between the two feet initially and will have to shift over to a projection through the supporting limb. In most instances, movement commands are designed so that the corrections of body posture required for a stable movement occur before the particular movement has started, as when lifting a heavy object. If the converse situation occurred, and body position was corrected only after a perturbation had taken place, movements would become much less precise than with feed forward control.

MOTOR PROGRAMS COORDINATE BASIC MOTOR PATTERNS

Both vertebrates and invertebrates have preformed microcircuits—neuronal networks that contain the necessary information to coordinate a specific motor pattern such as swallowing, walking, or breathing. When a given neuronal network is activated, the particular behavior it controls will be expressed. A typical network consists of a group of interneurons that activate specific groups of motoneurons in a certain sequence and inhibit other motoneurons that may counteract the intended movement. Such a group of interneurons is often referred to as a central pattern generator (CPG) or motor program. This CPG can be activated by will, as at the start of walking, or be triggered by sensory stimuli, as in a protective reflex or swallowing. In most types of motor behavior, sensory feedback may also form an integral part of the motor control circuit and may determine the duration of the motor activity such as the inspiratory phase of breathing (Fig. 27.4).

There are several different types of motor programs that are located along the neuraxis from the spinal cord to the forebrain. Together they constitute a set of standard but adaptable motor programs that can be referred to as a motor infrastructure (Fig. 27.5A).

The intrinsic function of the neuronal networks that comprise the CPGs have in most cases been difficult to

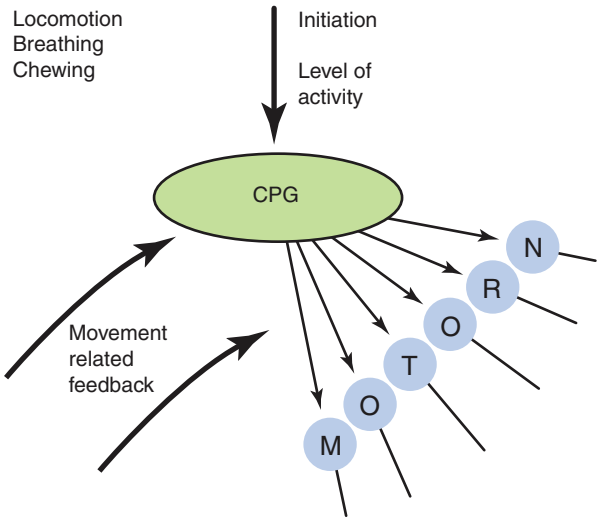

FIGURE 27.4 Motor coordination through interneuronal networks: central pattern generators. The brainstem and spinal cord contain a number of networks that are designed to control different basic patterns of the motor repertoire, such as breathing, walking, chewing, or swallowing. These networks are often referred to as central pattern generator networks (CPGs). CPGs contain the necessary information to activate different motoneurons and muscles in the appropriate sequence. Some CPGs are active under resting conditions, such as that for breathing, but most are actively turned on from the brainstem or the frontal lobes. For instance, the CPG coordinating locomotor movements is turned on from specific areas in the brainstem, referred to as locomotor centers. These descending control signals not only turn on the locomotor CPG, but also determine the level of activity in the CPG and whether slow or fast locomotor activity will occur. In order to have the motor pattern well adjusted to external conditions and different perturbations, sensory feedback acts on the CPG and can modify the duration of different phases of the activity cycle, providing feedback onto motoneurons. Although vertebrates as well as invertebrates have CPGs for a great variety of motor functions, the intrinsic operation of these networks of interneurons constituting the CPG is unclear in most cases. In invertebrates, a few CPG networks have been studied in great detail, such as the stomatogastric system of the lobster and networks coordinating the activity of the heart and locomotion in the leech. In vertebrates, detailed information concerning locomotor networks is only available in lower forms, such as the frog embryo and the lamprey.

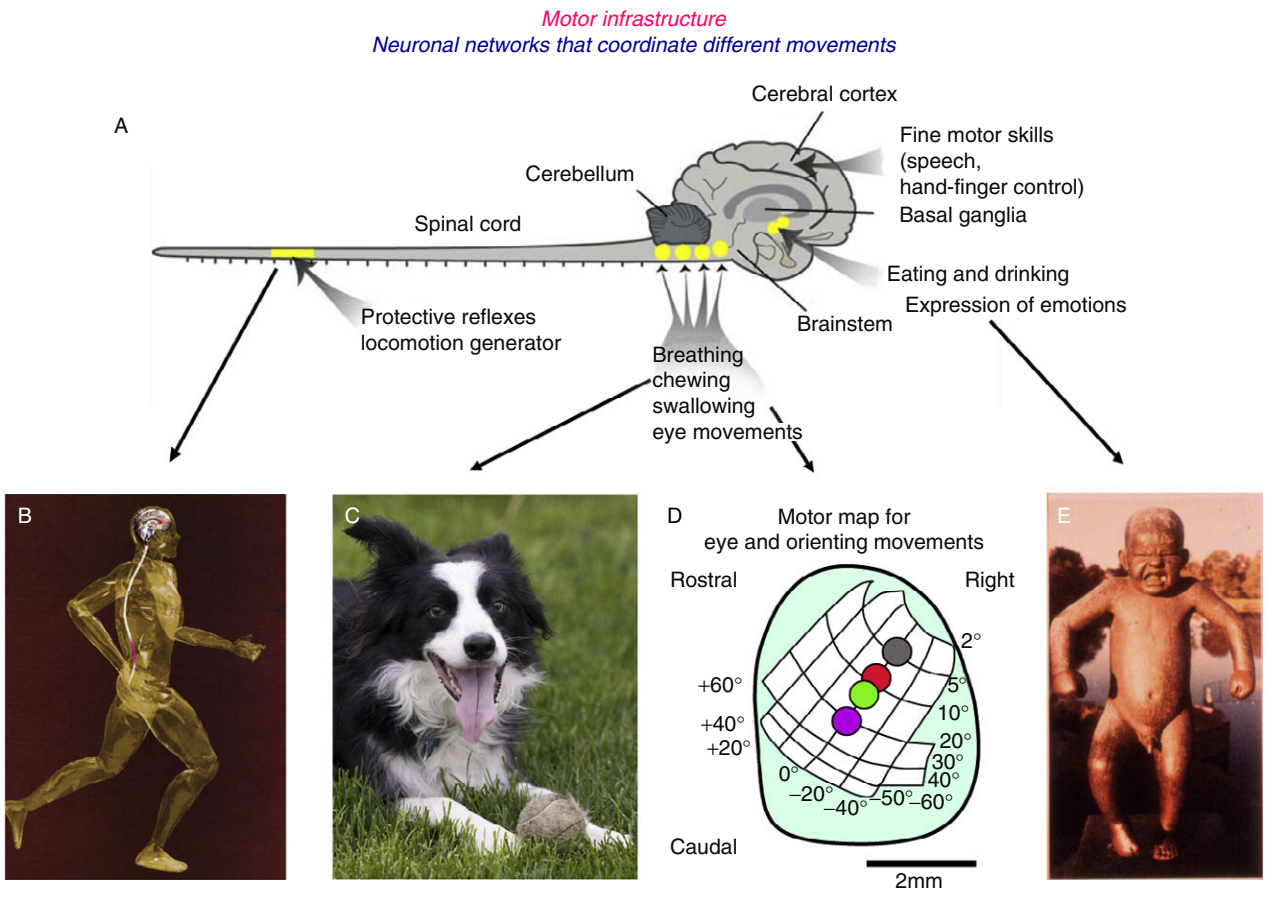

FIGURE 27.5 Location of different networks (CPGs) that coordinate different motor patterns in vertebrates. (A) Represents an overview of the location of the different CPGs in vertebrates. The spinal cord contains CPGs for locomotion (B) and protective reflexes, whereas the brainstem contains CPGs for breathing (C), chewing, swallowing, and a motor map for saccadic eye movements (D). The hypothalamus in the forebrain contains centers that regulate eating and drinking. These areas can coordinate the sequence of activation of different CPGs. For instance, if the fluid intake area is activated, the animal starts looking around for water, walks toward the water, positions itself to be able to drink, and finally starts drinking. The animal will continue to drink as long as the stimulation of the hypothalamic area is sustained. This is an example of recruitment of different CPGs in a behaviorally relevant order. The expression of emotion is represented by seven motor programs as illustrated for anger (E) by a child sculptured by Vigeland. The cerebral cortex is important, particularly for fine motor coordination involving hands and fingers and for speech.

deduce due to the complexity of the neuronal interactions. Box 27.1 provides an example from the locomotor CPG of the lamprey, in which the brainstem-spinal cord networks are understood.

Motor Patterns Triggered as a Reflex Response

1. Protective skin reflexes lead to withdrawal of the stimulated part of the body from a stimulus that may cause pain or tissue damage. The central program consists in this case of a group of interneurons that activate motoneurons and muscles, giving rise to an appropriate withdrawal movement. Motoneurons to antagonistic muscles are inhibited (reciprocal inhibition). The withdrawal reflexes of the limbs are often referred to as flexion reflexes, but in reality they represent a family of specific reflexes, each of which is designed to remove the specific skin region involved from the painful stimulus.
2. Coughing and sneezing reflexes remove an irritant from the nasal or tracheal mucosa by inducing a brief pulse of air flow at very high velocity (at storm or hurricane speeds). This is caused by an almost synchronized activation of abdominal and respiratory muscles, coordinated by a CPG, the activity of which is triggered by afferents activated by the irritant.
3. Swallowing reflexes are activated when food is brought in contact with mucosal receptors near the pharynx. This leads to a coordinated motor act with sequential activation of different muscles that propel the food bolus through the pharynx down the esophagus to the stomach. In this case the CPG is able to coordinate the motor act over several seconds, in contrast to the previous motor acts in which the activity occurs almost simultaneously.

BOX 27.1

CENTRAL PATTERN GENERATOR NETWORKS

To establish a network as a central pattern generator network (CPG), one needs to show that the motor pattern can be generated in the absence of sensory input. This is the case for all networks discussed in this chapter, although in most cases sensory information interacts with the CPG for phase transitions.

To understand the intrinsic function of a given network, one needs as a minimal requirement to identify which nerve cells are part of the network, the synaptic interactions within the network, and the membrane properties of each cell type. A network like the one controlling locomotion (Fig. B27.1) can be turned on by signals from the brainstem commands region. If a population of excitatory interneurons (E) is turned on, and they interact synaptically with one another to some degree, burst activity can be generated. Such groups of excitatory interneurons can be said to form a burst generating kernel. It is easy to understand that when a group of interneurons are activated, they will generate a train of action potentials, but what is the mechanism responsible for terminating the activity and thus for generating a burst? In the spinal network generating locomotion in the lamprey, the cellular properties of the neurons are of critical importance. During each burst calcium and sodium ions accumulate intracellularly due to both synaptic and spike activity that engages different types of ion channels (Fig. B27.1). This in turn leads to an activation of calcium-dependent K^+ channels and also potentially sodium-dependent K^+-channels. They act in a hyperpolarizing direction in each neuron and help terminate the activity. Since the neurons interact, there will also be less excitatory drive as neurons progressively drop out. In Figure B27.1, the excitatory kernel has been drawn with only two E excitatory neurons, but in reality they represent a population of perhaps 40 or 50 interneurons. These interneurons are glutamatergic and activate both NMDA and AMPA receptors. There are a number of complementary processes that make the neurons cease being active at the end of a burst, and conversely to recruit neurons at the onset of a burst.

In a network generating alternating activity—for instance, on two sides of a segment—there are two burst generating kernels, one on each side, connected with inhibitory neurons (Fig. B27.1). Thus when one kernel of excitatory neurons is active, the contralateral kernel is inhibited, and when its burst is terminated, the other side takes over due to the background drive from the brainstem. The crossed inhibitory neurons thus are responsible for the coordination beween the right and left sides, and they use glycine as a transmitter.

A generalizing conclusion is that in a number of burst generating circuits for, for example, different forms of locomotion, respiration, and saccadic eye movements, burst generating kernels of excitatory interneurons play a key role. In all cases the synaptic interaction is critical, and the cellular properties contribute significantly.

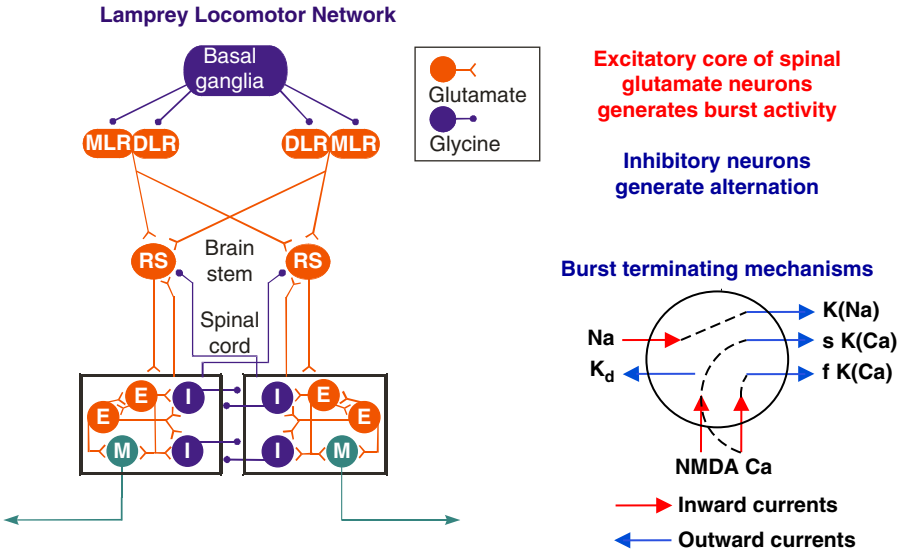

FIGURE B27.1 **The segmental locomotor network of the lamprey.** Schematic representation of the different components of the core neural circuitry that generates rhythmic locomotor activity. All neuron symbols denote populations rather than single cells. The reticulospinal (RS) glutamatergic neurons excite all types of neurons at the segmental level. The excitatory (E) neurons excite all three groups of neurons indicated, and the inhibitory neurons inhibit contralateral neurons and motoneurons (M). The reticulospinal neurons in turn receive excitatory drive from the mesencephalic (MLR) and diencephalic (DLR) locomotor regions, which at rest are under tonic inhibitory control from the output cells of the basal ganglia. When locomotor activity is to be initiated, the inhibitory control from the basal ganglia is removed (see above), and the network is free to operate. To the right, cellular mechanisms are indicated that aid in burst termination. During each burst, Ca^{2+} and Na^+ ions accumulate in the cell that in turn activate calcium and also sodium-dependent K^+ channels that progressively hyperpolarize the cells, thereby terminating ongoing spike activity.

Rhythmic Movements

1. Walking movements (or locomotor behaviors in general) are produced by CPGs in the spinal cord (or ganglia of invertebrates). These spinal CPGs are turned on by descending control signals from particular areas in the brainstem (locomotor areas), which also determine the level of locomotor activity (e.g., slow walking versus trot or gallop). The CPG then sequentially activates motoneurons/muscles that support the limb during the support phase and then move it forward during the swing phase. Sensory stimuli from the moving limb also contribute importantly to regulate the duration of the support phase and the degree of activation of different muscles that are sequentially activated in each step cycle. The relative importance of the sensory component varies between species and with the speed of locomotion. During very fast movements, there is actually no time for sensory feedback to act, and adjustments need instead to be performed in a predictive mode.
2. Chewing movements are controlled by brainstem circuits that in principle are designed in a similar manner to those of locomotion and generate alternating activity between jaw-opener and -closer muscles.
3. Breathing movements are continuously active from the instant of birth to the time of death, except for short voluntary interventions when speaking, singing, or choosing not to breathe for some other reason, like diving. The level of respiration (depth and frequency) is driven by metabolic demands (e.g., pCO_2) detected by chemosensors in the brainstem, where the respiratory CPG is also located. Sensory stimuli from lung volume receptors contribute by setting the level at which the inspiration is terminated and expiration takes over.

Eye Movements

Fast saccadic eye movements are used when looking rapidly from one object to another and are represented with a much more complex organization in the superior colliculus (mesencephalon) than the motor patterns discussed earlier. Saccadic eye movements with different directions and amplitudes can be generated by the stimulation of different microregions in the superior colliculus, according to a well-defined topographical map. Each microregion is responsible for activating a subset of brainstem interneurons, which in turn activates the appropriate combination of eye motoneurons in order to move the two eyes in a coordinated fashion from one position to another. The purpose is to bring the visual object of interest into the foveal region so that it can be scrutinized in the greatest detail. To recruit a saccadic eye movement to a specific site, cortical or subcortical areas have to access the appropriate microregions within the superior colliculus to trigger the specific eye movement desired.

Other types of eye movement control are used when tracking an object that is moving, as when watching a game of tennis. These tracking movements are represented in the cerebral cortex and the brainstem.

Posture

Animals, including humans, have the ability to position the body in a variety of postures. The most stable position is lying horizontally in bed, which requires little activity from the nervous system. The situation is very different when standing and even more so when supporting oneself on one leg. This requires a very structured command to handle the activation of different muscles in the legs, trunk, shoulders, and neck. The nervous system issues this complex motor command to achieve a certain position. The ability to maintain a stable position standing on one leg is then critically dependent on feedback from a variety of sensory receptors that detect falling to one side or the other. These receptors activate reflex circuits that try to counteract the impending loss of balance. Of great importance are the vestibular receptors located in the head, which sense head movements in the different directions. Vestibular reflexes act on the neck muscles to correct the position of the head, and vestibulospinal reflexes act on the trunk and the extensor muscles of the limbs. In addition, vestibular effects are also mediated indirectly by the reticulospinal system. Muscle receptors in neck and limb muscles are of equal importance. They also play a critical role in detecting and compensating for postural perturbations, in particular around the ankle, where skin receptors on the bottoms of the feet are activated. Finally, visual feedback may contribute as when one is standing on a moving surface such as the deck of a boat.

One can decide at will what posture to assume, whether standing on one leg or sitting in an armchair. In that sense, assuming different postures represents a set of voluntary motor acts organized at both the brainstem and forebrain level. At the same time, any given posture is stabilized in an "automatic" way by the sensory mechanisms described above.

ROLES OF DIFFERENT PARTS OF THE NERVOUS SYSTEM IN THE CONTROL OF MOVEMENT

The different basic motor patterns are present in different forms in most vertebrates and invertebrates. In the former, the underlying neural networks are located either in the brainstem or in the spinal cord, and in the

latter, in the chain of ganglia. In vertebrates, from fish to mammals the basic organization of the nervous system is similar with regard to the spinal cord, brainstem (medulla oblongata and mesencephalon), and diencephalon. Each species and larger group of vertebrates may have specializations related to particular types of functions, and complexity increases during evolution. The cerebral cortex, with its distinct lamination, is present in mammals and most highly developed in primates, including humans (Fig. 27.5).

Basic Motor Programs Are Located at the Brainstem–Spinal Cord Level

The brainstem–spinal cord is, to a large extent, responsible for the coordination of different basic motor patterns. The spinal cord contains the motor programs (CPGs) for protective reflexes and locomotion, whereas those for swallowing, chewing, breathing, and fast saccadic eye movements are located in the brainstem (mesencephalon and medulla oblongata). In most cases, however, both the brainstem and the spinal cord are involved to some degree. In mammals as well as lower vertebrates, the brainstem–spinal cord, isolated from the forebrain (di- and telencephalon), is able to produce breathing movements and swallowing, as well as walking and standing. These brainstem–spinal cord animals (referred to as decerebrate models) can thus be made to walk, trot, and gallop with respiration adapted to the intensity of the movements and to swallow when food is put in their mouth. However, they perform these maneuvers in a stereotyped fashion, such as a robot or a reflex machine. The movements are thus not goal directed nor adapted to the surrounding environment, but are nevertheless coordinated in an appropriate way.

Diencephalon and Subcortical Areas of Telencephalon Are Involved in Goal-Directed Behavior

Mammals that are devoid of the cerebral cortex but have the remaining parts of the nervous system intact have been used to investigate the importance of these areas. Such animals display a more advanced behavioral repertoire when compared to the brainstem animals described earlier. At first glance, these decorticate animals look surprisingly normal. They move around spontaneously in a big room and can avoid obstacles to some extent. They eat and drink spontaneously and can learn where to obtain food and search for food when supposedly hungry. They may also display emotions such as rage and attack other animals; however, they appear unable to interact in a normal way with other individuals of the same species. Even without the cerebral cortex, a surprisingly large part of the normal motor repertoire can be performed, including some aspects of goal-directed behavior. Thus the cerebral cortex is not required to achieve this level of complex motor behavior (however, see later discussion). The diencephalon and subcortical areas of the telencephalon of the forebrain contain two major structures that are important in this context: the hypothalamus and the basal ganglia.

Hypothalamus

The hypothalamus is composed of a number of nuclei that control different autonomic functions, including temperature regulation and intake of fluid and food. The latter nuclei become activated when the osmolality is increased (fluid is needed) or the glucose levels become low (food is required). Stimulation of the paraventricular nucleus involved in the control of fluid intake results in a sequence of motor acts involving a number of different motor programs. Continuous activation of this nucleus by electrical stimulation or local ejection of a hyperosmolalic physiological solution leads to an alerting reaction. The animal first starts looking for water (perhaps experiencing a feeling of thirst). It then starts walking toward the water, positions itself at the water basin, bends forward, and starts drinking. The animal will continue drinking as long as the nucleus is stimulated. These hypothalamic structures are thus able to recruit a sequence of motor acts that appear in a logical order. Other parts of this region can elicit rage and attack behavior, as was first described by the Nobel laureate Walter Hess. Humans have seven distinct motor programs to express different types of emotions from crying (already present directly after birth) to smiling, laughing and the display of anger. These motor programs are inborn but what you laugh at is of course culturally bound.

Basal Ganglia

Basal ganglia constitute a second major set of nuclei that is conserved from lamprey to man. They are of critical importance for the normal initiation of motor behavior. They are subdivided into an input region (the dorsal and ventral striatum) activated by the cerebral cortex, thalamus, and an output region referred to as pallidum (globus pallidus interna and substantia nigra reticulata). The output neurons are inhibitory and have a very high level of activity at rest. The purpose is to keep the different brainstem motor centers under tonic inhibition so that they are not activated under resting conditions and also thalamic neurons projecting back to the motor areas of the cerebral cortex. The input stage of the striatum determines the level of activity in the different pallidal output neurons. When a motor pattern, such as a saccadic eye movement, is going to be initiated, the pallidal output

neurons that are involved in eye motor control become inhibited by the striatum. This means that the tonic inhibition produced by these neurons at rest is removed, and the saccadic motor centers in mesencephalon (superior colliculus) are relieved from tonic inhibition and become free to operate and induce an eye saccade to a new visual target.

In contrast to the tonically active output neurons of the basal ganglia (pallidum), the striatal neurons are silent at rest and have membrane properties that make it difficult to activate them from cortex or thalamus, unless the dopamine system is active. The level of activity in dopaminergic neurons in the substantia nigra and associated nuclei determines the responsiveness of striatal neurons. If the level of dopamine activity is reduced, as in Parkinson's disease, it becomes very difficult to activate the striatal neurons and thereby to initiate and carry out most types of movements. This results in a severe handicap characterized by paucity of movement (hypokinesia). The converse condition with enhanced levels of dopamine in the basal ganglia (which can occur as a side effect of medication) results instead in a richness of movements, and even in unintended movements (hyperkinesias). These movements may be well coordinated, but without a purpose, and occur without the conscious involvement of the patient. Dopamine neurons are thus of critical importance for the operation of the striatum and they regulate the responsiveness of the striatal circuitry to input from the cerebral cortex and thalamus. Striatum in itself clearly has a key role for the operation of the entire motor system.

The Cerebral Cortex and Descending Motor Control

In the frontal lobe there are several major regions that are involved directly or indirectly in the execution of different complex motor tasks like Broca's area for speech, or the skilled movements used to control hands and fingers when writing, drawing, or playing an instrument. Some neurons in the frontal lobe are activated not only when we perform a given movement, but also when we see somebody perform the same type of movement. They are therefore called mirror-neurons and may underlie the ability to imitate. Many of these regions are organized in a somatotopic fashion. In the largest area, referred to as the primary motor cortex or M1 in the precentral gyrus, the legs and feet are represented most medially and the trunk, arm, neck, and head are represented progressively more laterally. Areas taken up by the hands and the oral cavity are very large in humans, and are much larger than that for the trunk. This is explained by the fact that speech and hand motor control require a greater precision and thus a larger cortical processing area than the trunk. The latter is important for postural control but is less involved in the type of skilled movement controlled by the motor cortex (Fig. 27.6).

The large pyramidal cells in the motor cortex send their axons to the contralateral side of the spinal cord and are able to activate their target motoneurons directly, but a number of interneurons in the brainstem or spinal cord are also influenced. These long projection neurons are called corticospinal neurons. Corticospinal neurons of the arm region in M1 thus project to arm motoneurons in the spinal cord, as well as interneurons involved in the control of arm, hand, and fingers. In addition to M1, other areas in the frontal lobe, such as the supplementary motor area and prefrontal areas, are involved in other aspects of motor coordination (Fig. 27.7).

The cortical influence on movements is exerted through several different channels, via direct projections to the input stage of the basal ganglia (striatum), through effects exerted via brainstem circuits and as mentioned above also directly to the spinal cord via corticospinal projections. The brainstem contains a number of descending pathways (rubrospinal, vestibulospinal, and reticulospinal pathways) that can initiate movements and correct

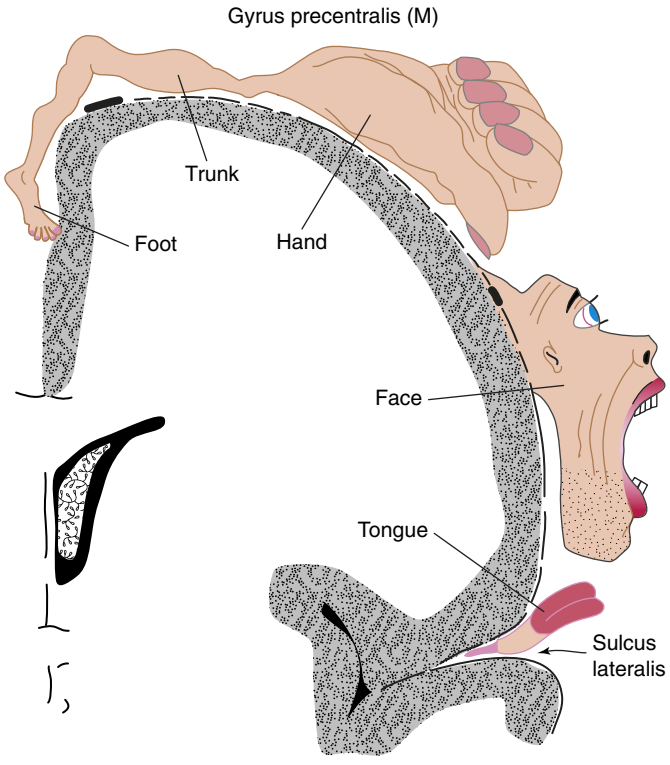

FIGURE 27.6 Organization of the primary motor cortex (M1). The different parts of the body are represented in a somatotopic fashion in M1, with the legs represented most medially, arms and hand more laterally, and the oral cavity and face even more so. Note that the two areas that are represented with disproportionally large regions are the hand with fingers and the oral cavity. They are represented in this way due to the fine control required in speech and fine manipulation of objects with the fingers. *Adapted from Penfield and Rasmussen (1950).*

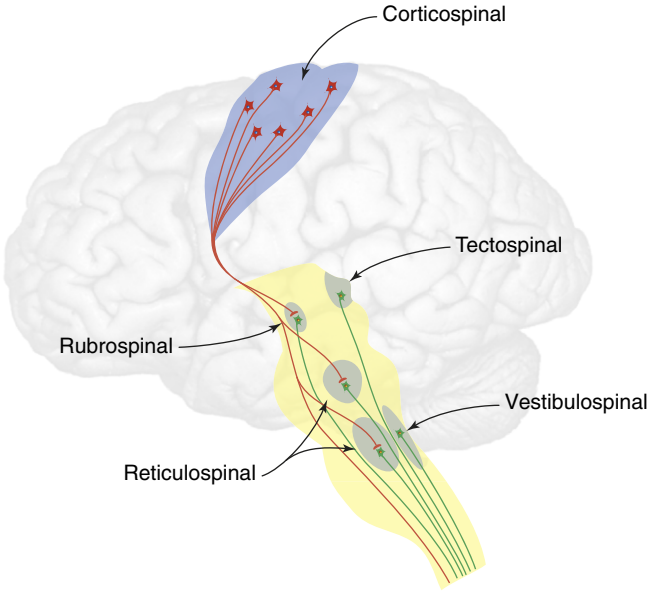

FIGURE 27.7 Descending pathways projecting from the brain that mediate motor actions to the spinal cord. From the cerebral cortex, including M1, a number of neurons project directly to the spinal cord to both motoneurons and interneurons. In addition, they also project to different motor centers in the brainstem, which in turn sends direct projections to the spinal cord. One of these centers is the red (rubrospinal) nucleus, which influences the spinal cord via the rubrospinal pathway. Corticospinal and rubrospinal pathways act on the contralateral side of the spinal cord and have somewhat overlapping functions. They are sometimes referred to as the lateral system, as most of the fibers descend in the lateral funiculus of the spinal cord. Vestibulospinal and reticulospinal pathways are important both for regulating posture and for correcting perturbations, and they mediate commands initiating locomotion. The different reticulo- and vestibulospinal pathways are sometimes lumped together as the medial system, as most of the axons project in the medial funiculus of the spinal cord.

motor performance, while others provide more subtle modulation of the spinal circuitry. The former act rapidly in the millisecond time frame that is required in motor control. Examples of the latter are the slow-conducting and slow-acting noradrenergic and serotonergic pathways. These pathways set the responsiveness of different types of neurons, synapses, and spinal circuits. The cortical control of motor coordination is, in addition to the effects via the basal ganglia, achieved through both direct action on spinal and brainstem motor centers but also to a significant degree by parallel action on a variety of brainstem nuclei. The execution of movements that are initiated from the cortex is, to a large degree, a collaborative effort of many parts of the nervous system. The reticulospinal and vestibulospinal pathways mediate the control of posture, and the former take part in the initiation of locomotion, via the CPG located in the spinal cord (Fig. 27.8).

Judging from experiments on mammals and primates and on patients that have suffered focal lesions of the frontal lobe, the cortical control of movement is of particular importance for dexterous and flexible motor coordination, such as the fine manipulatory skills of fingers and hands and also for speech. It is very difficult for a casual observer to see the difference between a normal monkey moving around in a natural habitat and a monkey that is lacking the corticospinal direct projections to the spinal cord but has all other cortical circuits intact. They are able to move around, climb, and locomote as normal monkeys. It is only when special tests are performed that one can see that delicate independent movements of the individual fingers are incapacitated. This is a type of motor coordination that is needed in monkeys and other primates for skilled manipulations of the environment, such as picking fine food objects from small holes.

The most flexible types of motor coordination, such as the skilled movements of the fingers and hands or in speech, involve the frontal lobes. These types of movements are often referred to as voluntary because they are performed at will. This terminology is commonly used, although inappropriate in that more basic types of motor coordination, such as the ones used when walking, chewing, or positioning ourselves in a relaxed posture, are also controlled by will, although motor coordination is handled to a larger degree by motor programs located at the brainstem–spinal cord level. Thus it appears important not to draw a clear-cut dividing line between the different types of movements, at least with respect to the voluntary aspect of their control.

It is also useful to realize that, to some degree, simple reflexes can also be modulated by will. For instance, the simple skin avoidance reflex (flexion reflex) that causes rapid withdrawal of a finger after touching something painful is subject to such control. Knowledge that the object will be sufficiently hot to be somewhat painful enables this modulation if it is important. If, however, the object is touched without knowing that it is hot, the hand will be withdrawn with the shortest possible latency. Thus, in the entire motor apparatus from the simplest reflex to a skilled movement, there is the possibility for modulation and flexibility. The human nervous system allows a remarkable combination of movements, adapted to different situations. This flexibility is perhaps greater for primates and humans than for any other species. However, other species may perform much better in particular types of specialized movements. A cheetah runs faster, a hawk catches prey at higher speeds, and a fly walks upside down on the ceiling.

Visuomotor Coordination—Reaction Time

Visuomotor coordination is amazing. Consider an approaching object like a ball that you would like to catch. This requires a rapid calculation of the path of the ball and being able to extend the arms and position the hands in the appropriate spot at just the right time. The motor command needs to consider not only the timing but also the

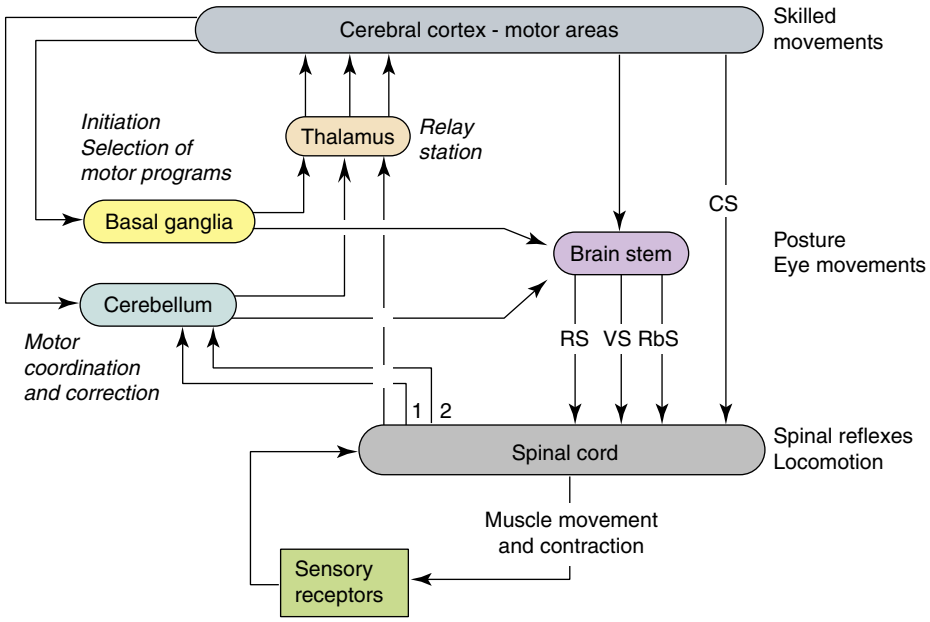

FIGURE 27.8 Summarizing scheme of the interaction between different motor centers. The different major compartments of the motor system and their main pathways for interaction are indicated. The basic functions of the different compartments and descending tracks are summarized on and below the scheme. CS, corticospinal; RbS, rubrospinal; VS, Vestibulospinal; RS, reticulospinal.

Basic functions of descending tracts

Cortico- and rubrospinal
1. Transmission of commands for skilled movements.
2. Corrections of motor patterns generated by the spinal cord.

Reticulospinal
1. Activation of spinal motor programs for stepping and other stereotypic movements.
2. Control of upright body posture.

Vestibulospinal
Generation of tonic activity in antigravity muscles

visuomotor details about joint angles from the eyes to the hand via the neck and head. How is this achieved? The parietal lobe processes visual information that will contribute to the initiation of the motor commands.

In order to arrive at an accurate and precise motor command, a wealth of information needs to be processed about the dynamic and static conditions of the different parts of the body in relation to each other and to the surrounding world. The processing time has been investigated experimentally by having a subject respond to a signal by performing a movement, such as pressing a button when a light goes on. The delay is around 0.1–0.2 s and is called the simple reaction time. It represents a minimal delay for a given test situation that cannot be shortened by training (Fig. 27.9).

The more complex the situation is, the longer the reaction time. If a choice is involved, such as responding by pressing different buttons to light stimuli of different colors, the time delays become much longer than in the simple reaction time task. The choice reaction task time increases in proportion to the level of complexity and the number of choices (Fig. 27.9).

When young children are tested, their reaction times are much longer than in adults. The simple reaction time for a 6-year-old can be three times that of a 14-year-old, and the difference with choice reaction times may be even larger. In everyday life this condition may have severe consequences, such as in an unexpected traffic situation. A 6-year-old will need at least three times more time to interpret what he or she sees. This is the basis for recommending that children below 11 years of age should not ride a bicycle in open traffic. It is noteworthy that this is a gradual maturation process, and training will not shorten the reaction time. During aging the choice reaction time tends to increase again, a factor that can be important when driving a car.

The cerebellum is also involved in the coordination of movement. Although it is smaller than the cerebral cortex

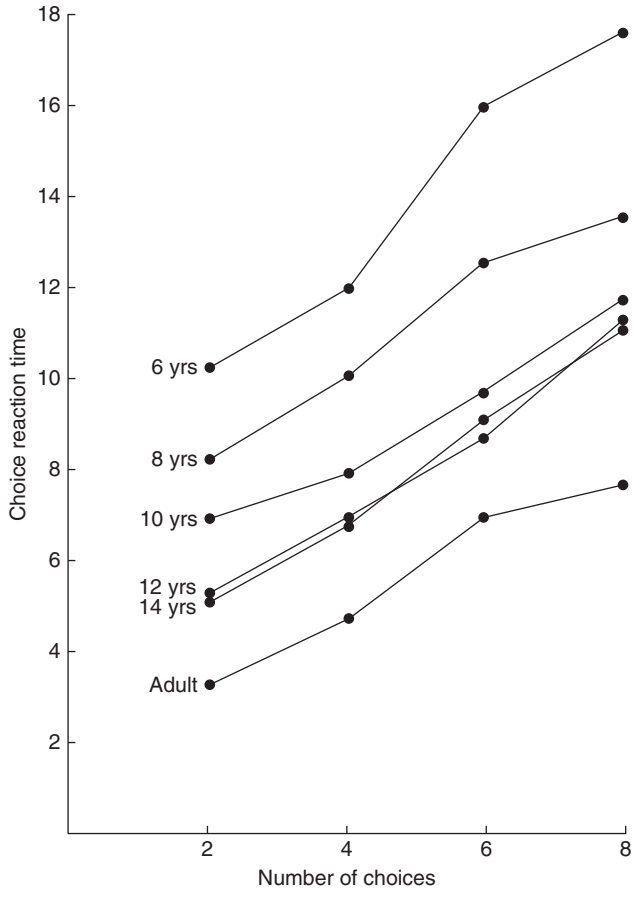

FIGURE 27.9 Reaction time tasks of different complexity and in different age groups. The choice reaction time is plotted versus the number of choices the subject is exposed to for six different age groups. A simple experimental situation with two choices takes an adult 0.3 s to initiate, but a 6-year-old needs around 1.0 s. A 10-year-old falls in between at around 0.7 s. An increase in the number of choices causes a marked increase in reaction time. From a practical standpoint, this provides important information when one considers the possibility for a child to cope with different demanding situations, such as moving around in a modern city. *Data replotted from Conolly (1970).*

in volume, it is thought to contain as many nerve cells as the latter. It has a very stereotyped neuronal organization with two types of inputs from mossy and from climbing fibers. These inputs not only carry information from the spinal cord about ongoing movements in all different parts of the body, but they also carry information from the different motor centers about planned movements even before a movement has been executed. The cerebellum also interacts with practically all parts of the cerebral cortex. This means that it is updated continuously about what goes on in all parts of the body with regard to movement and also about the movements that are planned in the immediate future.

Lesions of the cerebellum lead initially to great problems with postural stability and with a lack of accuracy of movements. Most movements can be carried out, but their quality is reduced drastically. The cerebellum was originally thought to be involved exclusively in the coordination of movement. In addition to motor control, evidence has accumulated that the lateral parts of cerebellum may also be involved in different cognitive tasks.

The cerebellum is subdivided into a great number of different microregions that each process different kinds of information. These different regions respond via their output neurons, called Purkinje cells. The cerebellar cortex contains only inhibitory interneurons, and the two input systems, climbing fibers and mossy fibers (via granular cells), provide the excitatory components. All Purkinje cells are inhibitory and project to the cerebellar nuclei, which in turn are excitatory and project to different motor centers in the brainstem and to the cortex via the thalamus.

Each granular cell receives very specific input from only a few mossy fibers, which are able to make them fire. The granular cell axons form parallel fibers in the cerebellar cortex, and thousands of parallel fibers impinge on each Purkinje cell that has a very extensive dendritic tree. It is believed that only a small portion of these parallel synapses are functional in any given moment but that they are available to become recruited in learning situations. In contrast, there is only one climbing fiber for each Purkinje cell. The climbing fibers can serve as "error detectors," at least under some conditions. Through the effects of climbing fibers on the Purkinje cells, the synaptic efficacy of the parallel fiber input to the Purkinje cell can be modified (depressed). This change in efficacy can last over many hours and possibly much longer and is referred to as long-term depression (LTD). It is generally thought that this LTD can contribute to motor learning (see later). With regard to basic movements such as posture, walking, and the much-studied eye blink reflex, the cerebellum is clearly involved through each movement phase. It is likely that the fine tuning and modification of movements that are required in different behavioral contexts involve the cerebellum. With regard to the eye blink reflex, motor learning has been demonstrated in terms of associating an unconditioned stimulus with a conditioned one. It requires that the cerebellar cortex be intact, which strongly suggests that the cerebellar cortex contributes importantly to this type of motor learning.

There is still, however, much to learn about the actual processing that goes on in the cerebellum, a structure that regulates the quality of motor performance and is involved in some forms of motor learning. A variety of complex motor tasks, including speech and handwriting, can still be performed, but with less accuracy. Thus, the motor programs for these learned tasks cannot be stored exclusively in the cerebellum. When new types of movements are learned, such as riding a bicycle, playing an instrument, or typing at a keyboard, the new stored programs for sequences of motor acts must also involve other

structures in the brain, most likely the basal ganglia and the cerebral cortex.

Motor Learning

All vertebrate and invertebrate species with a nervous system have a motor infrastructure that is determined evolutionarily. In the case of primates, including humans, there are preformed circuits (e.g., CPGs) that allow performance of a basic movement repertoire (e.g., locomotion, posture, breathing, eye movements), as well as basic circuits that underlie reaching, hand and finger movements, and sound production, as in speech. This constitutes the motor infrastructure that is available to a given individual after maturation of the nervous system has occurred.

The motor system is in addition characterized by its ability to learn, in what is referred to as motor or procedural learning. The cortex and basal ganglia play an important role for learning of new motor sequences and skills, and the cerebellum is indispensable for the quality of the different motor patterns and the ability to associate two stimuli, as during conditioned reflexes. When one is able to perform a movement with great precision, like hitting a ball, this may lead to an activation of the dopamine system and a feeling of satisfaction (reward). It has a marked ability to facilitate the development of synaptic plasticity, which is learning. It facilitates the particular synapses that were active as the successful movement was performed.

One can also learn motor sequences, as when playing the flute. The particular finger settings that produce a given tone can be retained in memory, along with the sequence of tones that produce a certain melody. Thus particular muscle combinations that produce a sequence of well-timed motor patterns are stored. Similarly, when learning to pronounce different sounds (phonemes) and combine them into words, the muscle activation patterns are stored. A simpler case occurs when learning to recombine basic movement patterns to be able to maintain equilibrium while bicycling. There are a large number of examples involving different types of motor learning and parts of the body.

It is characteristic of a given learned motor program that one can "call" upon it to perform a given motor act over and over again. Despite this, there is generally little awareness of the way in which the movement is actually performed in terms of the muscles involved and their timing. Information has thus been stored in the nervous system with regard to which parts of the infrastructure of the motor system should be used to produce a given learned motor pattern, as well as the exact timing between the different components. However, the details of the complex storage process are not yet fully understood.

CONCLUSION

After this overview of the motor control system, it should be apparent that biological evolution has succeeded in refining remarkable sensorimotor machinery capable of executing the motor tasks required for the full behavior of a given species. The degree of difficulty involved is apparent when watching the clumsiness and lack of flexibility in robots, characteristic of even the most advanced models that have been developed. Details of the different neural subsystems involved in motor control are dealt with in the following chapters.

CHAPTER

28

The Spinal and Peripheral Motor System

Most coordinated movements involve the use of several muscles, each with a precisely orchestrated timing and pattern of activation and relaxation. Contraction of an individual muscle is controlled by a pool of motor neurons that innervate that muscle. Patterned contraction of several muscles requires coordination between pools of motor neurons. For many movements, interneurons in the spinal cord provide the means for coordinating activity of different motor neuron pools. A key feature of spinal interneurons is their convergent and divergent connections that allow them to integrate signals from different sources. Interneurons that receive inputs from descending motor systems and sensory afferents, for example, can update a voluntary command for limb movement to incorporate feedback from the moving limb. Spinal interneurons also form connections with other spinal interneurons to create networks that generate rhythmic patterns of excitatory and inhibitory activity. These networks play a key role for organizing rhythmic, repetitive movements such as scratching or locomotion. In this chapter, we will use locomotion as an example of a motor behavior to illustrate how the neural elements of the spinal cord and peripheral neuromuscular system operate together to carry out a movement. As details of the motor neurons, spinal interneurons, muscles, and sensory afferents are presented, the primary focus will be on mammals, but variations that occur in other vertebrates and in invertebrates are highlighted in Box 28.1.

LOCOMOTION IS A CYCLE

Locomotion is the act of moving from place to place. Walking, swimming, and flying are modes of locomotion. All modes of locomotion consist of a cycle of patterned and rhythmic activity of different muscle groups. Locomotion can be described by the phase relationships between limbs and between muscle groups during the cycle. Nonlimbed vertebrates such as lampreys swim by alternately contracting and relaxing trunk muscles on the two sides of the body; the sides are in opposite phases of the cycle. Along the length of the lamprey's body, there is a slight phase lag between segments, creating the propulsive wave that moves it forward. In contrast, birds activate their wings synchronously in flight; the limbs are in phase, with no lag.

Stepping, the major form of mammalian locomotion, is a cycle with two phases: stance (the extension phase) and swing (the flexion phase). In people, the stance phase begins when the heel strikes the ground and the leg begins to bear weight. As stance progresses, the weight is gradually shifted forward, rolling from the heel to the ball of the foot. The swing phase begins when the toe leaves the ground and the leg moves forward. To accomplish this motor sequence within one leg, muscles acting across the hip, knee, or ankle are activated in a characteristic pattern (Fig. 28.1). In general, muscles that flex the joint are more active during the swing phase and extensor muscles during the stance phase. However, within each phase, the individual muscles have a more elaborate and finely graded timing and pattern of activation. Stepping can also be performed with different gaits. Gaits can be characterized by the cycle rate, the relative proportion of the cycle spent in swing and stance phases, and the phase relationships between limbs. At slow or moderate walking speeds (i.e., slow cycle rates), the extensor phase is longer than flexion and the extension phases of opposite legs overlap. In a walking gait both feet are in simultaneous contact with the ground for some period during the cycle. As the speed of stepping increases and the cycle is shorter, the duration of the extension phase shortens, with briefer periods of double foot contact. At high speeds where there is no overlap of extension phases between the legs, the gait switches recognizably from walking to running.

BOX 28.1

SPECIES DIVERSITY IN NEUROMUSCULAR SYSTEMS

Not all animals control muscle contraction in the same way as mammals. Differences are found in the proteins and structure of the muscle fiber, the number of neuromuscular junctions on each muscle fiber, the neurotransmitters used at the neuromuscular junction, and the number of motor neurons contacting each muscle fiber. Major differences are found in invertebrates, which often have evolved adaptations that suit their movement patterns or constraints imposed by their environments.

Some invertebrates require muscles that generate great forces or provide mechanical stiffness. One solution used by mussels, the nematode *C. elegans,* and the fruit fly *Drosophila* is the incorporation of molecules of paramyosin into thick filaments, so that additional cross-bridges can be formed. Mussel retractor muscles also have a specialized catch property, in which cross-bridges are tightly bound with low energy expenditure until the catch state is released by neurotransmitter action that leads to phosphorylation of twitchin, a titin-like molecule. Very slow movements can be achieved by long sarcomeres, since Ca^{2+} diffusion throughout the sarcomere takes longer. In mammalian muscle fibers, sarcomeres are generally 2–3 microns long, although longer sarcomeres are occasionally found in muscles that stiffen but do not twitch, such as the tensor tympani muscle of the cat eardrum. In contrast, claw muscles of crabs may have sarcomeres from 6 to 18 microns, and one marine worm was found to have sarcomere lengths of 30 microns.

Most mammalian muscles usually contain a mixture of muscle fiber types, but some animals have distinct muscles for fast and slow movements. Trout, for example, use red muscles composed of slow twitch fibers for sustained swimming and white, fast twitch muscles for leaping and rapid bursts of speed.

Mammals and birds use acetylcholine as the transmitter at the neuromuscular junction. So does *C. elegans*, but many other invertebrates use glutamate, including arthropods such as *Drosophila*, locust, and crayfish. Co-release of glutamate and peptides occurs at some neuromuscular junctions, such as the peptide FMRF-amide in the sea snail *Aplysia*. Crustacean muscles have separate excitatory and inhibitory neuromuscular junctions that use glutamate and GABA.

In mammals, most muscle fibers are innervated by a single motor neuron, with a few exceptions, such as laryngeal muscles and spindles. Innervation by more than one motor neuron is seen in some avian muscles, and many invertebrate muscles. The motor neurons may merely have an additive function, as in *Drosophila,* where recruitment of motor neurons produces graded contractions of the muscle. In other animals, the different motor neurons may play distinct roles. The locust jumping muscle has a dual arrangement, with one motor neuron that produces a rapid and powerful excitation and another that produces graded excitation and contraction.

Lastly, the central control of motor neurons differs. In mammals, a motor neuron action potential leads inevitably to a muscle fiber action potential. In crayfish, presynaptic inhibition of motor terminals allows modulation at a more distant site. Structural specializations, such as electrical synapses onto motor neurons and gap junctions between motor neurons, often occur in invertebrates, but generally are found only during development in mammals. The distributed structure of invertebrate systems and rich palette of ion channels expressed by motor neurons is favorable to the formation of motor pattern generating circuits.

Mary Kay Floeter

Central Pattern Generating Circuits

Although we are able to exert voluntary control over locomotion, the basic patterns of movement for locomotion can be generated by the spinal cord itself, without descending (from the brain) or sensory (from the periphery) inputs. The first demonstration came from Graham Brown (1911), who observed that cats in which the spinal cord and dorsal roots were cut were still able to walk on a treadmill as long as their weight was supported. Because there was no sensory feedback or descending input, he suggested that the rhythmic activity in the hindlimb muscles must be generated by a motor program within the spinal cord. The motor program, also known as a central pattern generator (CPG), needed to explain three important features of locomotion: first, its rhythmic and cyclical occurrence; second, coordinated alternation between flexor and extensor activity within the same limb; and third, alternation between opposite limbs. Brown proposed that the CPG consisted of two mutually inhibitory "half-centers," both under tonic excitation: one half-center drove muscles that flexed the legs and the other drove muscles that extended the legs. The mutual inhibition between the two half-centers would cause activity to oscillate between them, producing alternating limb flexion and extension.

CPGs are now thought to consist of networks of neurons that are synaptically or electrically connected,

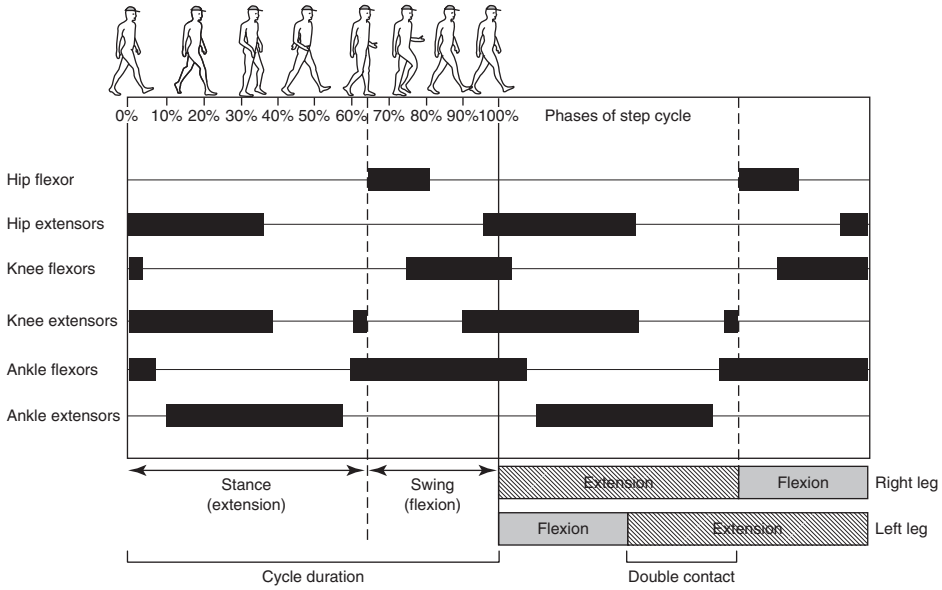

FIGURE 28.1 Schematic diagram of two step cycles in human locomotion. Drawings at the top illustrate the position of the limbs during one cycle. Dark horizontal bars below the drawings show the timing of activity in flexor and extensor muscles of the right leg. The division of each step cycle into stance (extension) and swing (flexion) phases is indicated at the bottom of the figure. During walking, the stance phases of the two legs overlap, with both feet in contact with the ground.

with cellular properties that generate rhythmic firing. CPGs are found in many areas of the central nervous system and are responsible for different types of patterned rhythmic activities such as breathing, chewing, swallowing and walking. The identification and characterization of the neurons that comprise the locomotor CPG in the spinal cord is an active area of research that will be discussed later in this chapter.

Sensory Contributions to Movement

During a movement, the sensory afferents from muscles, joints, and skin will each be activated in a distinct way, reflecting how that movement displaces joints, produces pressure on regions of skin, and stretches individual muscles. For rhythmic movements such as walking, these recurring "multisensory" feedback signals often reinforce activity of CPG circuits. However, when a perturbation occurs during the movement, the resulting sensory signal may evoke a reflex motor response that alters the movement. Many of these reflex responses adapt the movement in an appropriate way to proceed under the changed environmental conditions. Most sensory afferents produce these reflex effects through interneuronal circuits. (The stretch reflex is an exception.) The excitability of many of these interneuronal circuits is usually modulated during movement, allowing reflexes to be suppressed or enhanced at different phases. CPGs are one source of this phase modulation. Many reflexes can also be elicited when the organism is not moving, and in these situations the reflex tends to exhibit a more stereotyped motor pattern.

CONNECTING THE SPINAL CORD TO THE PERIPHERY

Ultimately, movement is carried out by muscles, and the motor commands from the central nervous system must be transmitted to motor neurons that innervate the muscles. The organization of motor neurons into pools, and the manner in which motor neurons' properties are matched to contractile and metabolic properties of the muscle fibers simplify many of the variables needed to be controlled to produce smooth movements with precise amounts of force. Feedback from sensory receptors of the muscle play a key role in monitoring the force and stretch of the muscle. This section will cover some of the basic properties of motor neurons, muscle, and muscle receptors.

Motor Neurons

Motor neurons are located in the ventral horn of the spinal cord. The pool of motor neurons that innervates an individual muscle forms an elongated column that typically extends over two or three spinal cord segments. Intermingled among the large α-motor neurons that innervate skeletal muscle fibers are smaller γ-motor neurons, which innervate muscle spindles, as well as β-motor neurons, which dually innervate skeletal muscle and spindles. The α-motor neurons are the largest neurons in the spinal cord, with myelinated axons that exit the spinal cord through the ventral roots and travel in peripheral nerves to innervate muscles. Their axons also give off small branches within the spinal cord, called recurrent collaterals, that synapse on inhibitory interneurons, called

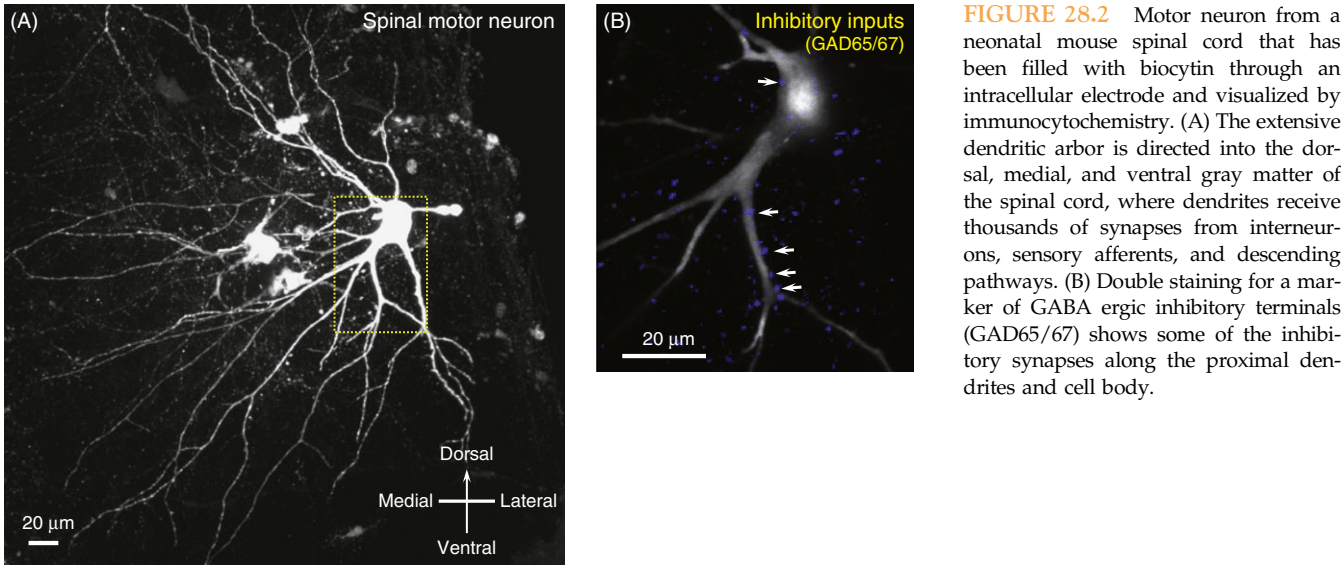

FIGURE 28.2 Motor neuron from a neonatal mouse spinal cord that has been filled with biocytin through an intracellular electrode and visualized by immunocytochemistry. (A) The extensive dendritic arbor is directed into the dorsal, medial, and ventral gray matter of the spinal cord, where dendrites receive thousands of synapses from interneurons, sensory afferents, and descending pathways. (B) Double staining for a marker of GABA ergic inhibitory terminals (GAD65/67) shows some of the inhibitory synapses along the proximal dendrites and cell body.

Renshaw cells (Alvarez & Fyffe, 2007), and other motor neurons. The extensive dendritic tree of motor neurons extends into the dorsal and ventral horns, receiving thousands of synaptic inputs from excitatory and inhibitory neurons (Fig. 28.2). At the neuromuscular junction, the synapse between the motor axon and the muscle fiber, acetylcholine is the transmitter used by mammals, but other transmitters, such as the peptide CGRP or glutamate/aspartate (Mentis et al., 2005; Nishimaru, Restrepo, Ryge, Yanagawa, & Kiehn, 2005), coexist in many motor neurons and may play a particular role during development and at the central synapses formed by recurrent collaterals.

Muscle Contraction

Movement is achieved by the contraction of muscles that are attached to the skeleton or soft tissues, such as muscles producing facial expressions. A skeletal muscle is made up of thousands of individual muscle fibers. Each muscle fiber is a multinucleated cell, a few centimeters long, that contains the contractile proteins, actin and myosin, arranged into thick and thin filaments in repeating units called sarcomeres (Fig. 28.3). The myosin molecule head region contains an ATP ase enzymatic activity that is sensitive to levels of intracellular calcium. Myosin heads are loosely bound to actin at rest, but when intracellular calcium rises, the cross-bridge strengthens, causing myosin to break down ATP. When this occurs, the cross-bridge loosens, and the myosin head swivels along the actin filament to another binding site. The repetition of this swiveling movement in the presence of elevated intracellular calcium and ATP causes thick and thin filaments to slide along each other and shorten the sarcomere length. Shortening of sarcomeres shortens the muscle, or if the muscle is carrying a heavy load, the muscle may only stiffen in an isometric contraction.

The process of muscle contraction begins with an action potential in the motor axon that causes release of acetylcholine at the neuromuscular junction. In mammals, normally every spike in the motor axon produces an action potential in the muscle fiber because an excess amount of acetylcholine is released (Box 28.2). In adult mammals, each skeletal muscle fiber has one neuromuscular junction innervated by one motor neuron. Muscle fiber action potentials lead to the activation of voltage-gated calcium channels in the membrane that interact with calcium release proteins in the sarcoplasmic reticulum, an organelle in the muscle fiber that stores and releases calcium near the sarcomeres. This interaction couples excitation to muscle contraction. Other proteins in the sarcoplasmic reticulum reuptake calcium, leading to relaxation.

Three Basic Muscle Fiber Types

Muscle fibers are classified into types according to their contractile and metabolic properties. Contractile properties refer to the muscle fiber's speed of contraction and relaxation, and the specific force it can produce. Contractile properties are mainly determined by the isoform of myosin that is expressed by the muscle fiber, particularly the myosin heavy chain gene, although the genes for other proteins associated with the sarcomere and the sarcoplasmic reticulum are expressed in fiber-type specific patterns that match the properties of the myosin isoform. The contractile properties of a muscle fiber are classified as slow twitch or fast twitch. Metabolic properties refer to whether aerobic or anaerobic pathways are used to produce energy (ATP) from fuels. Muscle fibers with abundant mitochondria are able to use oxidative (aerobic) metabolism, which

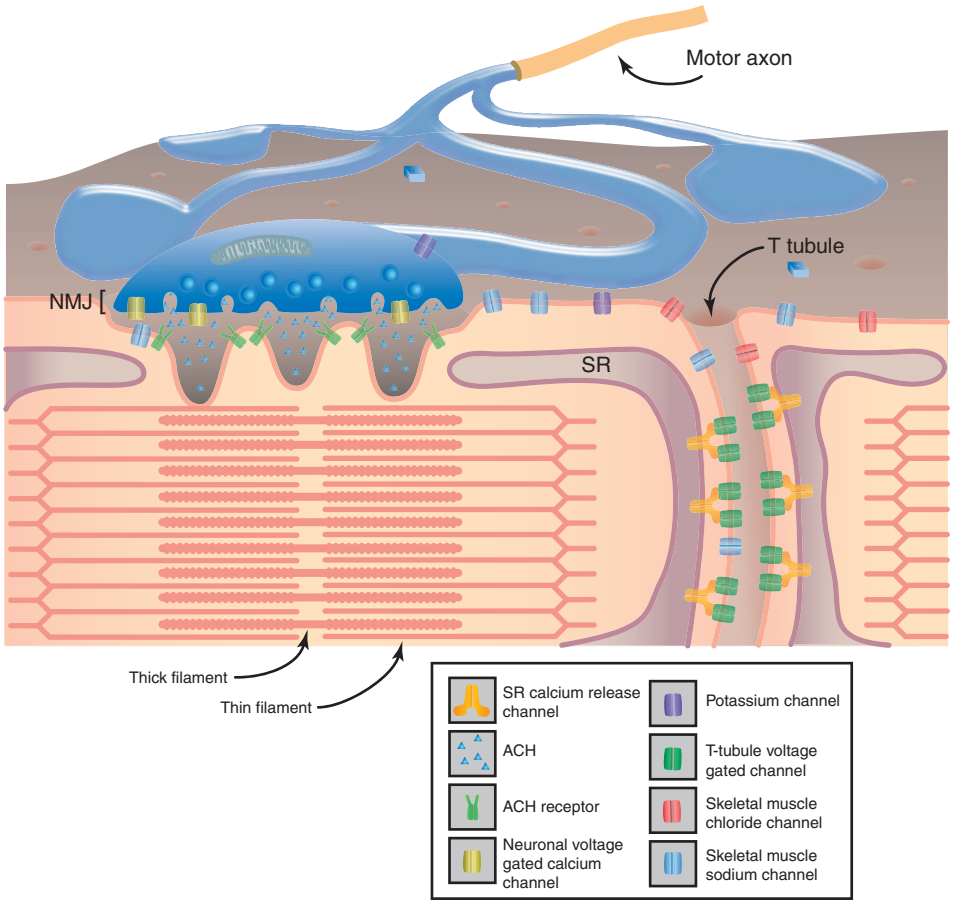

FIGURE 28.3 Diagram of the structure of the muscle showing the relationship between the thick and thin filaments that form the sarcomere, the sarcoplasmic reticulum (SR), and the location of the ion channels of the motor axon, neuromuscular junction, and muscle membrane. *With permission, modified from Cooper and Jan (1999).*

provides relative resistance to fatigue as long as there is a good blood supply. Muscle fibers with few mitochondria rely on stored fuel, such as glycogen, which can more easily be depleted and also produces lactic acid as a byproduct of glycolysis. There are three basic muscle fibers types in adult skeletal muscle. Type I fibers have a slow twitch but have a good capacity for oxidative metabolism. Type IIA fibers have a fast twitch and can use both aerobic and anaerobic metabolism, giving them an intermediate resistance to fatigue. Type IIB fibers produce a fast twitch, but rely mainly on anaerobic glycolysis for their energy. Most muscles contain a mixture of all three fiber types, in proportions that reflect the typical usage of the muscle.

Motor Unit Types

A "motor unit" is defined as one motor neuron and all of the muscle fibers it innervates. In mammals, each muscle fiber is innervated by only one motor neuron, but one motor neuron innervates many muscle fibers as its axon branches in the muscle. However, all muscle fibers of one motor unit are of the same fiber type. Motor units cluster into three basic types based on the three physiological properties of twitch speed, the amount of force produced, and fatigability (Fig. 28.4). Type S motor units are defined by the properties of slow twitch, small amounts of force, and high resistance to fatigue. Type FR motor units are defined by fast twitch, moderately large force, and relative resistance to fatigue. Type FF motor units have fast twitch, produce the highest forces, and fatigue quickly.

The physiological properties of the motor neurons and the muscle fibers they innervate are closely matched. Type S motor neurons innervate Type I fibers. Type S motor neurons have small cell bodies and dendritic arbors, allowing them to be depolarized easily. Afterhyperpolarization following each motor neuron spike promotes a steady rate of firing that allows forces produced by successive twitches of the muscle fibers to summate (Fig. 28.4B). With their steady firing rates and resistance to fatigue, Type S motor units are optimal for the sustained firing needed for postural and tonic movements. Each Type S unit individually contributes only a small amount of force to a muscle's contraction,

BOX 28.2

MYASTHENIA AND MYASTHENIC DISORDERS

Normally every action potential of the motor axon releases more than enough transmitter needed to produce a muscle fiber action potential. This occurs because both the amount of transmitter released from the presynaptic motor axon terminal and the density of AChRs on the postsynaptic muscle fiber exceed that needed to produce an end plate potential (EPP) large enough to initiate a muscle fiber action potential. Genetic or acquired diseases that reduce the safety factor of neuromuscular transmission are called myasthenic disorders (Fig. 28.B1). Myasthenic disorders cause weakness that fluctuates with use of the muscle. The most common is the acquired autoimmune disorder myasthenia gravis, caused by antibodies that bind to AChRs at the neuromuscular junction. The antibodies interfere with ACh binding and lead to internalization of AChRs and, ultimately, the loss of junctional folds. The reduced numbers of functioning AChRs produce a smaller EPP that fails intermittently to trigger a muscle fiber action potential. However, in myasthenia gravis the presynaptic terminal remains normal, such that a short burst of stimulation will produce facilitation of transmitter release, increasing the concentration of ACh in the cleft and transiently improving neurotransmission. Acetylcholinesterase inhibitors provide symptomatic improvement by blocking the breakdown of ACh, allowing a longer effect on residual receptors. Another autoimmune myasthenic disorder, Lambert–Eaton myasthenic syndrome, is caused by antibodies that bind to presynaptic voltage-gated calcium channels. Less ACh is released at the neuromuscular junction, producing small EPPs that fail to trigger action potentials

Congenital myasthenic syndromes (CMS) are extremely rare, but provide important insights into the function of components of the neuromuscular junction. Postsynaptic CMS stem from a deficiency and/or altered kinetic properties of the AChR. More than 40 different mutations in subunits of the AChR have been described. Most mutations decrease subunit expression or prevent subunit assembly or glycosylation, leading to reduced numbers of functioning AChRs and thereby smaller EPPs. In fast channel CMS, mutations produce decreased binding affinity for ACh, leading to a smaller quantal response and miniature EPP amplitude, without reducing the numbers of AChRs. In contrast, the slow channel CMS stem from mutations that prolong the channel opening episodes. Slow channel mutations cause depolarization block due to temporal summation of the prolonged EPPs. In the long term, cationic overloading of the postsynaptic region leads to destruction of the junctional folds and loss of AChRs. Presynaptic CMS are less common. They are caused by mutations that lead to a paucity of synaptic vesicles or defects in ACh resynthesis or vesicular packaging. As a result, fewer vesicles are released or fewer ACh molecules are contained in each vesicle, and EPPs are smaller. Identifying CMS as involving pre- or postsynaptic components and understanding how these alterations affect neuromuscular transmission are necessary for developing rational therapies for these disorders.

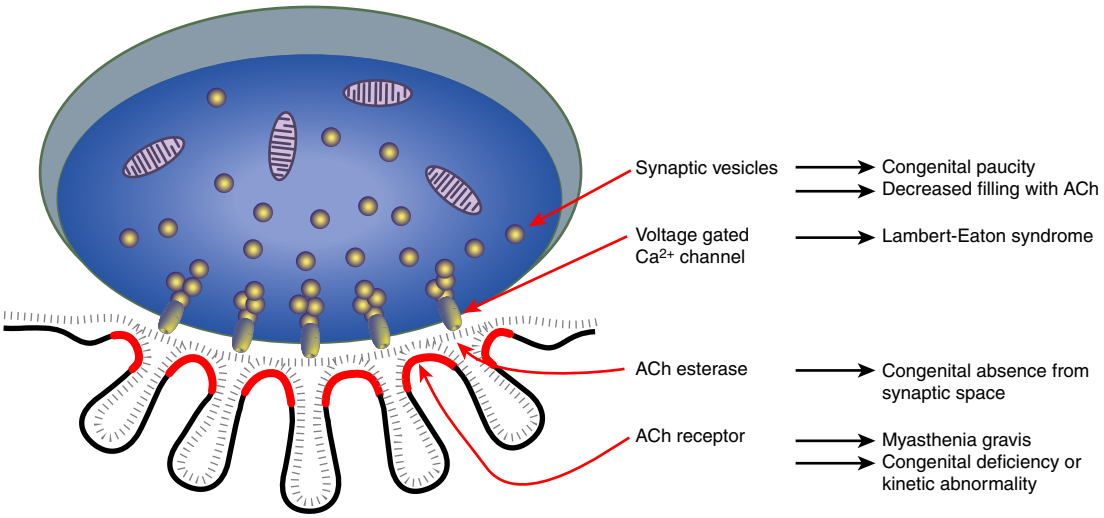

FIGURE 28.B1 Schematic diagram of a neuromuscular junction showing key components subserving neuromuscular transmission and the myasthenic disorders associated with these components.

Mary Kay Floeter

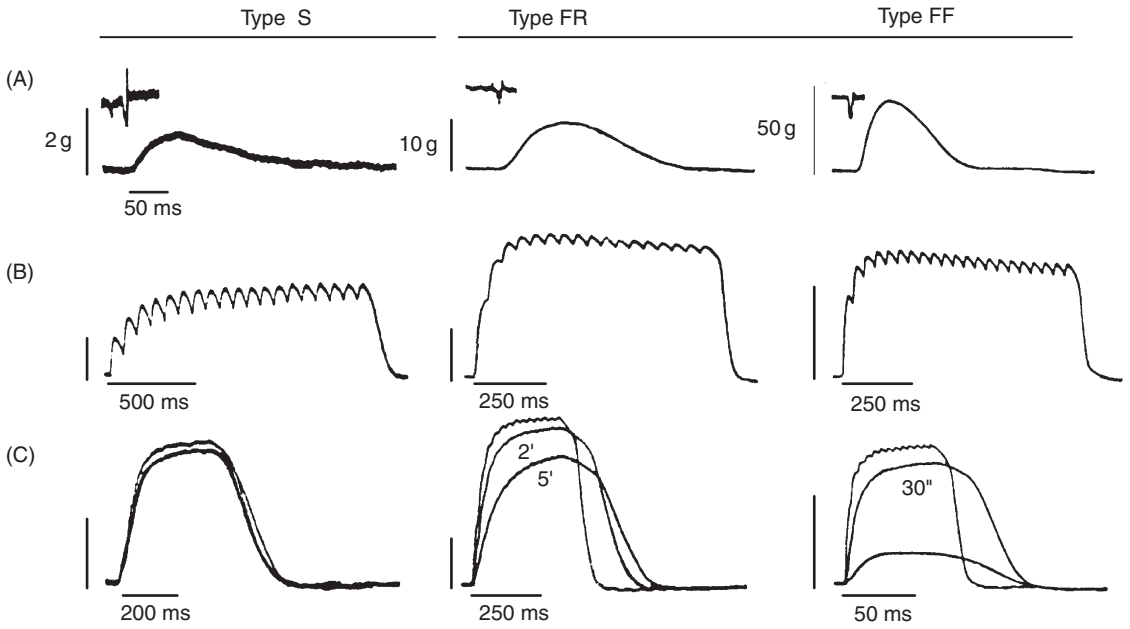

FIGURE 28.4 The three motor unit types (S, FR, and FF) can be defined experimentally by measuring their contractile properties and fatigability. Panels A–C show recordings of muscle force, with insets in A showing recordings of motor neuron action potentials. Note different time and amplitude calibration scales for each of the motor units. (A) Single twitches produced by one action potential of the motor neuron. (B) Maximal force produced by repetitive stimulation of the motor neuron to produce an unfused tetanus. In addition to differences in maximal force, the "sag" property, a dropping off of tension during maintained stimulation, is seen in FR and FF units. (C) Fatigability is demonstrated by a drop in the tension produced by a single twitch after short periods of activation, as noted. Note that S units show little fatigue, whereas FF units fatigue within 30 s. *Reproduced with permission from Burke, Levine, Tsairis, and Zajac (1973).*

but typically Type S units make up a large proportion of the motor units innervating a muscle. In contrast, Type F motor neurons have large cell bodies and dendritic arbors, shorter afterhyperpolarizations and somewhat faster firing rates. Type FR motor neurons innervate Type IIA muscle fibers, and Type FF motor neurons innervate Type IIB muscle fibers. Type FR motor units are optimal for fast, powerful movements. Type FF units are mainly used in movements that require brief bursts of muscle strength. Most muscles contain a mixture of motor unit types, intermingled in a mosaic pattern.

TABLE 28.1 Size-Related Properties of Motor Neurons

Properties that Increase with Size	Properties that Decrease with Size
Diameter of soma and axon	Resistance to fatigue
Conduction velocity	Ia EPSP amplitude
Complexity of axonal collaterals	Input resistance
Membrane area, dendritic extent	Membrane resistance
Rheobase	Time constant
Muscle fiber diameter	Duration of after-hyperpolarization
Maximum force output	Twitch contraction time
	Twitch relaxation time

The Size Principle and Orderly Recruitment

Most movements don't require a muscle to contract at its maximal strength, and only a fraction of the hundred or more motor neurons in the pool that innervates that muscle will need to fire. For most movements, motor units are recruited in an orderly sequence, first described by Henneman (1957), as based on the "size" of the motor neuron. According to the size principle, motor units that produce the smallest amounts of force are the first to begin firing, and motor units that produce larger forces will be progressively recruited as the muscle makes progressively stronger contractions. Many of the anatomical and physiological properties of the motor unit types correlate with measures of size (Table 28.1). These size related properties favor activation of motor unit types in the following order: Type S → Type FR → Type FF. The pool of motor neuron innervating each muscle contains varying proportions of Type S and Type F motor neurons, although generally Type S motor neurons are more abundant.

Many of the properties that produce orderly activation by size are stable and intrinsic to the motor neuron–cell body diameter, for example. Most extrinsic synaptic inputs also reinforce recruitment according to the size principle. This occurs because a synaptic current will produce a larger

postsynaptic potential in a smaller, compact neuron with a higher input resistance. Because most sources of synaptic input are distributed uniformly to a motor pool, EPSP or IPSP amplitudes correlate with the motor neuron size—larger in Type S motor neurons than Type F motor neurons. This means, for example, that stretch of a muscle that activates the primary muscle spindle (Ia) afferent will produce the largest Ia EPSPs in Type S motor neurons, and these will be the first units recruited to fire in the stretch reflex. In the less common situation in which synaptic inputs are not uniformly distributed to every motor neuron in the pool, alternative recruitment sequences are possible.

Stronger muscle contractions are produced not only by recruitment of additional motor units, but also by increasing the firing rates of motor units that are already actively firing. The relative use of recruitment and rate modulation to maintain a desired profile of force varies according to the muscle and the level of force. In some muscles, such as the small hand muscles, several motor units begin firing at low levels of force, and fine gradations of force are controlled by modulating their firing rates. In other muscles, recruitment and rate coding occur together in a more balanced fashion throughout the working force range of the muscle.

Muscle Afferents

Muscles contain two kinds of specialized sensory receptors that provide feedback to the spinal cord and brain. Muscle spindles sense muscle stretch or length, and Golgi tendon organs (GTOs) sense the load upon the muscle (Fig. 28.5). The spindle consists of an encapsulated bundle of modified muscle fibers, called intrafusal fibers, that lie within the muscle in parallel to the skeletal muscle fibers. The spindle receives both sensory and motor innervation. Sensory innervation is supplied by one primary afferent, the Ia fiber, and several secondary, group II afferents. Ia afferents are more sensitive to quick stretches, such as a tendon tap or vibration, and group II afferents maintain a firing rate proportional to the level of sustained stretch. Intrafusal muscle fibers are innervated by γ-motor neurons and β-motor neurons. The motor innervation of intrafusal fibers adjusts the tension of the spindle to compensate for changes in muscle length when a muscle contracts and shortens. When the muscle shortens the spindle can become momentarily slack, causing a pause in spindle afferent firing. However, during most voluntary movements, α and γ-motor neurons are co-activated such that the sensitivity of the spindle is maintained during the muscle shortening. Nevertheless, because γ-motor neurons have a separate innervation of intrafusal muscle fibers, the nervous system can separately adjust the sensitivity of the spindle for different types of movement.

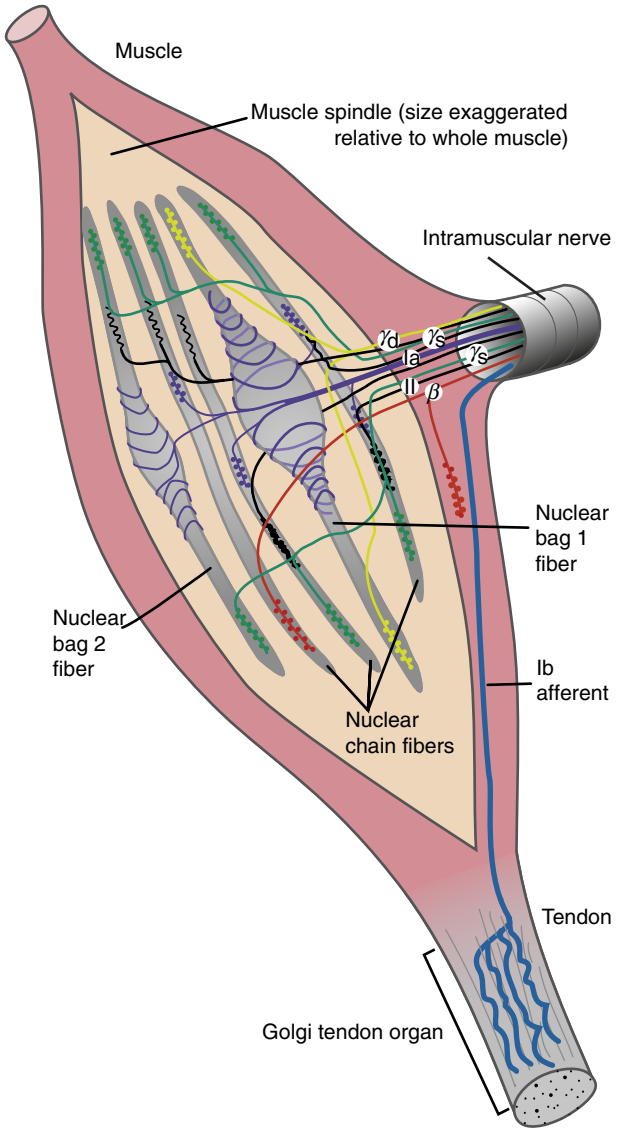

FIGURE 28.5 Structure and innervation of muscle spindles and Golgi tendon organs. The sensory innervation of the spindle is through primary (Ia) spindle afferents that innervate both nuclear bag and nuclear chain intrafusal muscle fibers and secondary (II) afferents that innervate nuclear chain fibers. Motor innervation of the spindle is supplied by static and dynamic γ-motor neurons and by β-motor neurons.

Golgi tendon organs lie at the junction of the muscle and tendon, in series with the muscle. GTOs are sensitive to the forces generated by muscle contraction against a load. Each GTO senses the force generated by a small number of motor units that insert onto a local region of the tendon. The axons of the GTOs are called Ib afferents. Like Ia afferents, they are large myelinated axons with fast conduction velocities. Unlike spindles, GTOs do not have motor innervation.

Muscles are innervated by smaller diameter and unmyelinated afferents, called group III and IV afferents, that respond to extracellular substances, such as the acidic substances released during fatiguing exercise. These slowly conducting afferents relay the sense of muscle pain and soreness and produce reflex actions with a relatively slow time course.

Stretch Reflexes

The muscle stretch reflex plays an important role in providing feedback during movements. The stretch reflex consists of a monosynaptic response from the direct connection between Ia afferents and motor neurons, that may be followed by polysynaptic reflex activity. At rest, the stretch reflex can be obtained by a quick stretch, such as by tapping on a muscle tendon, which produces a burst of action potentials in the Ia spindle afferents (Fig. 28.6). In the spinal cord, the Ia afferents synapse on the motor neurons of the muscle containing the spindle (the homonymous motor neurons) and, to a lesser extent, on motor neurons that innervate other muscles (heteronymous motor neurons). The rapid volley of glutamatergic Ia EPSPs caused by a quick stretch can summate in the motor neuron, and if sufficient depolarization occurs, an action potential occurs that produces contraction of the muscle, with a jerk of the limb.

If the stretch reflex is elicited during movement, the Ia EPSPs will summate with inputs from other sources such as CPGs and descending inputs. Stretch during the phase of movement when the muscle is active will add to other sources of motor neuron depolarization, and the reflex motor response will enhance the ongoing contraction. Stretch of the muscle when it is out of its active phase will produce a smaller motor response, if any. In this way, the spatial summation of postsynaptic potentials contributes to phase modulation of the stretch reflex. Additionally, there is modulation of the stretch reflex through presynaptic inhibition of the Ia afferents during movement (Rudomin, 2009). This presynaptic inhibition is produced by GABAergic spinal interneurons that synapse on the Ia afferent terminals, forming axo-axonic synapses (Betley et al., 2009). Presynaptic inhibition reduces the release of glutamate from Ia afferents, leading to smaller Ia EPSPs in the motor neuron, but it does not affect the size of other inputs to the motor neuron. The GABAergic interneurons mediating presynaptic inhibition are strongly activated by antagonist Ia afferents, that is, from spindles of muscles that produce the opposite movement, as well as by CPGs and descending inputs. Thus, presynaptic inhibition of a muscle's stretch reflex is strongest when the muscle contraction is out of phase with the movement cycle, when its antagonist muscle is contracting.

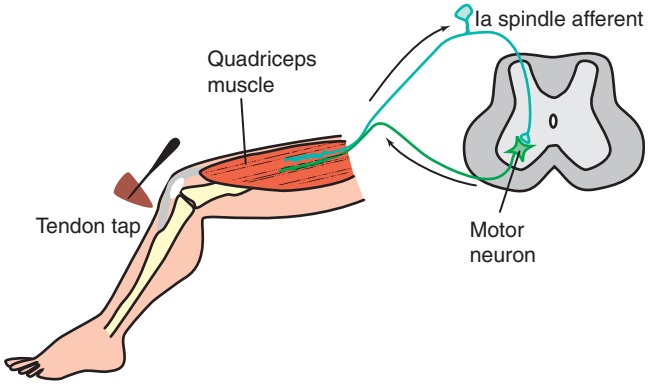

FIGURE 28.6 Basic circuitry underlying the knee-jerk stretch reflex. Ia spindle afferents from the quadriceps muscle make monosynaptic, excitatory connections on α-motor neurons that innervate the quadriceps.

Summary

Motor neurons are highly diverse in terms of their morphology, connectivity, and functional properties and differ significantly in their response to disease. There are two main types of motor neuron disease, amyotrophic lateral sclerosis (ALS) and spinal muscular atrophy (Box 28.3). Motor neurons innervating different muscles have recently been shown to degenerate in a preferential manner.

Muscles are innervated by motor neurons in the ventral horn of the spinal cord. The motor unit consists of one motor neuron and all the muscle fibers it innervates. Physiological properties of each motor neuron match the contractile and metabolic properties of its muscle fibers. Type S motor units have a slow twitch, high aerobic capabilities, and fatigue resistance. These smaller motor units are the first recruited for contraction and are heavily used for slow, sustained postural movements. Type F motor units innervate muscle fibers with a fast twitch and are recruited for more forceful or ballistic movements. Type FR motor units use aerobic and anaerobic metabolism and are relatively resistant to fatigue. Type FF motor units use anaerobic metabolism and fatigue quickly. In the pool of motor neurons innervating a muscle, motor neurons are recruited in an orderly fashion, beginning with Type S units that generate small amounts of force, followed by units that generate greater forces. As the muscle contracts, changes in its length are detected by spindles, specialized receptors that lie within the muscle. The load on the muscle is detected by a second specialized receptor, the Golgi tendon organ. These sensory receptors of the muscle provide feedback to the spinal cord allowing reflex changes in drive to the muscles.

BOX 28.3

MOTOR NEURON DISEASES

There are several neurological disorders that selectively affect motor neurons. Spinal muscular atrophy (SMA) is a hereditary disorder in which motor neurons develop normally but begin to degenerate not long after birth. Autosomal recessive SMA was described by neurologists long before its cause was known, and several different clinical phenotypes were described. SMA causing weakness in infancy was called Werdnig-Hoffman disease; SMA causing weakness later in childhood was called Kugelberg-Welander disease. Both forms of SMA are caused by a mutation in a gene called "survival of motor neuron" or SMN gene. The SMN protein is widely expressed in neurons and has a role in processing mRNAs. It is not known why motor neurons are more vulnerable to mutations of SMN than other cells. In an X-linked SMA, called Kennedy's disease or spinal and bulbar muscular atrophy (SBMA), weakness begins in adult life in affected males. Motor neurons innervating facial and jaw muscles are often affected early on. The mutation in SBMA is a triplet repeat expansion in the androgen receptor gene that leads to expression of an abnormal androgen receptor. The androgen receptor is expressed in motor neurons, and over time accumulation of the abnormal receptor leads to degeneration of the motor neuron.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a disease with degeneration not only of the motor neurons, but also of corticospinal neurons of the motor cortex. In most patients with ALS, the disease is not hereditary and its cause is unknown. There are a few hereditary forms of ALS that make up a small percentage of all patients with ALS. Nevertheless, the identification of familial ALS (FALS) genes has provided ideas about pathways that may be responsible for causing sporadic ALS. The first gene mutation identified in FALS encoded the enzyme superoxide dismutase, SOD1. Studies using transgenic mice expressing the mutant SOD1 gene showed that FALS was not caused by loss of enzyme activity, but by abnormal properties of the mutant SOD1 protein. Studies expressing mutant SOD1 in different cell types are revealing that glial and inflammatory cells may also contribute to motor neuron degeneration in FALS (Boillee, Vande Velde, & Cleveland, 2006). The ability to manipulate the expression of mutant genes in animal models promises to provide an invaluable contribution to finding causes and treatment of ALS.

SPINAL INTERNEURON NETWORKS

So far, this chapter has discussed how the output of the spinal cord produces muscle actions through the motor neurons. This section will focus on spinal interneurons—neurons with a cell body in the spinal cord and an axon that synapses on another spinal neuron. Spinal interneurons have three important functions for motor control: they relay sensory inputs from the periphery that may modulate the motor output, they relay as well as modulate signals from the brain via descending pathways, and they form networks that produce patterned rhythmic activity. It is important to note that some interneurons may participate in all three functions, switching from one role to another during specific movements or carrying on two roles simultaneously.

Historically, interneurons were identified and named by their axonal projections, the location of their soma, their neurotransmitter, or by a physiological effect or reflex that they mediated. Later, populations of neurons were identified by their pattern of activity during movements, visualized using activity-dependent dyes. More recently, molecular biology tools have enabled scientists to identify interneurons based on their gene expression pattern and cell lineage. Molecular markers have been used to identify several classes of interneurons and motor neurons. Four distinct populations of interneurons, designated as V0, V1, V2, and V3, have been identified in the ventral spinal cord by their developmental pattern of expression of transcription factors, proteins that regulate gene expression (Jessell, 2000; Goulding & Pfaff, 2005; Grillner & Jessell, 2009). The "V" denotes the *ventral* location, and each subclass appears at a distinct position along the dorso-ventral axis (0 most dorsal, 3 most ventral) of the ventral spinal cord (Fig. 28.7). The cellular identities of spinal interneurons are further refined by the emergence of combinations of transcription factors that are expressed in these neurons (Goulding 2009; Alaynick, Jessell, & Pfaff, 2011).

Models for Studying the Locomotor CPG Network

At the beginning of the chapter, we noted that the CPG network needed to produce three fundamental features of locomotion: generation of a cyclical rhythm, coordinated alternation between antagonist flexor and extensor muscles, and coordination between limbs. Figuring out what makes up a CPG—the neurons involved, the connections between

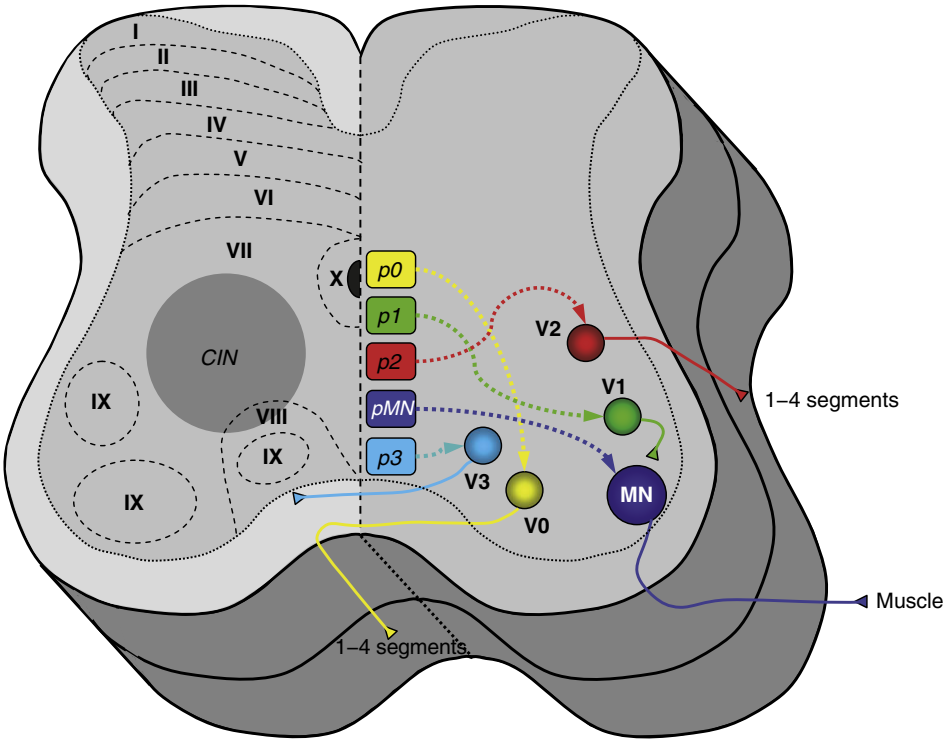

FIGURE 28.7 Cross-sectional schematic of the spinal cord depicting on the right side the origin of interneuron and motor neuron populations defined in developmental studies using molecular markers for cell identification. The ventral interneurons (V), derived from progenitors (p), are marked as V0–V3 based on the distinct position along the dorso-ventral axis (0 most dorsal, 3 most ventral) of the ventral horn. The left side of the spinal cord depicts the general location of commissural interneurons (CINs) and the Rexed's laminae. CINs are characterized based on the projection of their axons, as ascending, descending, or both.

these neurons, the synaptic interactions, and the contributions from cellular ion channels—is challenging. To tackle this problem, researchers construct models that can be tested and refined by experimental observations. As noted earlier, Brown (1911) first proposed a model with mutually inhibitory half-centers driving flexors and extensors. Grillner (1985) proposed three important modifications: (1) that at each joint, movement in one direction was produced by a "burst generator" unit, a half-center capable of independent rhythmic activity; (2) as in Brown's model, that flexion and extension at each joint were controlled by reciprocally connected burst generators to form a unit CPG; and (3) that multijoint coordination was achieved by loose or adjustable coupling between the mosaic of unit CPGs controlling each of the joints (Fig. 28.8).

Experimental findings have led to further refinements of the proposed organization of the CPG network. For example, the rhythm and timing of the network may be controlled separately from the patterning of the network output. In studies of locomotor rhythms in the neonatal rodent spinal cord, the CPG appears to be distributed among several spinal segments. Studies in the isolated neonatal rodent spinal cord preparation maintained *in vitro* (Fig. 28.9) show a difference in the rhythmogenic capacity between the rostral (upper) and the caudal (lower) segments of the lumbar spinal cord. The upper lumbar (L1–L3 in rodents) segments seem to be most important for rhythm generation compared to caudal lumbar segments (Cowley & Schmidt, 1997; Tresch & Kiehn, 1999). In experiments using calcium dyes to

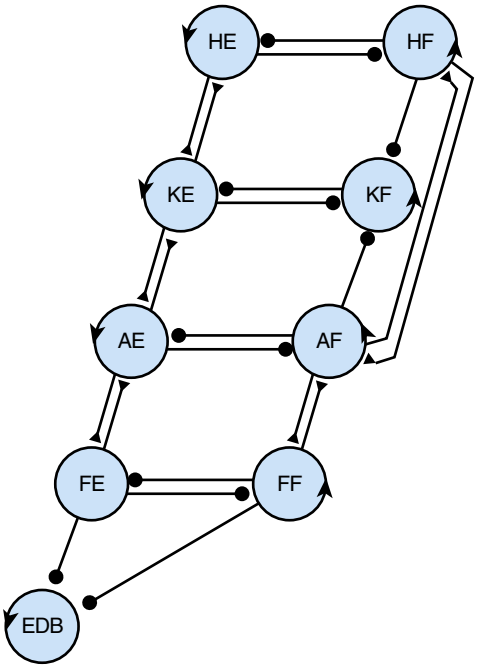

FIGURE 28.8 Scheme for multijoint coordination within the leg using a mosaic of "unit CPGs." Burst generators produce movement in one direction, extension or flexion, at the hip (HE, HF), knee (KE, KF), ankle (AE, AF), or foot (FE, FF), with a separate generator for the muscle that lifts the toes (EDB). Burst generators for flexion and extension at each joint are mutually inhibitory, forming a unit CPG that produces alternation. The strength of excitatory (triangles) and inhibitory (circles) connections between unit CPGs can vary to create a variety of different gaits. *Reproduced with permission from Grillner (1985).*

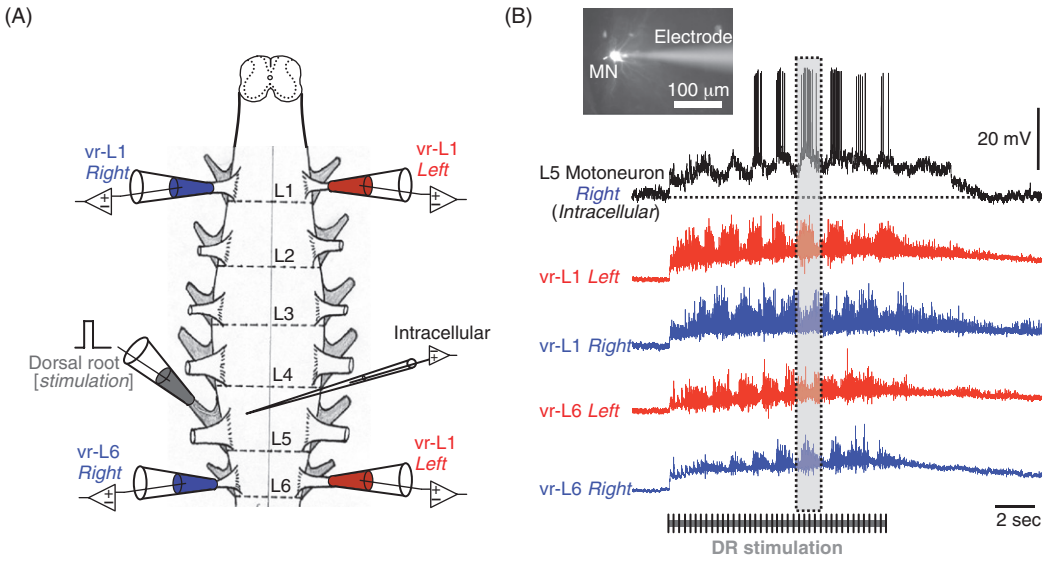

FIGURE 28.9 (A) Drawing of an isolated neonatal mouse spinal cord used in *in vitro* experiments. Suction electrodes are placed in the ventral lumbar (L) roots to record motor neuron activity (blue and red) or in the dorsal root (gray) to stimulate sensory afferents. Glass electrodes are used to record intracellularly from individual neurons in the spinal cord. (B) The image shows a motor neuron (MN) filled with a fluorescent dye and visualized with a microscope during intracellular recording. Sustained electrical stimulation of sensory afferents can evoke rhythmic activity in motor neurons (intracellular record) characterized by rhythmic membrane depolarization which reaches the threshold for action potentials. This stimulation also results in alternating rhythmic activity between the left and right side of the spinal cord [compare the activity in L1-left (red) and L1-right (blue)]. It also produces alternating activity between the upper (L1) and lower (L6) segments of the spinal cord [compare the 2 red traces or the 2 blue traces], as highlighted in the dotted box. The duration of afferent stimulation is indicated by the graded bar.

visualize motor neuron activity, rhythmic signals from different parts of the lumbar (L1, L2) and sacral (S1–S3) segments rose, peaked, and decayed in a rostrocaudal sequence, giving rise to a rostrocaudal "wave" of motor neuron activation during each locomotor cycle (Bonnot, Whelan, Mentis, & O'Donovan, 2002). The importance of the upper and mid-lumbar cord for rhythm generation has also been observed in the spinalized cat and is consistent with case reports in humans noting that irritative lesions of the upper lumbar cord produce stepping movements.

Excitatory Interneurons Responsible for the Rhythm

Maintaining rhythmic bursting in an interneuronal network requires a source of excitatory drive. Although this drive could be provided by tonic excitation, such as from descending pathways, a more robust rhythm is possible if there are excitatory cells within the network that have intrinsic properties that allow rhythmic and repetitive firing (Box 28.4). A few classes of rhythmically active excitatory interneurons have to date been identified in the mouse spinal cord and implicated in central pattern generation. The first type of interneurons is a population of V3-derived interneurons expressing the transcription factor Sim1 (Zhang et al., 2008). These interneurons release glutamate and target motor neurons, as well as V1 and V2 interneurons. The second type of interneurons is a subpopulation of V2 interneurons, termed V2a, which express the transcription factor *Chx10* (Crone et al., 2008; Zhong et al., 2010). The *Chx10*+ interneurons release glutamate and also contact motor neurons directly. Another candidate population of excitatory interneurons was first identified in mice with deletions in the genes for two axon guidance molecules, *EphA4* and *ephrinB3* (Kullander et al., 2003). These mice had an abnormal hopping pattern of gait. Subsequent study of interneurons expressing *EphA4* receptors showed that they were glutamatergic and rhythmically active during locomotor behavior (Butt, Lundfald, & Kiehn, 2005). Most of the interneurons were "last order" interneurons—that is, interneurons that synapse directly on motor neurons. Finally, another interneuron that is rhythmically active during fictive locomotion using isolated spinal cords of mice is the interneuron that expresses the transcription factor Hb9, which is also expressed in the motor neuron lineage during development (Hinckley, Hartley, Wu, Todd, & Ziskind-Conhaim, 2005; Wilson et al., 2005).

Although these interneurons have been proposed as candidates forming the rhythm generating circuitry of the CPG, it is important to note that more work needs to be done to prove their essential role in rhythmogenesis. Not all rhythmically active neurons are components of the CPG network. Some may receive rhythmic output from CPG neurons. Causality needs to be established

BOX 28.4

NONLINEAR PROPERTIES OF MOTOR NEURONS AND CPG INTERNEURONS

Experimental evidence from animal work indicates that motor neurons can participate actively in generating the rhythmic pattern observed during locomotion. Some motor neuron properties can be turned *ON* during locomotion due to synaptic inputs which in turn, produce nonlinear input–output relationships.

For example, there is a locomotor-dependent reduction in the threshold for spike generation, resulting in higher motor neuronal excitability. Two other motor neuronal properties susceptible to interact significantly with afferent inputs are the membrane potential oscillations known as *locomotor-drive-potentials* (LDP) and *plateau potentials*. LDPs are membrane potentials in motor neurons, in which a wave of depolarization during the active phase alternates with a wave of hyperpolarization during the antagonist phase of locomotion. Experiments in the cat have shown that the depolarizing phase is due to an excitatory synaptic drive, while the hyperpolarizing phase is due to an inhibitory drive.

Plateau potentials are a behavior of the membrane potential in which the potential jumps between two states (bistable behavior). This motor neuron behavior has been observed in animals such as the turtle, mouse, and cat. This behavior is mediated mostly by a persistent inward current that at least in part is mediated by calcium channels. Ionic currents responsible for the generation of plateau potentials in motor neurons are found predominantly in dendrites because they possess voltage-sensitive L-type calcium conductances. These currents are turned *ON* by some neuromodulators such as serotonin or noradrenalin. Data from animal experiments have shown that synaptic inputs on dendrites can recruit plateau potentials and evoke sustained discharge. It is possible therefore that dendritic activation can amplify the effect of synaptic inputs from either sensory or descending afferents. Although the role of plateau potentials is still unclear during normal development, one hypothesis is that motor tasks like posture or stepping recruit fatigue-resistant motor units readily with sustained discharge produced by persistent inward currents without continuous network inputs.

From animal experiments there are some preliminary data that indicate that plateau potentials and sustained discharge are also found in some spinal interneurons. As in motor neurons, these plateaus are facilitated by serotonin and noradrenalin. In a similar fashion as in motor neurons, plateau potentials activated in interneurons by neuromodulators released during locomotion may act as an amplification step of synaptic inputs in particular dendrites. Because interneurons integrate sensory and supraspinal information, this mechanism may be very effective in the transmission of inputs relevant for the generation of motor neuronal activities.

George Mentis

experimentally by temporarily and reversibly removing the participation of a population of interneurons during fictive locomotion. Strategies using genetic markers that identify specific populations of interneurons to drive selective expression of reversible inhibitors of activity provide a potential tool to test the contribution of distinct interneuron populations to CPG networks (Lechner, Lein, & Callaway, 2002).

Reciprocal Inhibition between Flexor and Extensor Muscles

Alternation between flexor and extensor muscles that act across the same joint is another fundamental feature of locomotion, as well as of many other limb movements. There are several spinal interneuron circuits that act in different ways to produce reciprocal inhibition between antagonist muscles. Presynaptic inhibition of antagonist Ia afferents by GABAergic interneurons, described earlier, prevents spindle afferents from activating a muscle when it is stretched by the contraction of its antagonist. Another interneuron, the glycinergic Ia inhibitory interneuron (IaIN), produces postsynaptic reciprocal inhibition. The IaIN was so named because it is activated by the muscle's Ia afferents and inhibits motor neurons innervating the antagonist muscle (Wang, Li, Goulding, & Frank, 2008). The IaIN synapses on the soma and main dendrites of motor neurons, producing a fast, potent IPSP that lasts only for several milliseconds. The IaIN develops from the V1 cell lineage, and can be recognized by its expression of the transcription factor *En1* (Siembab et al., 2010). Almost every input that excites a motor neuron will also excite the IaINs that project to its antagonist's motor neurons. For this reason, voluntary contraction of a muscle will produce inhibition of its antagonist muscle, and, likewise, the stretch reflex of a muscle will produce inhibition of its antagonist. The excitability of IaINs is determined by their many inputs, and the strength of reciprocal inhibition

can be varied to allow movements that use co-contraction. IaINs are rhythmically active during locomotion, even without feedback from muscle stretch (Pratt & Jordan, 1987). This observation led to the proposal that IaINs were involved in producing the flexor-extensor alternation of the locomotor CPG. However, this proposal is not supported by more recent studies using neonatal mice in which the V1 lineage neurons were reversibly inactivated. In this study, the locomotor rhythms became slower, but still exhibited alternation of flexors and extensors (Gosgnach et al., 2006).

Interneurons Involved in Left–Right Coordination

Interlimb coordination is the third fundamental feature of locomotion. To date, the leading candidate interneurons for coordinating activity between the limbs during locomotion are several populations of commissural interneurons (Fig. 28.10). Commissural interneurons have axons that cross the midline of the spinal cord at the level of the ventral commissure. They can be subdivided into three classes based on the direction of their axon: descending, ascending, or both (bifurcated axon). Descending commissural interneurons have been extensively studied in the rodent spinal cord during early development. Their axons project at least two spinal segments away from their soma to make contacts with other ventral horn interneurons and motor neurons. Some ascending commissural interneurons are cholinergic and are thought to transmit information to the upper parts of the spinal cord. Many of the commissural interneurons arise from the V0 and V3 cell lineage. The V0 lineage gives rise to ascending commissural interneurons, whereas the V3 lineage comprises a mixed population of commissural as well as ipsilaterally projecting neurons. In transgenic mice lacking the V0 commissural interneurons, the coordination between left and right legs was disrupted during locomotor rhythms, with episodic synchronous activation between sides (Lanuza, Gosgnach, Pierani, Jessell, & Goulding, 2004). These results suggest that this class of ascending commissural interneurons contributes, in part, to side-to-side interlimb coordination.

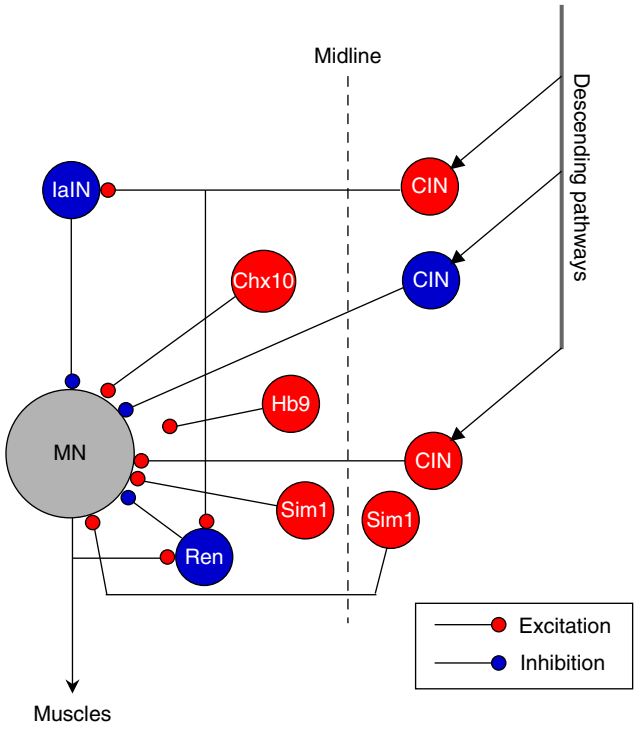

FIGURE 28.10 Schematic model with some of the known candidate interneurons that are involved in the modulation of the mammalian locomotor CPG. Excitatory interneurons (red) with rhythmic activity include classes of commissural interneurons (CIN) and the interneurons identified by expression of Sim1, Chx10, and Hb9 transcription factors. Inhibitory interneurons (blue) that participate in termination of excitatory bursts include the Renshaw (Ren), the Ia interneuron (IaIN), and some commissural interneurons (CIN). *Modified from Grillner (2006).*

Recurrent (Renshaw) Inhibition

The recurrent collaterals of motor neurons synapse on a population of inhibitory interneurons in the ventral horn, called Renshaw cells (Renshaw, 1946). Renshaw cells use glycine or GABA as their transmitter and during development may contain both transmitters. Renshaw cells project back to homonymous motor neurons and synergist motor neurons in adjacent segments. They provide a negative feedback reflex called recurrent inhibition that limits the firing of motor neurons (Eccles, Fatt, & Koketsu, 1954). During locomotor rhythms, Renshaw cells are rhythmically active, as expected, since they receive rhythmic synaptic inputs from motor neurons. Their role in voluntary movements is uncertain, but one possibility is that they enhance the contrast between the active motor neurons and quiescent synergist motor neurons in adjacent segments. Renshaw cells arise from the V1 cell lineage, as do IaINs. During development, Renshaw cells, like IaINs, receive input from Ia afferents (Mentis, Siembab, Zerda, O'Donova, & Alvarez, 2006). In the studies in neonatal mice, mentioned above, reversible inactivation of the V1 lineage neurons that produced slowing of locomotor rhythms included Renshaw cells and IaINs (Gosgnach et al., 2006).

Summary

In addition to serving as relays for sensory and descending pathways, interneurons of the spinal cord interconnect to form CPG networks that can produce rhythmic firing. Several models of the CPG network have been proposed to guide experimenters. There has been significant progress in unraveling the

interneuronal network that forms the spinal central pattern generator for locomotion. New experimental techniques have allowed the identification in neonatal rodents of interneurons that are candidates for mediating some of the fundamental properties of locomotion: rhythmicity, alternation of antagonist muscles, and interlimb coordination.

DESCENDING CONTROL OF SPINAL CIRCUITS

Neural circuits in the brainstem, cerebellum, and cerebral cortex are activated with locomotion and other movements. For locomotion, the cerebral cortex not only formulates conscious decisions about initiating and maintaining walking, but plays a role in adaptations of gait, particularly visually guided walking. Recordings from corticospinal neurons in cats as they stepped over obstacles placed in their field of vision showed that many corticospinal neurons changed their firing rates, often with a timing appropriate for driving the altered contraction patterns of specific muscles (Drew, Prentice, & Schepens, 2004). Corticospinal input, affecting motor neurons directly or through spinal CPG interneurons, can alter the limb's trajectory with a high degree of precision, in a similar manner to a goal-directed reaching movement. In people, clinical observations and experimental studies suggest that supraspinal regions play a more active role in locomotor control than in lower mammals (Box 28.5).

BOX 28.5

NEURAL CONTROL OF HUMAN WALKING

Human walking is a complex behavior that is based on integration of activity from descending supraspinal motor commands, spinal neuronal circuitries, and sensory feedback. Accumulating evidence suggests that humans, as well as other species, have a network in the spinal cord that is capable of generating basic rhythmic walking activity. Rhythmic leg movements can be induced by epidural electrical stimulation after a clinically complete spinal cord injury (SCI). Spontaneous involuntary rhythmic leg movements have also been reported after a clinically complete and incomplete SCI. However, even though this evidence suggests the existence of a CPG network in humans, in all these cases sensory input likely contributed to rhythm generation. Furthermore, clinically complete injuries are not always anatomically complete. As a result, the evidence for existence of a CPG in humans remains indirect.

Noninvasive electrophysiological techniques have provided information about how certain brain structures contribute to human walking. For example, the involvement of the primary motor cortex, where the corticospinal tract originates, has been demonstrated, in part, with transcranial magnetic stimulation (TMS). Several groups have found changes in the size of motor evoked potentials (MEP) in lower limb muscles elicited by TMS during walking, showing that transmission in the corticospinal tract is modulated during the gait cycle. However, TMS of the motor cortex activates cells with monosynaptic or polysynaptic connections to the spinal motor neurons. The size of the MEPs elicited by TMS reflects not only cortical excitability changes, but also changes at a sub-cortical level. To more precisely identify the various sites activated by the magnetic stimulus, Petersen, Christensen and Nielson (1998) tested the effect of TMS on the H-reflex, an electrical homologue of the monosynaptic stretch reflex, during walking. They found that at least part of the MEP modulation was caused by changes in the excitability of corticospinal cells with direct monosynaptic projections to the spinal motor neurons. They also found that TMS over the motor cortex at intensities below the threshold for activating spinal motor neurons depressed ongoing muscle activity in the tibialis anterior muscle of the leg during walking. This effect was thought to be caused by activation of cortical inhibitory interneurons targeting cortical pyramidal tract neurons (Petersen et al., 2001).

During human walking, sensory feedback plays an important role in driving the active motor neurons and providing error signals to the brain that can be used to adapt and update the gait pattern. In healthy humans, a study in which a plantarflexion perturbation was induced during the stance phase of the gait cycle provides clear evidence for this. This experiment showed a drop in electromyographic (EMG) activity in the plantarflexor muscles, even when the common peroneal nerve that innervates the ankle dorsiflexor muscles was blocked by local anesthesia (Sinkjaer, Anderson, Ladouceur, Christenson, & Nielson, 2000). These results demonstrated that sensory feedback from plantarflexor muscle contributed to the active drive of motor neurons during walking. Additional information about the contribution of sensory feedback to the control of locomotion has been gathered from studies that investigate changes in EMG responses in lower limb muscles after stimulation of cutaneous and proprioceptive afferents during walking. The amplitudes of the EMG responses to electrical stimulation are dependent on the phase (or time) of stimulation during

BOX 28.5 *(cont'd)*

the gait cycle. For example, electrical stimulation of the human sural nerve results in facilitation of the ankle flexor muscle tibialis anterior during early swing, but leads to suppression when delivered during late swing (reflex reversal). It has been proposed that the phase-dependent modulation of EMG responses may have functional relevance at various times in the step cycle. For example, a flexor reflex is appropriate at the onset of the swing phase when the leg is flexed, but the same reflex is not convenient at the end of the swing phase when the foot is ready to take up body weight. To some extent this modulation is mediated by supraspinal centers. To examine this possibility, a combination of cutaneous input and activation of supraspinal pathways by TMS has been used during the gait cycle. Available data suggest that long-latency reflexes elicited by cutaneous electrical stimulation are in part transcortically meditated.

In summary, in recent years a combination of neurophysiological techniques has provided important insights that have improved our understanding about the neural control of human walking. This behavior is based on the integration of activities from spinal circuitry, sensory feedback, and descending motor commands.

Monica Perez

Brainstem Control of Spinal Interneuron Networks

The brain transmits signals for movement to the spinal cord through several descending fiber tracts: corticospinal, vestibulospinal, and reticulospinal, as described in the following chapter. For locomotion, supraspinal regions are thought to activate spinal cord CPGs through brainstem relays. In decerebrate cats, electrical stimulation of several areas of the brain can elicit stepping. These include the diencephalon and cerebellum, but the most critical region is an area in the brainstem near the pedunculopontine nucleus known as the mesencephalic locomotor region (MLR). The MLR receives inputs from several forebrain regions, including the basal ganglia. The MLR does not connect directly to spinal CPG neurons, but synapses on reticulospinal neurons in the pons and medulla that receive a wide variety of sensory and descending inputs. Some of the reticulospinal axons in the pontomedullary formation travel in the ventral and ventrolateral tracts (funiculi) of the spinal cord. Lesions of these funiculi disrupt the ability to initiate and maintain locomotion. Sparing of at least some fibers in the ventrolateral funiculus markedly improves locomotor recovery after spinal lesions in cats (Rossignol, Drew, Brustein, & Jaing, 1999) and could be critical for the recovery of locomotor movements after spinal injury in humans.

In addition to their role in triggering rapid changes in locomotion and regulating postural balance, descending fiber systems also modulate physiological properties of spinal neurons. For instance, the plateau potentials and bistability in motor neurons (Box 28.4) depend on tonic activity in descending serotonergic pathways. Stimulation of the dorsolateral funiculus of the spinal cord in turtles, an area which is thought to contain descending pathways from the raphe nucleus, increased the excitability of motor neurons and promoted production of plateau potentials.

SENSORY MODULATION

Although spinal CPGs can generate the basic pattern of neural activity that organizes muscle contractions into a recognizable movement such as locomotion, the final pattern is fine-tuned by sensory inputs as well as descending systems. As noted earlier, most sensory inputs affect motor neurons through polysynaptic, interneuronal circuits. The interneurons that process sensory information typically integrate sensory signals with inputs from a variety of sources, including CPG networks and descending pathways. As a result the reflex motor response can vary depending on the phase of the movement cycle, or it may only occur when the animal is in the "state" of moving, or it may even be reversed between resting and active states. Earlier we discussed the muscle sensory receptors and some of the reflex changes they mediate. This last section will present a sampling of other sensory reflex pathways.

Flexor Reflexes

A wide variety of sensory stimuli can evoke reflex flexion of the limb. Flexor reflexes may have several roles: they serve a protective function, reflexively withdrawing the limb from potentially harmful stimuli, and they may be used in movements that require coordinated multijoint flexor movements. Usually the reflex consists of contraction of muscles that flex several joints coupled with relaxation of muscles that extend those joints. Extension of the contralateral limb may also occur. Flexor reflexes can be elicited by group II and III muscle afferents, joint afferents, and high- and low-threshold cutaneous afferents. Because these afferents elicit a common action, they are sometimes called "flexor reflex afferents" (FRAs). The muscles activated by the sensory stimulus respond with short and long latency bursts of contraction. These contraction components are thought to be generated by distinct

interneuron circuits. The late components can be differentially enhanced by treatment with L-dopa in spinalized animals. It has been suggested that interneurons mediating the late flexor reflex could function as a half-center for flexion, as proposed in models of the locomotor CPG.

Cutaneous Reflexes

In contrast to the widely distributed flexor reflex, there are a number of reflexes in which stimulation of small areas of skin evokes a reflex limited to a few muscles. One example of a local cutaneous reflex is the stumbling corrective reaction. When the skin on the top of the foot is stimulated during walking, the foot is lifted higher, as if to step over an obstacle. The stumbling corrective reaction is phase dependent, occurring only when the limb is in the swing phase of the step cycle. This and several other local cutaneous reflexes are oligosynaptic, involving only a few interneurons. The last-order interneurons in these cutaneous reflexes connect with relatively limited sets of motor neurons. It has been proposed that such interneurons offer a means to control or alter activity of specific muscles during movement without involving the interneurons of pattern generating circuitry.

Summary

Several areas of the brain give rise to descending pathways that connect to spinal interneurons and, to varying extents in different species, to motor neurons. Areas of the brainstem are critical for relaying descending commands for locomotion. Volitional movements also seem to employ spinal interneuron circuits for organizing routine patterns of muscle contraction, within the context of a planned goal. Sensory feedback from skin, joints, and most muscle afferents provide fine-tuning of basic movement patterns. The reflex motor responses evoked by most sensory afferents are relayed through interneurons.

CHAPTER

29

Control of Movement

Four major pathways descend from the brain to the spinal cord to control muscles that move the skeleton. These pathways arise in the vestibular nuclei (vestibulospinal), in the brainstem reticular formation (reticulospinal), in the red nucleus (rubrospinal), and in the cerebral cortex (corticospinal). While these four descending pathways work together to provide seamless control of movements from postural reflexes to delicate manipulation, they can be separated broadly into two main systems. Vestibulospinal and reticulospinal pathways can be grouped together as a medial system: their axons descend through the brainstem and spinal cord close to the midline, and chiefly innervate axial and proximal limb musculature in which motoneurons lie medially in the ventral horn. The corticospinal and rubrospinal pathways together can be considered a lateral system: their axons descend in the lateral column of the spinal cord and chiefly innervate limb musculature, particularly distal musculature, in which motoneurons lie laterally in the ventral horn. More than just an anatomical distinction, the medial and lateral systems have different principal functions. The medial system provides postural control. Monkeys with medial system lesions fall over when they attempt to ambulate and climb, but when supported, they can use their hands and fingers adeptly in retrieving food pieces from narrow holes (Lawrence & Kuypers, 1968b). The lateral system provides fine control of voluntary movement. Monkeys with lateral system lesions rapidly recover the use of all four extremities in activities such as ambulation and climbing, but they are unable to make the fine finger movements needed to extract small pieces of food from narrow holes (Lawrence & Kuypers, 1968a). This chapter examines the contributions of first the medial and then the lateral systems to control of movement.

THE MEDIAL POSTURAL SYSTEM

Vestibular and Reticular Nuclei Control Posture and Reflex Behaviors

Early experimenters found that some degree of postural and reflex control remains after higher brain centers are completely cut off from the brainstem and spinal cord, and that the extent of preserved motor function is determined by the level of the transection that disconnects the upper portions of the brain. There is no functional regeneration of central neuronal pathways after damage, and when the spinal cord is separated from all of the brain above, as can occur in motor vehicle or equestrian accidents, the result is quadriplegia, loss of all voluntary movement and postural control in the arms and legs. Only the spinal reflexes discussed in the preceding chapter return, and those return only when spinal cord neurons recover excitability after a prolonged period of limp (flaccid) paralysis called spinal shock.

Transections at higher levels of the neuraxis leave part of the brainstem connected with the spinal cord. Chronic bulbospinal cats, those with medulla and spinal cord below the transection, show primitive attempts at righting themselves when placed on one side. Effective righting may be observed in chronically surviving animals subjected to transection that leaves the mesencephalon intact below the level of the cut. As the level of transection is raised, posture and balance become progressively closer to normal. The decorticate animal produced by the ablation of cerebral cortical tissue has many apparently normal postural reactions, lacking only certain placing and stepping reactions. Progressively higher brain transections enable more of the vestibular (balance) and proprioceptive (muscle

© 2013 Elsevier Inc. All rights reserved.

and position sense) circuitry that participates in postural control, as well as improving the overall balance between excitatory and inhibitory influences on the spinal cord.

Nuclei of the brainstem reticular formation with intact spinal projections after high brainstem transaction include the locus ceruleus and raphe nuclei, the origins of descending noradrenergic and serotonergic neuromodulatory axonal projections that alter excitability of neurons in the spinal cord, as discussed in the preceding chapter. Parts of the raphe nuclei also have a role in circadian rhythms (Chapter 39), and projections of the locus ceruleus are involved in attention (Chapter 46) and internal reward (Chapter 41). Other areas of the reticular formation involved in motor control have specific functions in generation of the locomotor rhythm (MLR, mesencephalic locomotor region, Chapter 27) and rapid eye movements (PPRF and MRF, Chapter 32). Nuclei of the reticular formation are most often studied from the perspective of their contributions to specific functional systems described in other chapters and through the actions of their monoamine neuromodulators noradrenalin (norepinephrine) and serotonin. Vestibular nuclei influence several brain regions and are studied for their contributions to spatial cognition, autonomic function, eye movements, and postural reflexes.

The Vestibular Apparatus Senses Head Rotation and Tilt

The sensory inputs most important for postural responses are visual, proprioceptive, and vestibular. Vestibular sensory signals from the labyrinth of the inner ear provide direct information about rotations of the head and its orientation with respect to gravity. Two types of vestibular transducer organs—semicircular canals and otolithic maculae—are located within the labyrinth of the ear and respond to accelerations of the head in space. The three semicircular canals and the two otolithic maculae are stimulated by rotational and linear acceleration, respectively. The mechanical structure of the sense organ determines the nature of the effective stimulus (Wilson & Melvill-Jones, 1979).

The labyrinth (Fig. 29.1) is outlined by the bony labyrinth, a set of passages in the skull. The bony labyrinth is lined with membranes that contain endolymph and which make up the membranous labyrinth. The membranous labyrinth has a large central vessel called the utricle, another vessel called the saccule, and three narrow passages that emerge from the utricle and loop around to rejoin it. These three loops form circular passages for endolymph and are known as semicircular canals. The canals are oriented orthogonal to one another: there is a lateral or horizontal canal, an anterior or superior canal, and a posterior canal. A semicircular canal is excited by rotational accelerations, and the mechanical structure of the canal converts acceleration into a rotational velocity signal. The three canals in each labyrinth are oriented for excitation by rotations toward that side of the body, horizontally, diagonally forward, and diagonally backward for the horizontal, anterior, and posterior canals, respectively. Thus, each labyrinth is excited by head rotation toward its side, called ipsilateral rotation. Canal afferents fire action potentials at a rate approximately proportional to the velocity of head rotation in the direction of the canal orientation. In contrast with the auditory system, in which 8th nerve afferents are narrowly tuned to specific frequencies of sound (see Chapter 25), vestibular nerve afferents are broadly tuned, responding to the entire range of head motion frequencies.

There are two otolith organs in mammals: the utricle (utriculus) and saccule (sacculus). The names apply to the fluid chambers in which they lie, and the specific locations of the receptors are called the maculae. The two maculae are small regions that contain hair cells innervated by vestibular afferents. Like auditory and semicircular canal hair cells, bending of their cilia is the excitatory stimulus for macular hair cells, and the cilia are imbedded in a gelatinous mass above the cell bodies. Unlike canal hair cells, the otolithic hair cell maculae rest in large chambers, in which fluid motion is thought to exert little or no force on the cilia. Instead, the gelatinous mass holding the cilia contains dense crystals, the otoconia or statoconia, and the entire mass above the hair cells of a macula is acted on by gravity or linear acceleration because of its higher density than the endolymph. The otoconial mass sags in the direction of a head tilt. This sagging, or the equivalent lagging of the mass behind a linear acceleration, provides the natural stimulus for otoliths.

The utricular macula lies horizontally on the floor of its cavity. When the head is still and held approximately erect with respect to gravity, there is no stimulus to this organ, but tilts from the erect posture will excite utricular afferents. Microscopic examination of the utricular macula shows that the hair cells are not all oriented with their cilia arranged in the same direction, and different directions of tilt excite different populations of utricular afferents. The direction of the hair cell, indicated by its structural orientation, corresponds to the best direction of tilt for exciting the receptor. Each utricular macula has hair cell orientations capable of responding to any direction of head tilt, but ipsilateral tilt excites a predominant number of afferents. Thus, as for the semicircular canals, we say that ipsilaterally directed head motion is excitatory. The saccular macula is placed vertically on the side of the saccule, approximately in a parasagittal plane. There is a strong acceleration stimulus to the saccular macula when the head is erect and little or no stimulus when the head is lying on either side. The sacculus responds vigorously when the head bobs up and down, as during locomotion. In summary, two types of vestibular signals are available to assist balance: ipsilaterally directed rotational head

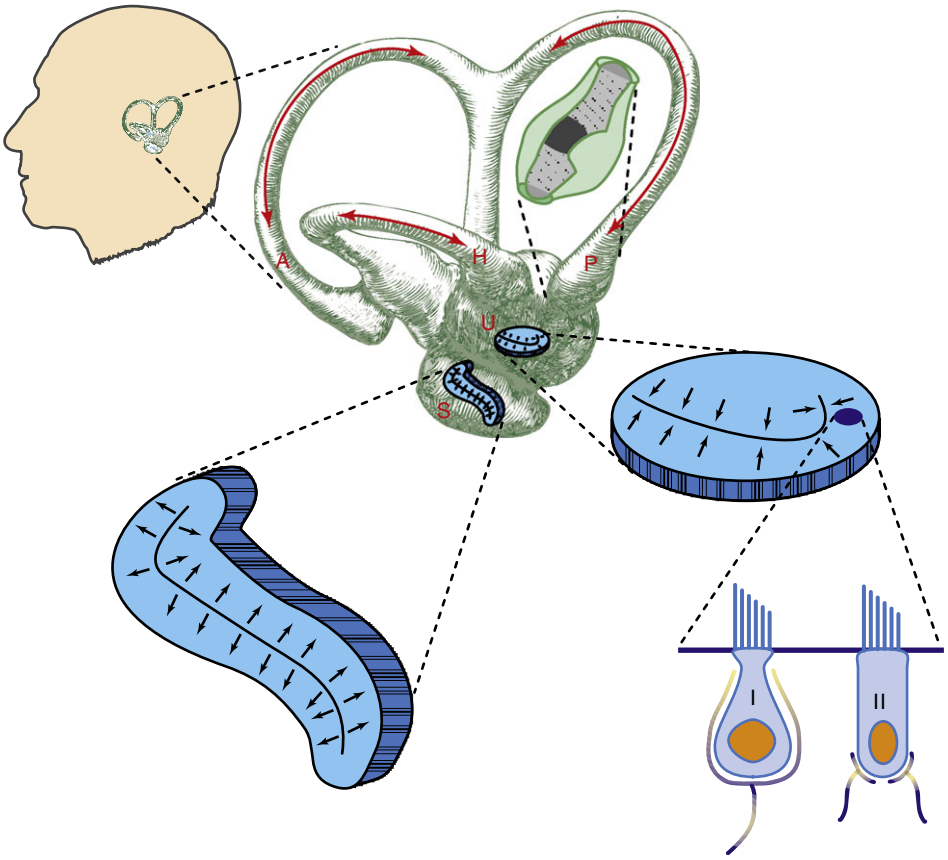

FIGURE 29.1 Vestibular canals and otoliths. The position and orientation of the labyrinth (not to scale) in the head are shown at the upper left of the figure. An enlarged view of the labyrinth shows the directions of head rotation and endolymph flow (red arrows) that excite each of the three semicircular canals. The horizontal orientation of the utricular macula and vertical orientation of the saccular macula are shown schematically. More highly magnified views of the receptor regions of a canal and of the otolith organs are shown with the cupula of the canal colored dark gray and the best directions for excitation of otolith hair cells marked by black arrows. At the lower right are two anatomical types of hair cell: the calyx or type I and bouton-ending or type II receptor. The tallest cilial extension on each cell is the kinocilium. A, anterior semicircular canal; H, horizontal semicircular canal; P, posterior semicircular canal; S, saccule containing saccular macula; U, utricule containing utricular macula; I, type I receptor; II, type II receptor. *Based on studies reviewed by Wilson and Melvill-Jones (1979).*

velocity is signaled by the semicircular canals and ipsilaterally directed head tilt or an equivalent linear acceleration is signaled by the utricular otoliths.

Vestibular Nuclei Convey Head Motion Signals to Many Brain Regions

Four brainstem vestibular nuclei receive inputs from the vestibular portion of the VIIIth nerve (Fig. 29.2). The medial, lateral (Deiter's), and descending (inferior) nuclei contribute to the medial and lateral vestibulospinal tracts which provide direct vestibular influence on the spinal cord. Neurons in the superior and medial vestibular nuclei mediate vestibulo-ocular reflexes (Chapter 32). The medial vestibular nucleus also sends projections to brainstem autonomic nuclei and to the parabrachial nucleus, which integrates viscerosensory signals and has bidirectional connections with the amygdala. Ascending pathways from each of the vestibular nuclei project to thalamic nuclei, which influence widespread regions of the cortex.

Neurons in the Vestibular System Are Specialized for Fast Behaviors

To effectively stabilize the body and eyes during self-motion, the vestibular system must rapidly convey head motion signals to motoneurons. The vestibular system is the fastest of all sensory systems; rapid head movements can evoke eye movements in less than 10 msec. Several mechanisms ensure that the central processing of head motion signals is both fast and accurate. Vestibular nerve afferents and central vestibular neurons fire tonically at high rates—about 50–100 Hz when the head is not moving—and modulate their firing rates in response to head movement. High firing rates enable head motion signals to be encoded both rapidly and bidirectionally; for example, vestibular nucleus neurons receiving inputs from horizontal canal afferents increase firing rates when the head turns to the same side (ipsiversively) and decrease firing rates when the head turns to the opposite side (contraversively). As with vestibular afferents, central vestibular nucleus neurons are broadly tuned for head movement frequencies and their firing rates are linearly modulated by head movement.

Central vestibular synapses and neurons are specialized for linear signaling over a wide range of firing rates. At well-studied synapses onto pyramidal cells in the hippocampus and cortex, synaptic efficacy is influenced strongly by the recent history of presynaptic activity (see Chapter 10). In contrast, across the behaviorally relevant range of afferent firing rates, central vestibular nerve synapses exhibit neither short-term depression nor

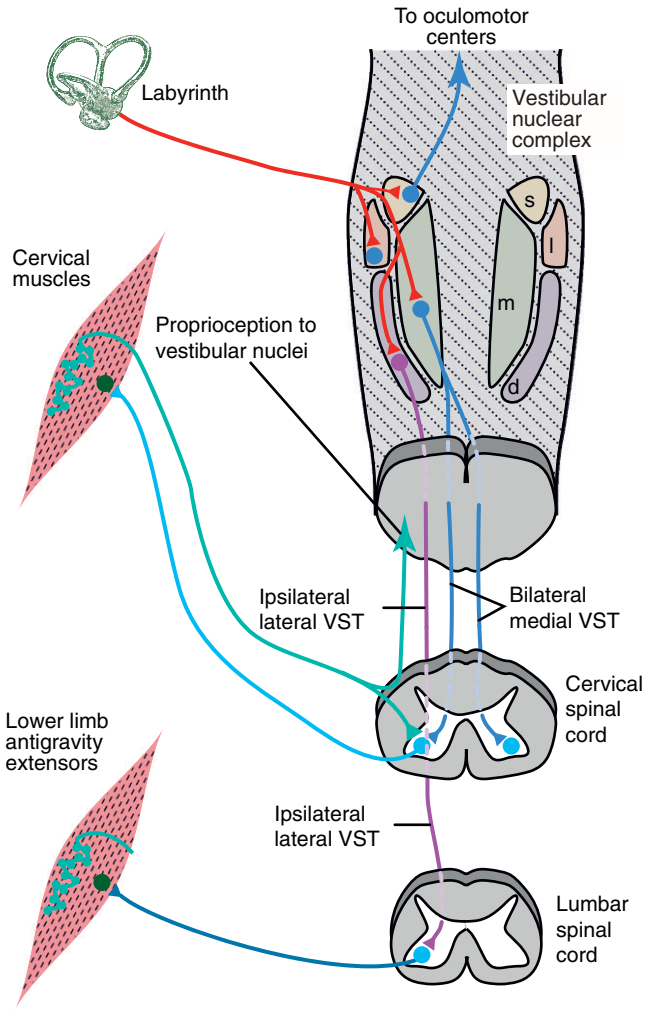

FIGURE 29.2 Vestibular and proprioceptive reflex signal inputs and major pathways from the brainstem vestibular nuclei. The medial vestibulospinal tract projects bilaterally to the cervical spinal cord to mediate the vestibulocollic reflex. The lateral vestibulospinal tract descends to lumbar levels of the spinal cord to influence limb extensors involved in balance. Neck muscle proprioceptors send signals to vestibular nuclei to participate in cervicocollic reflexes and interactions among reflexes. d, descending vestibular nucleus; 1, lateral vestibular nucleus; m, medial vestibular nucleus; s, superior vestibular nucleus; VST, vestibulospinal tract.

short-term facilitation, enabling them to transmit signals that accurately reflect head motion (Bagnall, McElvain, Faulstich, & du Lac, 2008). Postsynaptic vestibular nucleus neurons fire spontaneously in the absence of synaptic stimulation, enabling rapid responses to synaptic inputs. They express sodium and potassium channels that enable them to sustain firing at high rates (see Chapter 31) as well as calcium-activated potassium channels which enable them to respond to synaptic inputs with linear changes in firing rates (Kolkman, McElvain, & du Lac, 2011). These synaptic and cell biological properties of vestibular neurons enable vestibulo-motor reflexes to respond rapidly and linearly to head motion.

Vestibulocervical and Vestibulospinal Reflexes Stabilize Head and Body Posture

Vestibulocervical (neck or collic reflexes) and vestibulospinal reflexes use canal and otolith signals to stabilize the posture of the head and body. These reflexes act as "negative feedback" systems (Schor, Kearney, & Dieringer, 1988). When the head and body rotate or tilt in any direction, the vestibular stimulus excites pathways that contract neck and limb muscles that oppose the motion so that the undesired movement is reduced or corrected. The importance of vestibulocervical and vestibulospinal reflexes is demonstrated by damage to the labyrinth or VIIIth cranial nerve. Unilateral labyrinthectomy causes an initial postural disability, with leaning or falling toward the side of the lesion. Bilaterally symmetric semicircular canal plugging, which removes head velocity signals with little loss or imbalance in tonic vestibular nerve activity, produces head instability with oscillations that may persist for several days.

Electrical activation of the vestibular pathways shows that vestibulocervical reflexes are mediated primarily by excitatory and inhibitory connections of the bilaterally projecting medial vestibulospinal tract and that ipsilateral excitation of leg antigravity muscles is carried via the lateral vestibulospinal tract. The bulk of the lateral vestibulospinal tract projects from the lateral vestibular nucleus to the lumbar spinal cord for vestibulospinal reflex control of upright body posture. Vestibular nuclei also project heavily to reticular nuclei, and only lesions that impinge on both vestibulospinal and reticulospinal pathways substantially blunt vestibular reflex responses.

The bilateral, mixed excitatory and inhibitory connections of the vestibulocervical reflex circuits indicate that its actions are complex, and considerable effort has been devoted to explicating the exact nature of these actions. The excitatory lateral vestibulospinal tract projection to ipsilateral extensor motoneurons offers a simple example of negative feedback: When the head and body tilt to one side, canals and otoliths of the labyrinth on that side are excited, and the lateral vestibulospinal tract carries this excitation to the ipsilateral leg extensor motoneurons. The ipsilateral leg is thus extended to oppose the tilt and maintain upright posture.

Initial quantitative studies of the vestibulocervical reflex used sinusoidally oscillating stimuli and concentrated on the timing of the reflex head torques or the electromyographic activity that accompanied neck muscle contractions The conclusion from these studies was that central vestibular circuits process low frequency (slow) head movements and high frequency (fast) movements in distinct ways. At low frequencies a portion of the velocity signal from the semicircular canals is converted to a head position signal appropriate for repositioning the head in response to a slow change in head angle. At high

frequencies, however, vestibulocervical reflex circuitry introduces a "phase lead," or anticipatory response, which works in conjunction with the canal afferent signal to produce movements with short response times. As such, the reflexive behavioral responses oppose head angular acceleration, as would be appropriate given that inertia of the head must be overcome for adequate compensation during rapid head motion.

The limbs and trunk represent a more complex mechanical system than the neck and head, complicating the analysis of vestibulo-spinal reflexes. Electromyographic recordings in decerebrated animals have shown that limb extensors at low frequencies of vestibular oscillation are excited in phase with head position. For example, when the head rolls slowly to the left, the left forelimb extends as if to brace against further displacement. The likely source of signals exciting these responses is the otolith organs. As the frequency of head oscillation increases, the timing of vestibulospinal responses corresponds more closely to head rotation velocity, indicating that semicircular canal signals begin to predominate over otolith signals in vestibulospinal responses at higher frequencies.

Body musculature could be coordinated to compensate for a particular direction of head and body rotation using a variety of strategies, but only general features of vestibulocervical and vestibulospinal synergies are known (Baker, Goldberg, & Peterson, 1985). Each of the major neck muscles responds to vestibular stimulation (rotation) in many different directions, specific for each neck muscle, that do not reflect the directional sensitivity of any single semicircular canal. Instead, the responses to rapid motions reflect a weighted sum of canal and otolith inputs. The appropriate postural response to a particular pattern of vestibular stimulation depends on many factors, including the position of the head, trunk, and limbs. The cerebellum is critical for the complex, context-dependent computations that mediate vestibulo-spinal reflexes (Chapter 31).

The Cervicocervical Reflex Stabilizes the Head by Opposing Lengthening of Neck Muscles

The proprioceptive contribution to reflex stabilization of the head and body has been examined in many of the same ways as vestibular contributions (Peterson, Goldberg, Bilotto, & Fuller, 1985). The use of proprioceptive signals is more complicated than for vestibular signals, as any of the muscles of the neck, trunk, or limbs could provide an input to influence any other muscle or synergistic group of muscles. The neck stretch or cervicocervical reflex has been studied most extensively. Like the stretch reflex for limb extensors, the cervicocervical reflex opposes lengthening of the muscles concerned and so is a negative feedback compensatory system.

The cervicocervical reflex has been analyzed by rotating the trunk of experimental animals while holding the head fixed in space. This stimulates neck proprioceptors without stimulating vestibular sense organs. Nevertheless, the results are reminiscent of the vestibulocervical reflex. At low frequencies of neck rotation cervicocervical reflex muscle contractions correspond to the extent of muscle stretch, but at higher frequencies the responses occur more rapidly, corresponding to the velocity or acceleration of muscle stretch. The directionality of neck muscle responses to stretch matches that of vestibulocervical responses fairly well. Common directionality implies that signals for vestibular and stretch reflexes to neck muscles share central circuitry.

The Brainstem Controls Coordinated Postural Reactions

A variety of reflexes contribute to the maintenance of overall body posture. The tonic neck or cervicospinal reflexes are the best known of these, but the supporting reactions, placing reactions, righting reactions, hopping or stepping reactions, and others are also useful parts of the neural control of posture. The tonic neck reflex adjusts the extension of the limbs in response to the angle of the head on the trunk. Roberts (1967) showed that stretching the neck by rolling the spine to one side elicited tonic flexion and extension of the forelimbs, as if the support surface had been tilted to produce the rotation. The placement of a limb on the ground initiates a set of reflex reactions that stiffen the limb into a supporting pillar. This response is called the "positive supporting reaction" and depends on the integrity of the brainstem. As discussed earlier, righting reactions also depend on the brainstem, and "optical righting reflexes" mediated by vision require an intact cerebral cortex. Stable posture requires that the feet be not only rigid but placed correctly on a supporting surface, and the placing reactions of quadrupeds contribute to this by moving the feet toward a visible surface (visual placing reaction) or onto a surface that has tactile contact with the top of the foot, chin, or whiskers (tactile placing reactions). Although a tactile placing reaction may be evoked in primitive form in spinalized animals, it is generally held that at least the lower brainstem must be intact for tactile placing to occur effectively. Finally, if balance reactions are insufficient to maintain stable posture, as when the support surface is moved beneath the foot, the limb may hop to a new position where stable posture is possible (hopping reaction). The action of the righting reflex of cats during falling is familiar to all. Humans show a similar (but less graceful) reaction to an unexpected drop, measurable as a short latency electromyographic response in the gastrocnemius muscle. In cats, this response survives blockage of the semicircular canals, but not total labyrinthectomy, and so appears to be mediated by otoliths.

Balance Depends on Context-Dependent Postural Strategies

An important tool for exploring body stability is the posture platform, a base on which subjects can stand and be subjected to displacements of the underlying supporting surface. The posture platform is used with body position sensors and electromyography to evaluate standing posture (Horak & Nashner, 1986; Horak & Shupert, 1994; Nashner, 1982). Even on a perfectly stable support surface with vision, somatosensory, and vestibular senses all active, a standing person will sway slightly. When the eyes are closed, sway is greater. When the visual surround is linked to the subject's head position, visual information is misleading and sway is increased. When the support surface tilts along with the body, sway increases because proprioceptive information is misleading. The vestibular system thus works in combination with proprioception and vision to promote postural stability. How multisensory signals are appropriately weighted and combined to produce a reliable and integrated sense of self motion is an area of active research (Angelaki & Cullen, 2008)

Sudden displacement of the platform on which a subject stands allows measurement of the latencies and patterns of electromyographic activity in the postural muscles of the legs. When the subject is standing on a large platform that is displaced forward or backward, the leg muscles contract in sequence from ankle to thigh to hip, and motion occurs primarily about the ankle joint. When the platform displacement is forward, the ankle flexor tibialis anterior on the front of the calf is first to be excited (flexion is the toe-up direction), at about 80–100 ms after the displacement. This is followed about 20 ms later by contraction of the quadriceps thigh muscles and then later still by contraction of trunk musculature. Backward displacement first elicits excitation of the gactrocnemius muscle at the back of the calf to extend the ankle, followed by excitation of thigh and trunk muscles antagonistic to those excited by forward displacement (Fig. 29.3). The overall postural reaction of distal-to-proximal excitation has been termed an "ankle strategy" for maintaining balance.

Although the ankle strategy dominates in simple forward–backward displacement, other strategies are available, and postural reactions adapt to alterations in the support surface or sensory inputs. Displacement of a support surface that is short compared to the foot, or rotation of the support instead of displacement, demands a different postural response. In these cases a hip strategy is adopted, in which the body is bent at the hips so that the lower half of the body moves in the same direction as it does during ankle strategy reactions while the upper body moves in the opposite direction. Thus, during a forward, front downward tilt of a supporting platform, the hips move backward and the head forward. This shifts the center of gravity, which has moved forward due to the displacement,

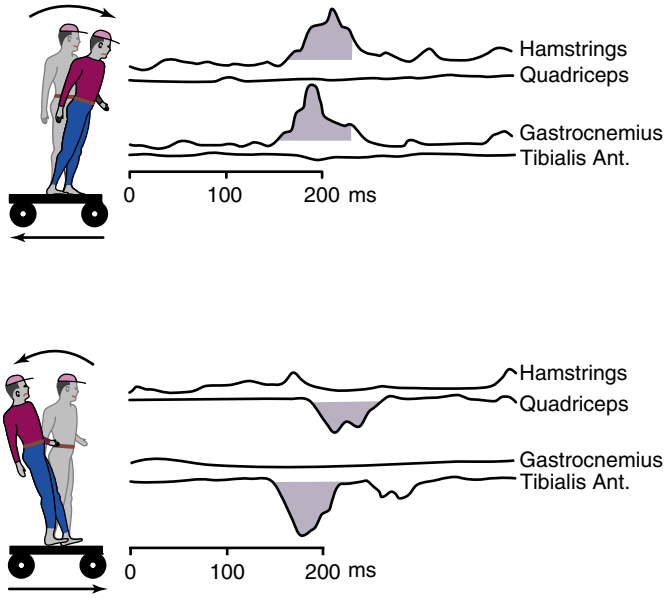

FIGURE 29.3 Sequencing of muscle activation in response to displacement of a supporting platform. When the supporting surface is displaced backward (at 0 ms), flexor muscles are excited first in the distal lower limb segments (gastrocnemius, about 80 ms latency) and then in the proximal segment (hamstrings, about 100 ms latency). Forward displacement of the platform activates lower limb extensors, again in a distal (tibialis anterior) to proximal (quadriceps) sequence. Black arrows mark the first detected electromyographic response to displacement. *Based on studies by Horak and Nashner (1986).*

backward so that it is placed over the support again. Other work has documented a stiffening strategy of muscle cocontraction in response to base rotation and a multilink strategy that includes ankle, hip, and neck joint motions in response to translation. Stiffening, ankle, and hip or multilink strategies are applicable to the sway that occurs during normal standing on commonly encountered kinds of surfaces and may represent basic units of postural reaction. The range of postural reactions recorded from standing human subjects argues for a complexity beyond that observed in the vestibulocervical or vestibulospinal reflexes studied during rotation or tilting of animal subjects.

Vestibular Damage Results in Disorders of Postural Control

Control of posture involves many regions of the nervous system, and it is not surprising that disorders of posture can result from damage to the sensory periphery or to telencephalic, cerebellar, brainstem, or spinal centers. The striking motor consequences of lesions of the basal ganglia may include profound effects on posture, such as the rigidity and general poverty of movement associated with Parkinson's disease (Chapter 30). Damage to the anterior vermis of the cerebellum can exaggerate decerebrate rigidity, and cerebellar patients show poorer performance

BOX 29.1

VESTIBULAR PLASTICITY

The experience of sailors getting their "sea legs" demonstrates that postural reflexes and balance can adapt over time to produce better performance in new circumstances. Clear evidence for this comes from the study of postural control in astronauts. After a space flight, astronauts rely more heavily than before on visual cues for postural orientation, and they show degraded performance in their responses to disturbances generated by a posture platform. Sway during standing is increased dramatically when visual cues are removed, and the body segments move in a less coordinated manner than before space flight. Nonetheless, the performance of astronauts after the experience of space flight is quite remarkable; they are able to balance adequately within hours of landing and regain their preflight postural performance within a few days.

The behavioral strategies and cellular mechanisms that mediate compensation for vestibular loss have been studied in animal models. Following unilateral labyrinthectomy (surgical removal of the inner ear), animals exhibit transient postural impairments, such as rolling and tilting toward the side of the lesion, which resolve within hours. Two distinct mechanisms account for the rapid recovery of postural stability despite the persistent impairment of vestibular function. First, the influence of the remaining senses that signal self-motion—proprioception and vision—increases rapidly following vestibular loss. Second, cellular mechanisms of plasticity in vestibular nucleus neurons enable the available sensory signals to recalibrate postural reflexes.

in posture platform situations, with less adaptive modification of responses, as expected from our knowledge of cerebellar function (Chapter 31).

Many types of disease or damage of the vestibular system affect posture (and generally also cause dizziness), including vestibular neuritis, peripheral or central tumors or infarction, and Meniere's syndrome (Baloh & Honrubia, 1990) (see Box 29.2). Bilateral involvement and acute, episodic, or chronic time courses occur in many vestibular disorders. The most obvious form of vestibular system damage is unilateral labyrinthectomy, performed either experimentally in animals or as the result of disease or surgical intervention against disease in humans. The postural symptoms immediately following loss of vestibular input to one side of the brain vary across species, with nonmammalian and "lower" mammalian species typically showing a more prominent tilting of the head and body toward the side of damage. Vestibular afferents have a high level of resting activity, and leaning toward the side of lost vestibular signals makes sense in that the spontaneous or resting activity of the remaining vestibular apparatus is signaling, in effect, motion toward the intact side because it is not balanced by equal resting activity from the damaged side. To counter this neural stimulus, the affected individual tilts away from the directions of apparent motion. This static postural effect of unilateral labyrinthectomy is accompanied by dynamic postural deficits, seen in experimental animals as weakened ipsilateral limb extensor responses and delayed responses to sudden drops. Remarkable compensation for unilateral labyrinthectomy occurs over a period of a few weeks, during which there is considerable recovery (see Box 29.1).

Patients with long-standing bilateral vestibular loss may perform well on posture platforms when visual and somatosensory cues are present, but fail completely to maintain upright stance when the support surface and visual surround both sway with the patient so that only vestibular information is accurate. Patients with recent bilateral vestibular loss or who have not yet compensated for vestibular loss also do poorly when vision and support surface are unreliable, but these patients perform poorly if only one sense, be it vision or somatosensory, is made an unreliable indicator of balance.

Summary

Axons from vestibular and reticular nuclei in the brainstem descend in pathways located ventromedially in the spinal cord to provide postural tone and balance. Balance is maintained by negative feedback reflexes that are stimulated by the vestibular canals and otoliths. The vestibulocervical reflex excites neck muscles via the medial vestibulospinal tract to oppose head tilt, and vestibulospinal reflexes carried by the lateral vestibulospinal tract excite ipsilateral limb extensors to oppose body tilt. Vestibular, muscle stretch, and other reflexes work together to coordinate posture and balance, and the medial system adopts different strategies for balance control depending

BOX 29.2

MENIERE SYNDROME

The typical patient with Meniere syndrome develops a sensation of fullness and pressure along with decreased hearing and tinnitus in one ear. Vertigo follows rapidly, reaching a maximum intensity within minutes and then slowly subsiding over several hours. Often the patient is left with a sense of unsteadiness and nonspecific dizziness that can go on for days after the acute vertiginous spell. In the early stages, hearing loss is completely reversible, but as the disease progresses, residual hearing loss becomes a prominent feature. The tinnitus is typically described as a roaring sound similar to the sound of the ocean. These episodes occur at irregular intervals over years, with periods of remission unpredictably intermixed. Eventually, most patients reach the so-called "burnt-out phase," where the episodic vertigo disappears and severe permanent hearing loss remains.

The clinical syndrome was first described by Prosper Meniere in 1861, but Hallpike and Cairns made the initial clinical-pathological correlation with hydrops of the labyrinth in 1938. Patients with Meniere syndrome invariably show an increase in volume of endolymph associated with distention of the entire endolymphatic system. Herniations and ruptures in the membranous labyrinth commonly occur, which may explain the episodes of hearing loss and vertigo.

Delayed endolymphatic hydrops occurs in an ear that has been damaged years before, usually by infection. With this disorder, the patient reports a long history of hearing loss, typically since childhood, followed many years later by episodic vertigo but without the typical auditory symptoms. The pathologic findings are remarkably similar to idiopathic Meniere syndrome, suggesting a common etiology. A subclinical viral infection could damage the resorptive mechanism of the inner ear, leading to an eventual decompensation in the balance between secretion and resorption of endolymph.

The key to the diagnosis of Meniere syndrome is to document fluctuating hearing levels in a patient with the characteristic clinical history. In the early stages, the sensorineural hearing loss is usually greater in the low frequencies. Some patients with Meniere syndrome develop abrupt episodes of falling to the ground without loss of consciousness or associated neurologic symptoms. These episodes have been called "otolithic catastrophes" because they are thought to result from a sudden mechanical deformation of the otolith receptor organ. Patients often report feeling as though they were pushed to the ground by some external force.

Because the cause of Meniere syndrome is usually unknown, treatment is empiric. Medical management consists of symptomatic treatment with antivertiginous drugs and long-term prophylaxis with salt restriction and diuretics. Many different surgical procedures have been tried but none has been consistently effective. Shunt operations to decrease the endolymph pressure have not been successful because the implanted drain devices are encapsulated rapidly by fibrous tissue. Destructive surgeries (removing the labyrinth or cutting the vestibular nerve), can stop the episodes of vertigo but do not change the tinnitus and progressive hearing loss.

Robert W. Baloh

on the body support surface and information from sensory inputs. The medial postural system can adapt to different postural situations, but its actions can be compromised by central neural damage or unbalanced by peripheral vestibular loss. The reflexive control of body stability and posture by the medial descending system allows the lateral descending system to specialize in execution of precise voluntary movements of the extremities.

THE LATERAL VOLUNTARY SYSTEM

While the medial system thus provides underlying postural control for stance, ambulation, and orientation of the head, the lateral system superimposes the ability to make more sophisticated, voluntary movements in response to complex features of the external environment (perceived through the senses) and internal state (stored memories, knowledge, and emotion). Much of this control is mediated by specialized regions of the cerebral cortex. Outflow from this motor cortex dominates the lateral descending system, particularly in primates and humans.

Components of the Lateral Voluntary System

The Corticospinal Projection Is the Most Direct Pathway from the Cerebral Cortex to Spinal Motoneurons

For more than a century, electrical stimulation of a limited portion of the frontal lobe of the cerebral cortex has been known to evoke movements. Electrical stimulation of this "excitable cortex" evokes movements readily because this region has relatively direct connections to

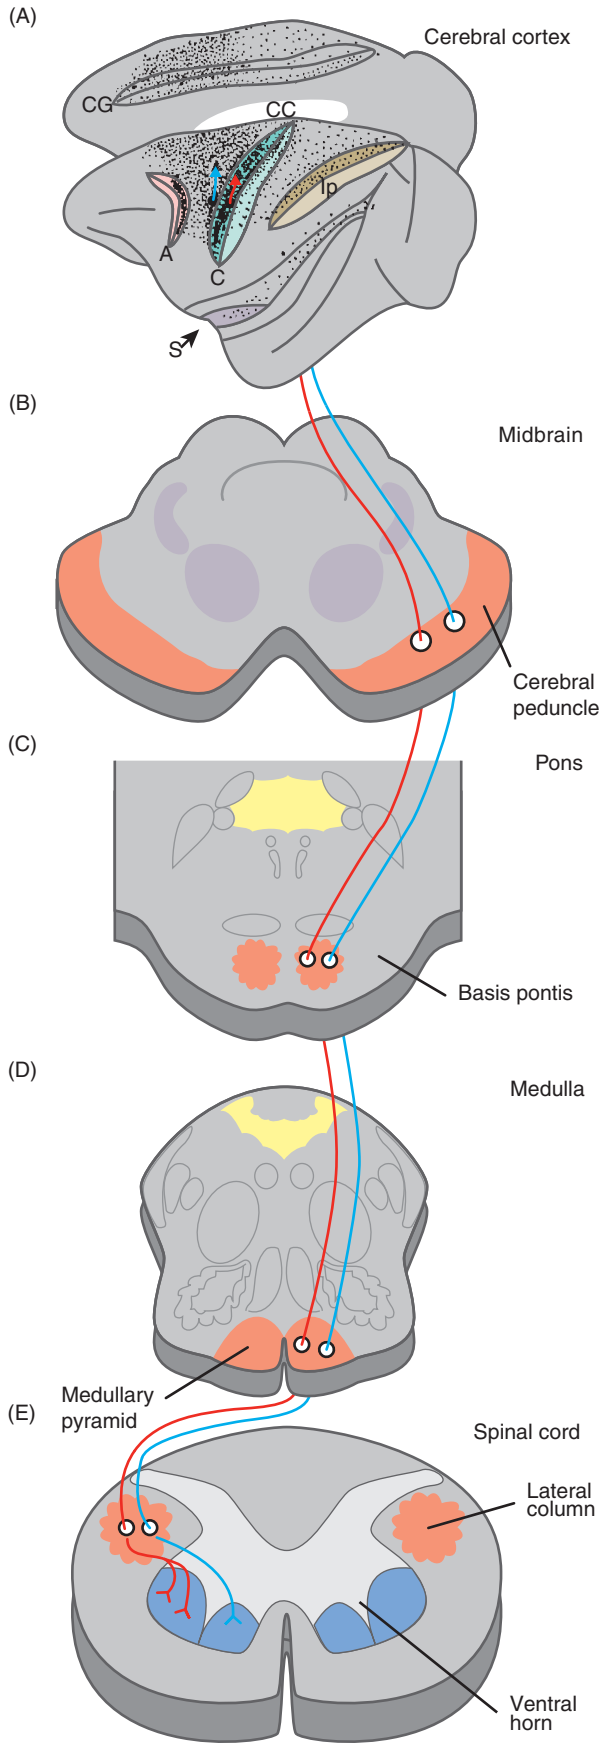

FIGURE 29.4 The corticospinal projection in the macaque monkey. (A) The density of corticospinal neuronal somata is shown by stippling in this lateral view of the left cerebral hemisphere; the superior medial surface of the hemisphere is also shown (above) as if reflected in a mirror. The central sulcus (C), arcuate sulcus (A), cingulate sulcus (Cg), intraparietal sulcus (Ip), and Sylvian fissure (S) are drawn as if pulled open to reveal the neurons in their banks. Two schematic corticospinal neurons, one relatively posterior and the other relatively anterior in area 4, send their axons down through the midbrain (B), pons (C), medulla (D), and spinal cord (E), which are drawn in cross section. In the spinal cord, the former corticospinal axon leaves the lateral column to terminate in the dorsolateral ventral horn, whereas the latter axon terminates in the ventromedial ventral horn.

spinal motoneurons. In primates with a central sulcus (Rolandic fissure) in the neocortex, cortical neurons with axons projecting to the spinal cord are found most densely in the anterior bank of the central sulcus. The density of such neurons decreases from there rostrally to the precentral sulcus (posterior bank of the arcuate sulcus in macaque monkeys) and medially to the cingulate sulcus (Fig. 29.4). This territory corresponds to cytoarchitectonic areas 4 and 6 of Brodmann. Additional corticospinal neurons in areas 1, 2, 3, 5, and 7 of the parietal lobe project to the dorsal horn of the spinal cord to regulate sensory inflow.

The axons of neurons that project from the cerebral cortex to the brainstem and spinal cord have large pyramid-shaped somata in cortical layer V. Their axons leave the cortex, pass through the centrum semiovale, and enter the internal capsule, along with many other axons from other cortical areas. Axons from the motor cortex are concentrated most heavily in the middle third of the posterior limb of the internal capsule. As axons descend from the internal capsule below the thalamus, they come to lie on the ventral surface of the brainstem. Here, they form the cerebral peduncle of the midbrain, where the corticospinal axons are concentrated in the middle third. Some descending axons end in or send collaterals to the red nucleus. At the level of the pons, the descending axons of the peduncle become intermixed with pontine nuclear neurons in the base of the pons (basis pontis). Most of these axons synapse on pontine neurons, providing input from the cerebral cortex to the cerebellum. Other descending axons synapse in the pontomedullary reticular formation, providing input to the reticulospinal system and to brainstem motor pattern generators (Chapter 27). The continuing corticospinal axons collect to form the medullary pyramid (Box 29.3). As the medulla blends into the spinal cord, the vast majority of corticospinal axons cross the midline and enter the lateral column of white matter on the opposite side of the spinal cord. Because of this decussation of the pyramidal tract, the left motor cortex controls movements on the right side of the body and vice versa. A small minority of corticospinal axons

BOX 29.3

PYRAMIDS IN THE BRAIN

Inspection of the ventral surface of the medulla reveals a structure that looks like a small pyramid. This medullary pyramid turns out to be the collected bundle of corticospinal axons. The corticospinal tract therefore is often referred to as the pyramidal tract. Axons of noncorticospinal descending pathways do not pass through the medullary pyramid and therefore can be described collectively as extrapyramidal pathways. At one time these pathways were thought to receive their major controlling inputs from the basal ganglia. Human neurologic disorders that result from dysfunction of the basal ganglia thus came to be known as "extrapyramidal syndromes." This term is misleading, however. More recent work has shown that many of the brainstem nuclei giving rise to extrapyramidal pathways receive cortical input and that much of the output of the basal ganglia is directed via the thalamus back to cortical motor areas. Many manifestations of extrapyramidal syndromes may therefore be played out through cortical motor areas, even via the pyramidal tract. Indeed, surgical lesions of the pyramidal tract once were used to ameliorate some extrapyramidal syndromes.

Marc H. Schieber and James F. Baker

remain uncrossed and continue caudally as the ventral (or anterior) corticospinal tract near the ventral midline of the spinal cord.

As descending corticospinal axons reach their target levels in the spinal cord, they enter the spinal gray matter, where they ramify and synapse. The majority of corticospinal axons synapse on premotor interneurons in the intermediate zone (Rexed's laminae VII and VIII), and relatively few synapse directly on spinal motoneurons in Rexed's lamina IX. The somata of most corticospinal neurons with monosynaptic connections to motoneurons lie posteriorly in area 4, and their monosynaptic connections are made on the motoneurons of distal limb muscles, whose somata are clustered in the dorsolateral ventral horn. Corticospinal axons from neurons located more anteriorly typically synapse in the ventromedial portion of the ventral horn, where the motoneurons of proximal limb muscles and axial muscles are located. Some corticospinal axons cross the midline spinal gray matter to reach the ventromedial ventral horn ipsilateral to their origin; such doubly decussating corticospinal axons, along with the uncrossed ventral corticospinal tract, may be partly responsible for the relative preservation of trunk and proximal limb movements after unilateral damage to the cortex.

Indirect Pathways to the Spinal Cord Involve Centers in the Brainstem

The corticospinal tract is not the only output pathway through which the cerebral cortex contributes to motor control (Kuypers, 1987). The presence of other, less direct pathways in the macaque has been demonstrated by cutting the medullary pyramid on one side. Stimulation of the cortex on that side still evoked contralateral movements. The somatotopic organization of the cortex in the operated animals was similar to that in normal macaques, although the thresholds for stimulation were raised and distal movements were evoked less often.

Intermixed with corticospinal neurons in layer V of areas 4 and 6 are corticorubral neurons, whose axons project to the red nucleus (RN). Some corticospinal axons also send collaterals to the RN. In addition to cortical inputs, the RN also receives considerable input from the cerebellum (Chapter 31). Many RN neurons, particularly those in the caudal, magno-cellular portion, in turn send their axons across the midline and into the lateral column of the spinal cord, terminating most heavily in the dorsolateral region of the ventral horn. These descending axons from the RN constitute the rubrospinal tract. A pathway thus exists from the cortex to the RN to the spinal cord. The activity of rubrospinal neurons indicates that they play a significant role during voluntary movements of the arm, hand, and fingers. The rubrospinal pathway thus works synergistically with the corticospinal pathway in controlling limb movements.

A second pathway involves neurons scattered in the medial reticular formation of the pons and medulla. The medial reticular formation receives input from cortical motor areas and projects via the ventral column of the spinal cord to the ventral horn, chiefly its ventromedial portion. The axons that make this projection constitute the reticulospinal tract. Although the reticulospinal tract is also part of the medial descending system, the activity of some reticular formation neurons indicates that they also participate in controlling reaching and grasping movements (Baker, 2011).

Organization of the Motor Cortex

The original "motor cortex" is now appreciated to be comprised of several cortical areas. These areas are considered "motor" because (1) they project to other motor

structures, (2) their ablation causes deficits in movement, and (3) their stimulation evokes or alters movements.

The Motor Cortex Is Subdivided into Multiple Cortical Motor Areas

In addition to its descending projections to spinal motoneurons, the motor cortex has cytoarchitectonic features that distinguish it from other regions of the cerebral cortex. The somata of many pyramidal neurons in layer V, the output layer, are exceptionally large (Betz cells). In addition, the neurons of layer IV, the granular layer that receives thalamic input, are very sparse compared to other areas of the neocortex, and hence the motor cortex has been described as dysgranular (area 6) or agranular (area 4) cortex. Based on cytoarchitectonics, myeloarchitectonics, and histochemical features, the motor cortex of macaque monkeys can be subdivided into the cortical motor areas shown in Figure 29.5A. In general, these subdivisions show three mediolaterally oriented strips of cortex, with the primary motor cortex (M1) most posterior and two premotor strips progressively more anterior. Each of these premotor strips has a subdivision on the

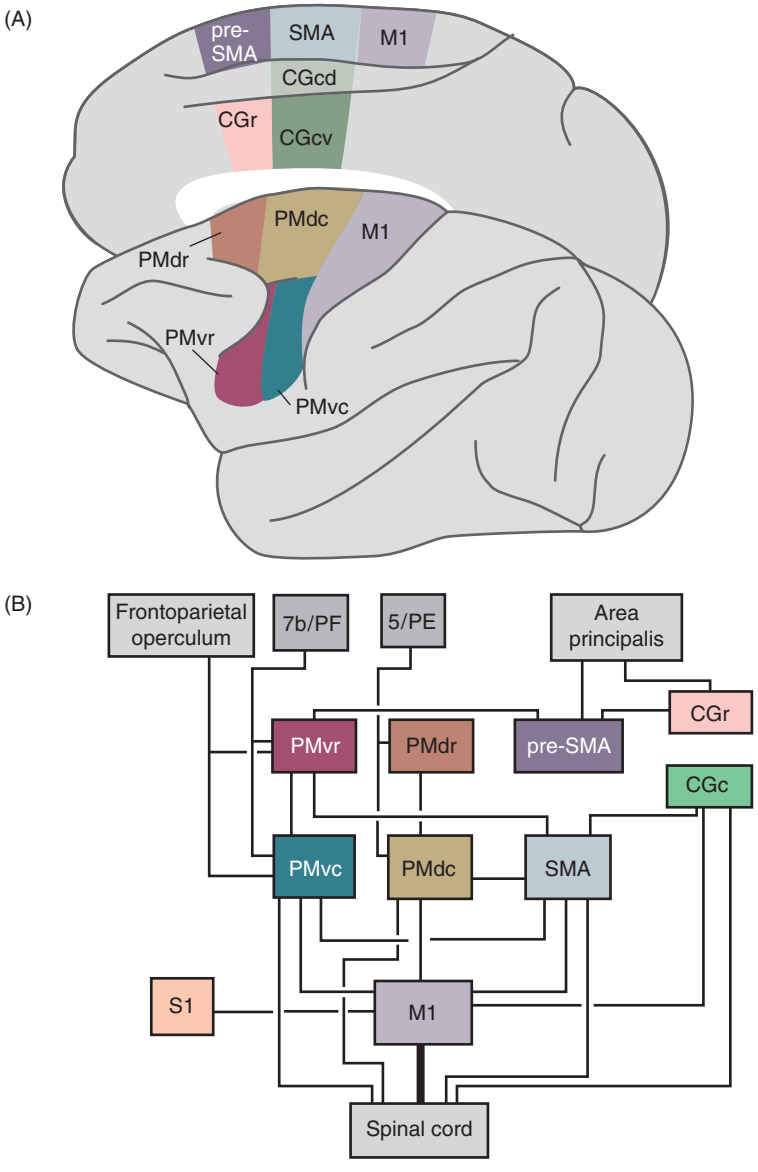

FIGURE 29.5 Cortical motor areas. (A) Diagram of a macaque brain showing current parcellation of cortical motor areas in the frontal lobe. *Modified from Matelli, Luppino, and Rizzolatti (1991).* (B) Connections of the cortical motor areas. Most corticocortical connections are reciprocal. CGc,-cingulate motor area, caudal; CGr,-cingulate motor area, rostral; M1, primary motor cortex; PMdc, premotor cortex, dorsal caudal; PMdr, premotor cortex, dorsal, rostral; PMvc, premotor cortex, ventral, caudal; PMvr, premotor cortex, ventral, rostral; Pre-SMA, presupplementary motor area; SMA supplementary motor area proper. Thin lines to the spinal cord from PMvc, PMdc, SMA, and CGc indicate that corticospinal projections from these areas are not as strong as that from M1.

medial wall of the hemisphere, a second subdivision on the dorsal convexity, and a third on the ventral convexity. In addition to these subdivisions of Brodmann's areas 4 and 6, areas 23 and 24 in the banks of the cingulate sulcus and on the medial surface of the hemisphere in the cingulate gyrus contain at least two additional cortical motor areas. Cortical motor areas differ, not only in their intrinsic composition, but also in their interconnections with other parts of the central nervous system.

Cortical motor areas differ in their connections with the thalamus. M1, PMv, and SMA, for example, connect primarily with VPLo/VLc, area X, and VLo in the thalamus, respectively. These differences are significant because thalamic nuclei VPLo/VLc and area X receive major inputs from the cerebellum, whereas VLo receives major input from the basal ganglia. Thus, information processed by the cerebellum is directed largely to M1 and PMv, whereas information from the basal ganglia is sent largely to SMA.

Cortical motor areas also differ in their connections with one another and with other regions of the cortex (Fig. 29.5B). For example, when horseradish peroxidase (HRP) is injected into the hand region of M1, separate patches of retrogradely labeled neuronal somata are found in PMv, PMd, SMA, CGc, and CGr, indicating that each of these areas sends a separate projection to the hand region of M1. In contrast, other motor cortical regions do not project directly to M1. Instead, PMvr projects to PMvc, PMdr projects to PMdc, and pre-SMA projects to PMvr. The extensive connectivity between motor cortical areas subserves the dynamic visuomotor transformations required to successfully grasp an object (Davare, Kraskov, Rothwell, & Lemon, 2011).

Different cortical motor areas also receive input from different cortical sensory and association areas: M1 receives input from the primary somatosensory area (S1), PMv receives input from visual association area 7b, particularly the anterior intraparietal area (AIP), and PMd receives input from somatosensory association area 5 and the parietal reach region. Because of these inputs, many motor cortex neurons have somatosensory receptive fields. Neurons located caudally in M1 tend to respond to cutaneous modalities, whereas neurons located rostrally in M1 tend to respond to deep modalities. The somatosensory input of an M1 neuron is generally related to the output function of that neuron. For example, caudally located M1 neurons that control the fingers may have cutaneous receptive fields on the fingers (Fig. 29.6A), whereas more rostrally located M1 neurons that control the biceps or triceps may have deep receptive fields in those muscles.

PMv receives both somatosensory and visual input via areas 7b and AIP. Both the somatosensory and the visual receptive fields of PMv neurons tend to be large, and when single PMv neurons receive both types of sensory information, the fields tend to be related (Fig. 29.6B).

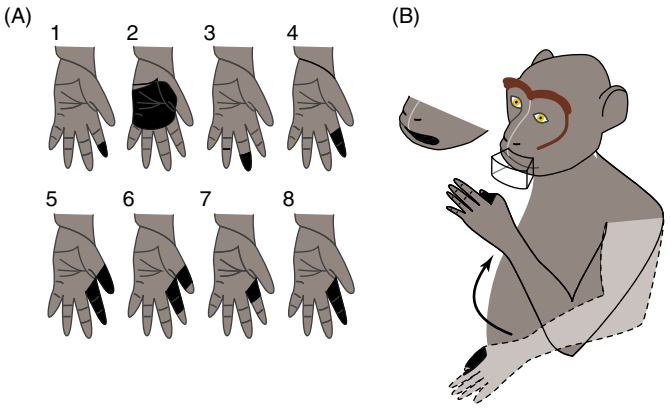

FIGURE 29.6 Sensory receptive fields in M1 and PMv. (A) Black regions show the tactile receptive fields of eight M1 neurons recorded at loci where intracortical microstimulation evoked flexion of the monkey's index and middle fingers. Other neurons at the same loci responded to passive extension of those fingers. *From Rosen and Asanuma (1972).* (B) A single PMv neuron responded to visual stimuli moving near the mouth, to tactile stimulation of the lips and of the skin between the thumb and the index finger, and to flexion of the elbow. *From Rizzolatti, Scandolara, Matelli, and Gentilucci (1981).*

A neuron with a somatosensory receptive field covering the forearm, for instance, may respond to visual stimuli moving near the forearm. Interestingly, if the forearm is moved to a different position, the visual receptive field of the PMv neuron moves with the forearm. The somatosensory inputs to both PMv and M1, plus the visual inputs to PMv, reflect the role of sensory inputs in guiding ongoing movements as they are being generated by cortical motor areas.

Somatotopic Organization in the Motor Cortex Is Not a One-to-One Map of Body Parts, Muscles, or Movements

The organization of the primary motor cortex, M1, has been studied more extensively than that of other cortical motor areas. Within the M1 of primates, the face is represented laterally, the lower extremity (or hindlimb) and tail medially, and the upper extremity (or forelimb) in between (Fig. 29.7). This overall organization of M1 according to major body parts is termed somatotopic. The somatotopic organization of M1 becomes evident in clinical neurology. Lesions on the lateral convexity of human M1 cause weakness or paralysis of the contralateral face, more medial lesions on the convexity affect the contralateral hand and arm, and lesions on the medial wall of the hemisphere affect the leg and foot.

Moreover, distal parts of the extremities and acral parts of the face (lips and tongue) are most heavily represented caudally, whereas proximal parts of the extremities and axial movements are most heavily represented rostrally. Those parts of the body that are used for fine manipulative movements (such as lips, tongue, and fingers in primates)

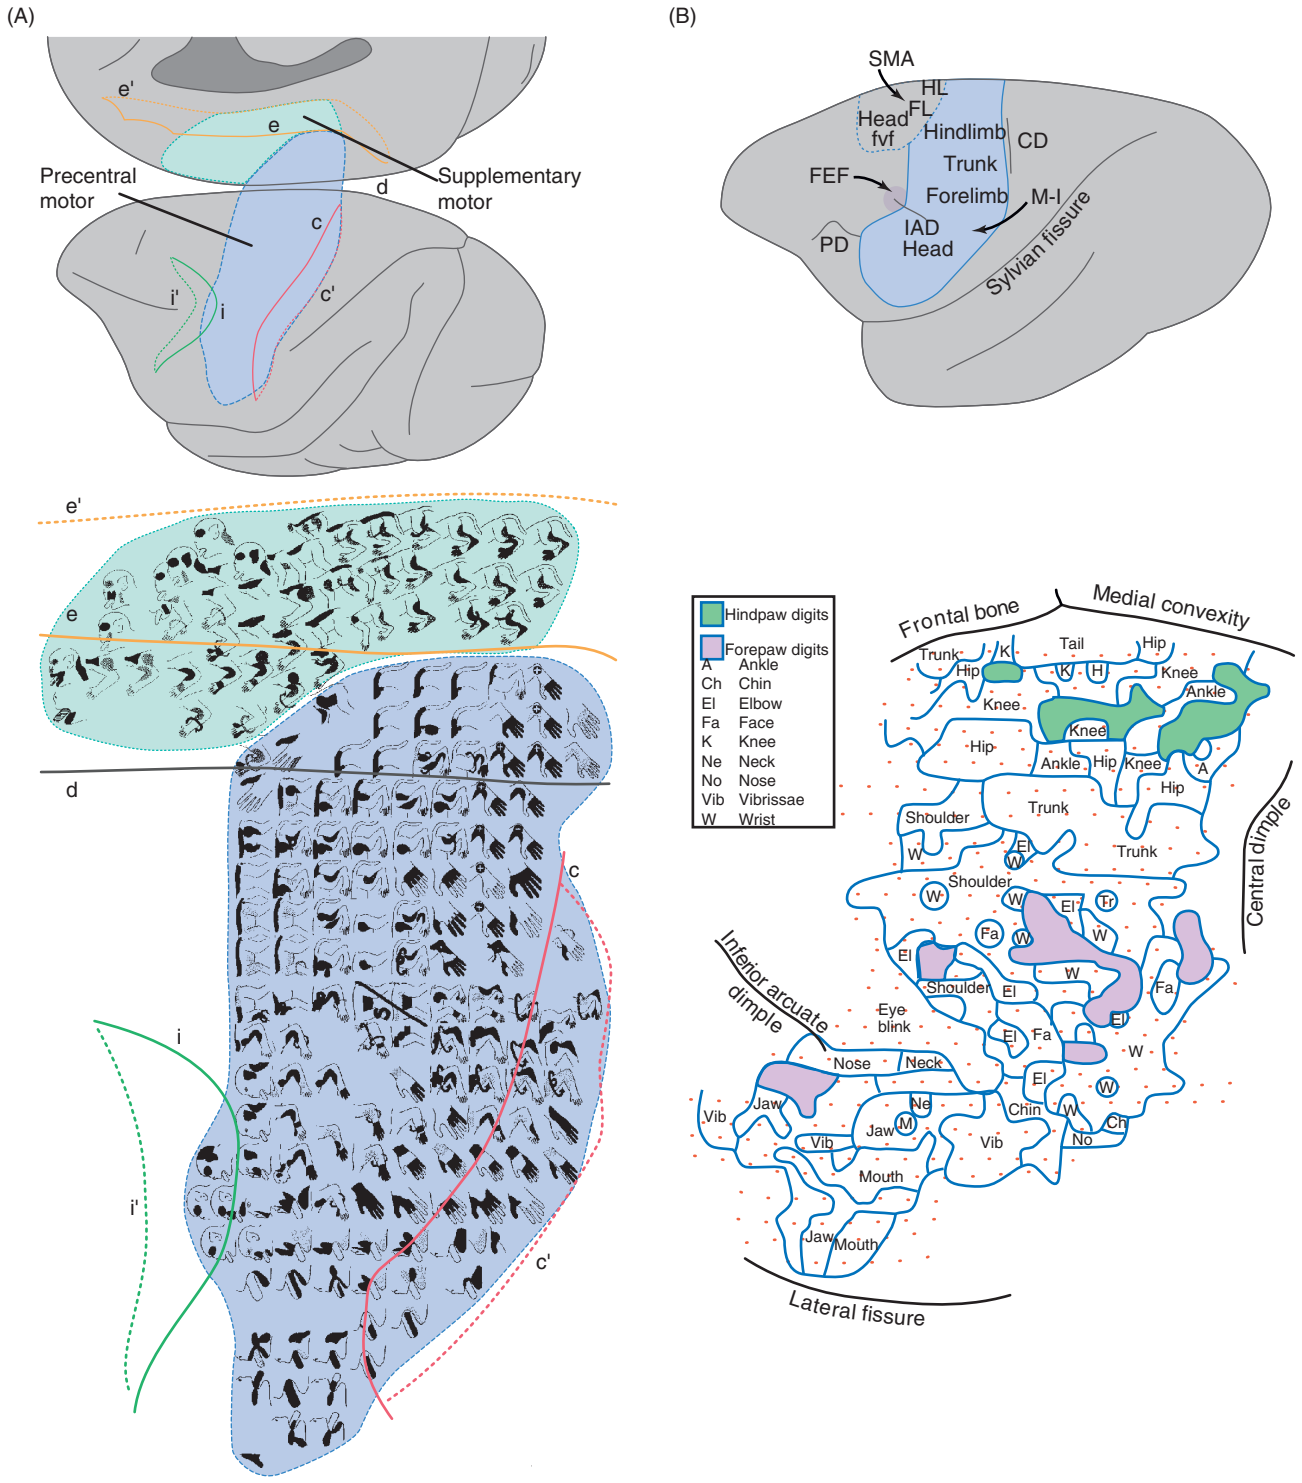

FIGURE 29.7 Somatotopic maps in M1. (A) Map by Woolsey et al. (1952) in which each figurine represents in black and gray the body parts that moved a lot or a little, respectively, when the cortical surface at that site was stimulated. In addition to the primary representation on the convexity, their map shows a secondary representation on the medial surface of the hemisphere, called the supplementary motor area (SMA). As defined in this study, M1 and SMA each included several of the currently defined cortical motor areas. (B) Intracortical microstimulation of M1 in an owl monkey produced this map, consisting of a complex mosaic of different body parts. In this species, the central sulcus is only a shallow dimple, and M1 is entirely on the surface of the hemisphere. Each dot represents a stimulated locus, and lines surround adjacent loci from which movement of the same body part was evoked. Note that the forepaw digits (purple) and the hindpaw digits (green) are represented in multiple areas separated by areas representing nearby body parts. *Modified from Gould, Cusic, Pons, and Kaas (1986).* In both A and B, the inset at the top indicates the region of the frontal lobe enlarged below.

are generally represented over a wider cortical territory than body parts used in gross movements such as ambulation. Penfield, in his cartoon of the motor homunculus (little man), and Woolsey, in his cartoon of the motor simiusculus (little monkey), conveyed this apparent magnification of certain body parts with respect to cortical territory by distorting the size of body parts relative to their normal proportions.

The somatotopic organization of M1 is not, however, a one-to-one mapping of body parts, muscles, or movements. Within the arm representation, for example, the cortical territory representing any particular part of the arm overlaps considerably with the territory representing nearby parts. This overlap results from three features of M1's organization: convergence, divergence, and horizontal interconnection.

M1 outputs arising from a wide cortical territory converge on the spinal motoneuron pool of any given muscle. Convergence of M1 outputs has been shown by delivering intracortical microstimulation while observing the body for evoked movements and/or recording electromyographic (EMG) activity from multiple muscles. Maps of which body parts move or which muscles contract upon threshold stimulation at different cortical sites look like a complex mosaic (Fig. 29.8A). As the stimulation current is increased, the mosaic pieces representing a given muscle coalesce into a larger and larger territory that overlaps more and more with the territories of other muscles. These findings indicate that any given muscle is controlled by a large territory in M1 and that the territories for different muscles overlap (Fig. 29.8B). Using retrograde transneuronal tracing with rabies virus, these large and overlapping cortical territories for different muscles recently have been demonstrated anatomically as well.

A second factor contributing to the overlap of territories in M1 is the divergence of output from single cortical neurons to multiple motoneuron pools. Intracellular staining has shown that a single corticospinal axon may have terminal ramifications within the motoneuron pools of multiple muscles over several segmental levels of the spinal cord (Fig. 29.9A). Moreover, spike-triggered averaging of EMG activity has demonstrated that single M1 neurons can have relatively direct effects on the motoneuron pools of multiple muscles (Fig. 29.9B). These findings indicate that single M1 neurons have output connections that diverge to innervate the spinal motoneuron pools of multiple muscles (Fig. 29.9C).

A third factor contributing to overlapping representation is the horizontal interconnectivity intrinsic to M1. Although most horizontal axon collaterals of neurons in layer V extend only 1–2 mm, some extend across the upper extremity representation, interconnecting even the territories of proximal and distal muscles

Because of convergence, divergence, and horizontal interconnections, neuronal activity is widely distributed

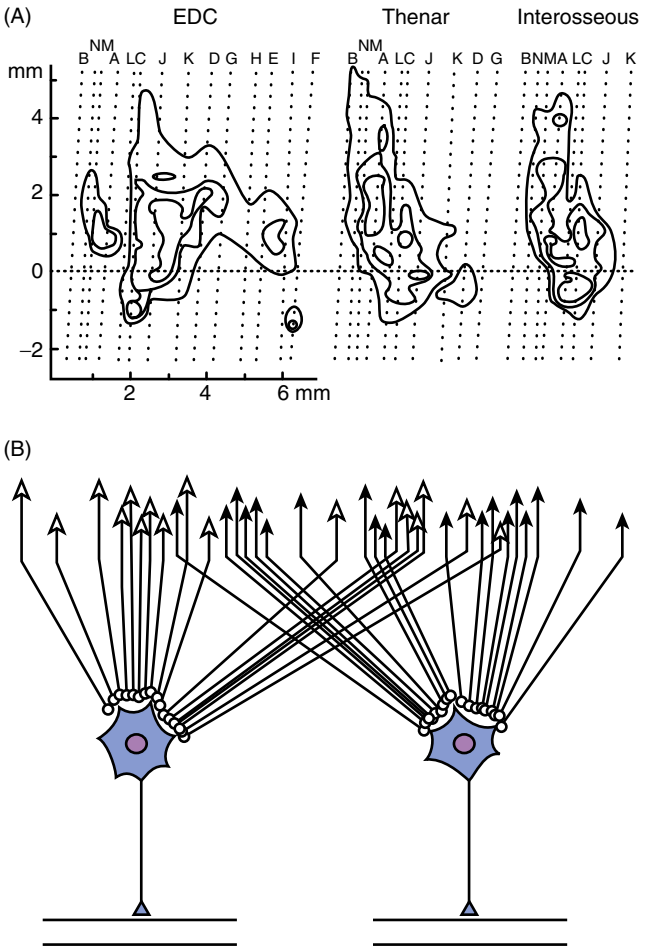

FIGURE 29.8 Convergence of M1 outputs to single muscles. (A) Isothreshold contours show the points at which EMG responses were evoked in three different muscles—extensor digitorum communis (EDC), thenar, and first dorsal interosseus—by intracortical microstimulation in the anterior bank of the central sulcus. (B) Data shown in A indicate that the cortical input to the motoneurons of any muscle originates from a wide territory in M1 and that the cortical territory providing input to a given muscle overlaps extensively with the cortical territory providing input to other muscles in the same part of the body. *Modified from Andersen, Hagan, Phillips, and Powell (1975).*

in M1 during natural movements, even discrete movements of single body parts. In monkeys trained to perform individuated movements of each finger, individual M1 neurons are active during movements of multiple fingers, and neurons throughout the M1 hand area are active during movements of any given finger. Likewise, in humans performing movements of different fingers, activity is distributed over the entire M1 hand representation whether the subject is moving a single finger or the whole hand. Although the entire hand representation may be activated for movement of any given finger, monkey and human studies have shown a tendency for the center of activation during movements of the thumb to be located laterally to that for movements of other fingers, consistent with the

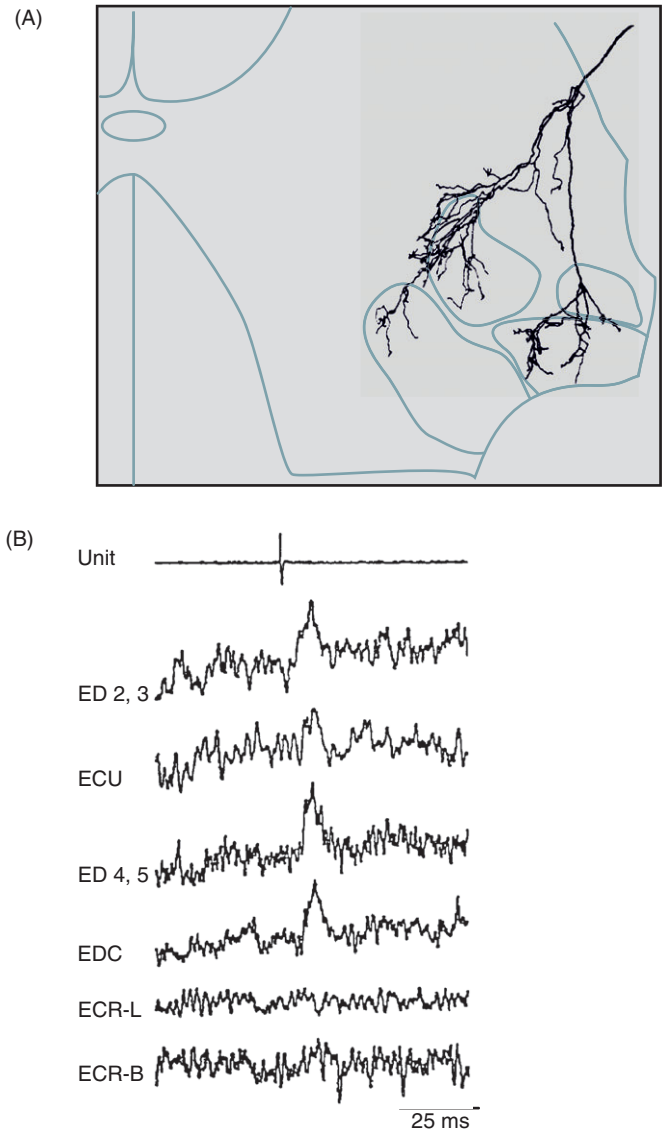

FIGURE 29.9 Divergence of M1 outputs to multiple muscles. (A) Tracing of a single corticospinal axon ramifying in the ventral horn of the spinal cord shows terminal fields in the motoneuron pools of four forearm muscles. *From Shinoda, Yokota, and Futami (1981).* (B) Action potentials in a cortical neuron (top trace) are followed at a fixed latency by peaks of postspike facilitation in EMGs recorded from four of six recorded forearm muscles (lower traces), consistent with monosynaptic excitation of all four motoneuron pools by that cortical neuron. The EMGs are rectified and averaged responses to 7051 action potentials in the cortical neuron. *From Fetz and Cheney (1980).* (C) These anatomic and physiologic findings indicate that the output of single corticospinal neurons often diverges to influence multiple muscles. *From Cheney, Fetz, and Palmer (1985).*

somatotopic orientation of the hand in the classic simiusculus and homunculus.

The somatotopic representation in M1, like that in the primary somatosensory cortex, has a certain degree of plasticity. The cortical territory representing a given muscle can enlarge when nearby body parts are denervated experimentally. Threshold stimulation in the cortical territory that had represented a denervated body part then comes to evoke movements in nearby body parts. Enlargement of a given muscle's cortical territory occurs as well when that muscle is stretched passively or used intensely for a prolonged period. Furthermore, in normal humans who are actively practicing a complex sequence of finger movements, the cortical territory representing a given finger muscle enlarges as the subjects become skilled at performing the sequence. Because such changes can occur within several minutes, they probably are mediated by long-term potentiation and/or depression at existing synapses. This ability of the M1 cortex to reorganize may in part underlie motor recovery seen in humans after damage to M1 or the corticospinal tract.

Control of Voluntary Movements by the Motor Cortex

Several methods have enabled investigators to explore how cortical motor areas contribute to the production and control of voluntary movement in awake, behaving subjects. Whereas microelectrodes record the action potentials of single neurons, measurements made by functional imaging or by recording surface potentials reflect the net activity of thousands of cortical neurons and millions of synapses.

Multiple Cortical Areas Are Active When the Brain Generates a Voluntary Movement

These different methodologies now make it clear that many cortical areas in addition to the primary motor cortex are active during the planning and execution of voluntary movements. During performance of either a simple keypress or a complex movement sequence, for example, functional imaging studies in humans have shown

bilateral activation of the primary sensorimotor hand representation, the supplementary motor area, and the ventrolateral premotor cortex, plus contralateral activation of the dorsolateral premotor cortex and the medial cortex rostral to the SMA. Whereas such techniques provide information on the parts of the cortex that are active in a given situation, studies of electrical potentials provide information on the time course of activation. For simple self-paced movements, cortical electrical potentials over the SMA and M1 begin to change as early as 1 s prior to the movement. As the time of movement onset approaches, the amplitude of these bilateral electrical potential shifts increases (the Bereitschaft potential). At the time of the movement, a further increase in amplitude occurs over the somatotopically appropriate region of M1 contralateral to the moving body part. Given that many cortical areas are active in controlling movement raises the question: What does each area contribute to control?

M1 Neurons Control Movement Kinematics and Dynamics

In one of the earliest studies of single neuron activity in awake behaving animals, Evarts recorded the activity of M1 pyramidal tract neurons in monkeys trained to raise and lower weights using flexion and extension wrist movements (Fig. 29.10). The discharge frequency of many M1 neurons changed systematically in temporal relation to either flexion or extension. A typical flexion-related neuron, for example, began to discharge several hundred milliseconds before wrist flexion began. As the onset of a flexion movement approached, the discharge frequency of the neuron increased, accelerating still more as the flexion movement was made. The neuron was silent during extension. The time course of these movement-related changes in single neuron activity parallels the time course of cortical electrical potential shifts.

Evarts went on to demonstrate that the discharge frequency of M1 pyramidal tract neurons (PTNs) varied in relation to a number of mechanical parameters of the movement the monkey was making. By changing the weights the monkey had to lift, Evarts showed that PTN discharge frequency varied with the force the monkey exerted. Comparison of PTN discharge with simultaneous force recordings revealed that bursts of PTN firing were correlated with sudden increases in the exerted force, indicating a relationship between firing frequency and the rate of change of force.

Subsequent studies revealed that the discharge of M1 neurons can be related to the direction of movement, the position of a particular joint, or the velocity of movement (Kalaska, 2009). Many neurons in the SMA, PMd, and parietal area 5 (which projects to SMA and PMd) also fire in relation to movement direction, and some PMv neurons fire in relation to movement force. Therefore, neurons in several nonprimary cortical motor areas participate with

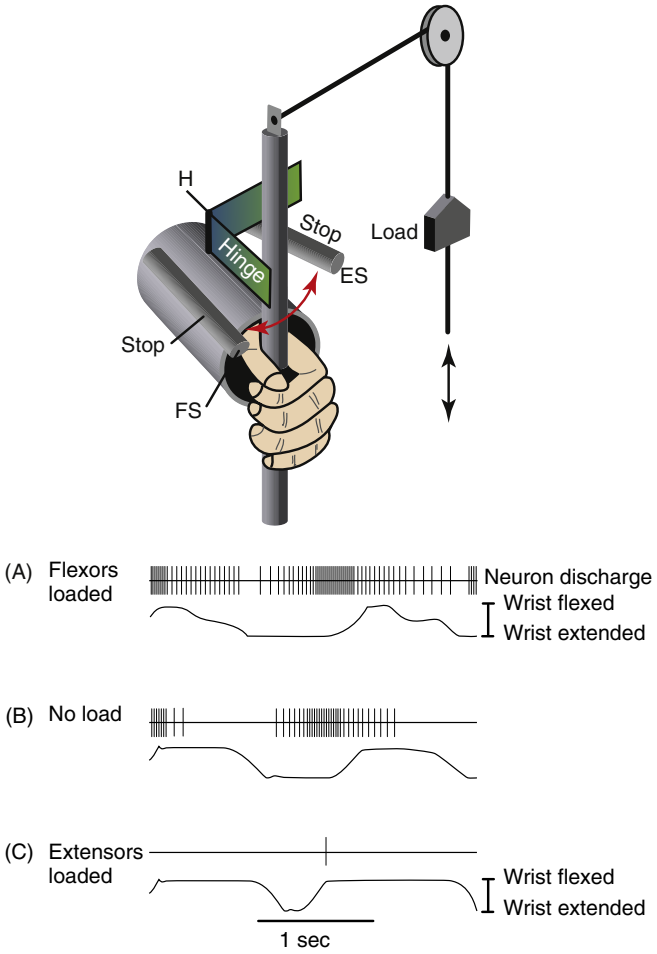

FIGURE 29.10 Discharge of a single M1 neuron in a monkey making flexion and extension wrist movements with wrist flexors loaded (A) and unloaded (B) and with wrist extensors loaded (C). The discharge rate of this neuron was greatest when the monkey used its wrist flexor muscles against a load. *Modified from Evarts (1968).*

those in M1 to control movement parameters such as direction, force, position, and velocity.

Although very strong correlations can be found between the discharge frequency of a given neuron and a particular movement parameter, an M1 neuron does not simply encode a single parameter. Rather, single M1 neurons show various degrees of correlation with direction, force, position, and velocity. Thus, the discharge of a single neuron in the motor cortex may influence several movement parameters.

Conversely, any given parameter or other feature of a movement is represented not by the discharge of a single M1 neuron, but by the ensemble activity of a large population of cortical neurons. Although a single M1 neuron typically discharges during reaching movements in several directions, for example, when the activity of many M1 neurons is combined appropriately, the population of M1 neurons can be shown to represent movement direction

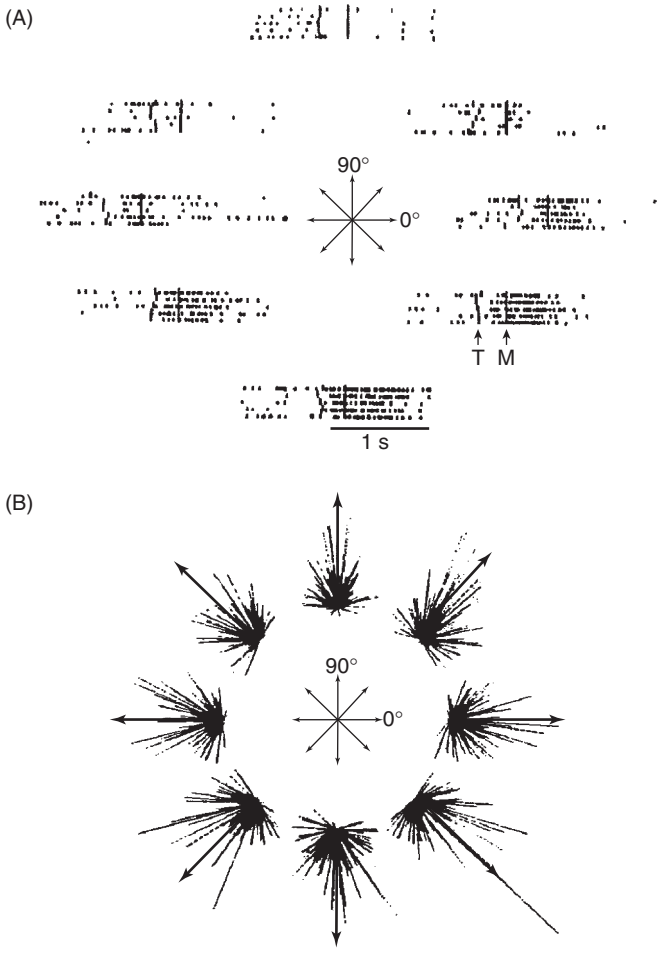

FIGURE 29.11 (A) Discharge of a single M1 neuron before and during arm movements in a monkey. Movements (represented by arrows) started from the same central point and ended at eight different points on a circle. The eight rasters show that the activity of this neuron was related to movements in four of the eight directions. The neuron discharged most intensely for movements down and to the right and was inhibited during movements up and to the left. (B) For each of the eight movements, the discharge of each M1 neuron is shown as a line pointing in the preferred direction of the neuron. Each line starts at the movement end point, and its length is proportional to the intensity of the discharge of that neuron during movement in that direction. Although the discharge of single neurons rarely identified any single movement direction with accuracy, the population vectors (arrows) summing the discharge of an ensemble of M1 neurons adequately specify each of the eight movement directions. *From Georgopoulos (1988).*

precisely (Fig. 29.11). Researchers have correlated the force, rate of change of force, position, and velocity of movements more accurately with the summed, weighted activity of a number of simultaneously recorded M1 neurons than with the discharge of any single neuron (see Box 29.4).

Cortical Motor Areas Prepare Voluntary Movements Based on a Variety of Cues

Cortical areas outside the primary motor cortex seem to be especially concerned with using a wide variety of sensory and other information as "cues" to select and guide movements. Insight into these cortical processes has been obtained by separating in time a cue instructing which movement to make from a second cue to execute the instructed movement. This creates a period between the two cues during which the subject knows what movement to make, but is not making the movement per se. During such an instructed delay period, many neurons in M1, SMA, and PMd discharge at their highest rate while the subject waits to move in a particular direction (Fig. 29.12). Such directional delay period activity is more common in PMd and SMA than in M1, where activity during movement execution predominates. During the delay between instruction and trigger, PMd, SMA, and other areas appear to store information on the direction of the impending movement. Indeed, neurons sometimes discharge in error during the delay, as if the monkey has seen a cue other than the one actually given and is preparing to move in the wrong direction. When such error discharges occur, the monkey often does make the wrong movement. The delay period discharge of such neurons thus represents stored information, not about which cue the monkey has seen, but rather about what movement the monkey will make.

The direction instructed usually is the same as the direction of the actual movement. To pick up a pencil, for example, you look at the pencil and then move your hand to the same place. Your brain transforms the visual location of the pencil into the location to which your hand is moved. Insight into how cue direction is transformed into movement direction has come from tasks in which these two features were experimentally dissociated, as if you looked at a pencil in a mirror and then reached to pick up the real pencil instead of the mirror image. To dissociate cue direction and movement direction experimentally, researchers have trained monkeys to perform mental rotation tasks in which a cue at one location instructs a movement to a different location.

Such tasks have been used to study neurons in the area principalis of the dorsolateral frontal lobe, in PMd, in SMA, and in M1. In each of these cortical areas, the activity of some neurons correlates best with the direction of the instructional cue, whereas the activity of other neurons correlates best with the direction of the actual movement. In general, from the area principalis, through the PMd and SMA to M1, the percentage of cue-related neurons decreases and the percentage of movement-related neurons increases. Moreover, as time progresses from the appearance of the instructional cue to the execution of the movement, the discharge of the neuronal populations encode cue direction initially and movement direction subsequently. The transformation of cue direction into movement direction thus involves many cortical motor areas and progresses throughout the reaction time of the subject.

BOX 29.4

MOTOR NEUROPROSTHETICS

The fact that a subject's movements can be decoded from populations of neurons, combined with the recently developed ability to implant devices in the brain that record populations of neurons simultaneously, has led to the development of brain-computer interfaces (BCIs) and brain machine interfaces (BMIs). These are devices in which a number of simultaneously recorded neurophysiological signals are decoded as a population, and the decoded output then is used to control either a cursor on a computer screen (BCI) or a physical device such as a robotic arm (BMI). While recordings of neuron spikes generally provide the best decoding, other types of neurophysiological signals—local field potentials recorded from penetrating microelectrodes (LFPs), recordings made from various sites on the surface of the brain (electrocorticographic, ECoG), or recordings obtained from the scalp (electroencephalographic, EEG)—all can provide decodable information about a subject's movements. With current systems, subjects can control the movement of an artificial arm in three-dimensional space, and can open and close the hand. The hope is that with further development of such neuroprosthetic systems, amputees may be able to have dexterous control of a prosthetic arm and hand, and paralyzed patients may be able to work on a computer or move in a normal fashion by driving electrical stimulation of their own, otherwise intact muscles (Lebedev & Nicolelis, 2006).

In addition to the potential for useful devices controlled directly from the brain, the field of neuroprosthetics is expanding our understanding of the motor cortex. In a typical BCI session, neurophysiological activity is recorded while a normal subject performs arm movements that control a cursor on a computer screen, like when you move a computer mouse to control a cursor. A decoding algorithm then is derived from the recorded data to predict which patterns of neurophysiological activity correspond to which movements. Next, the decoding algorithm is used to drive a computer cursor. If in this "brain control" mode the subject again is asked to move the cursor to different locations on the screen, however, a number of interesting things often happen. The tuning relationship between neurophysiological activity and movement may change, and the subject may stop moving entirely, even though the computer cursor continues to move under direct control by the cortical activity. Exactly how the cortical activity becomes dissociated from movement of the limb (Schieber, 2011), and how the cortical activity adapts to control the BCI, are currently questions under investigation (Green & Kalaska, 2011).

Some Cortical Motor Areas are Involved in Movements in Response to Either Internal or External Cues

Another aspect of movement preparation that differentially involves certain cortical motor areas has to do with whether the instructions about what to do come from internally remembered or externally delivered cues. In one experiment, for example, monkeys were trained to touch three of four pads in randomly selected sequences that were cued when the pads were lit in sequence. Once a monkey was accustomed to a given sequence, the lights were gradually dimmed until the monkey was performing the correct sequence based only on internally remembered cues. After several of these remembered trials, the pads were lit in a different sequence for several trials. Whereas neurons in M1 showed similar discharge rates during the internally remembered and externally cued trials for a given sequence, SMA neurons were generally more active during the internally remembered trials, and PMv neurons were generally more active during the externally cued trials (Fig. 29.13).

Summary

Axons from the cerebral cortex and from the red nucleus in the brainstem descend in pathways located dorsolaterally in the spinal cord to control voluntary movements. In addition to corticospinal and rubrospinal pathways, the motor cortex also sends projections to the red nucleus and to the pontomedullary reticular formation, providing additional pathways for voluntary control. Multiple cortical motor areas—distinguished by their inputs, their cytoarchitecture, and their interconnections with other cortical areas and with the thalamus—make different contributions to the control of voluntary movements. The most detailed motor map is found in the

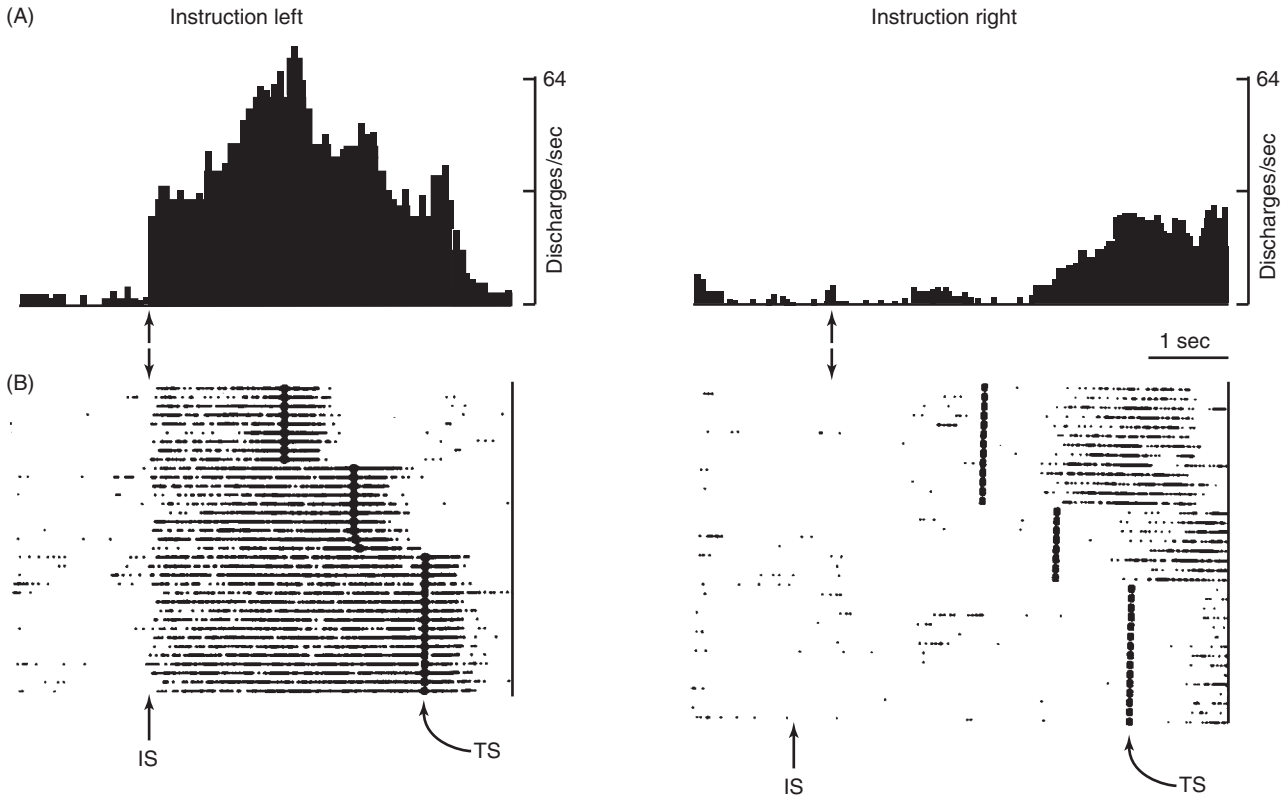

FIGURE 29.12 Directional delay period activity in a PM neuron. (A) As a monkey performed a delayed-reaction paradigm, this neuron began to discharge shortly after receiving instructions (IS) to perform a leftward movement. Discharge continued until after the monkey had subsequently received a separate triggering signal (TS, which occurred at three different time intervals after the IS) and performed the movement. During the delay between IS and TS, while the monkey did not move, the discharge of the neuron encoded the direction of the instruction, the direction of the impending movement, or both. (B) When the instruction was for rightward movement, this neuron did not discharge until after the movement had been made, presumably as the monkey was then preparing to move back to its original position. *From Wise and Strick (1996).*

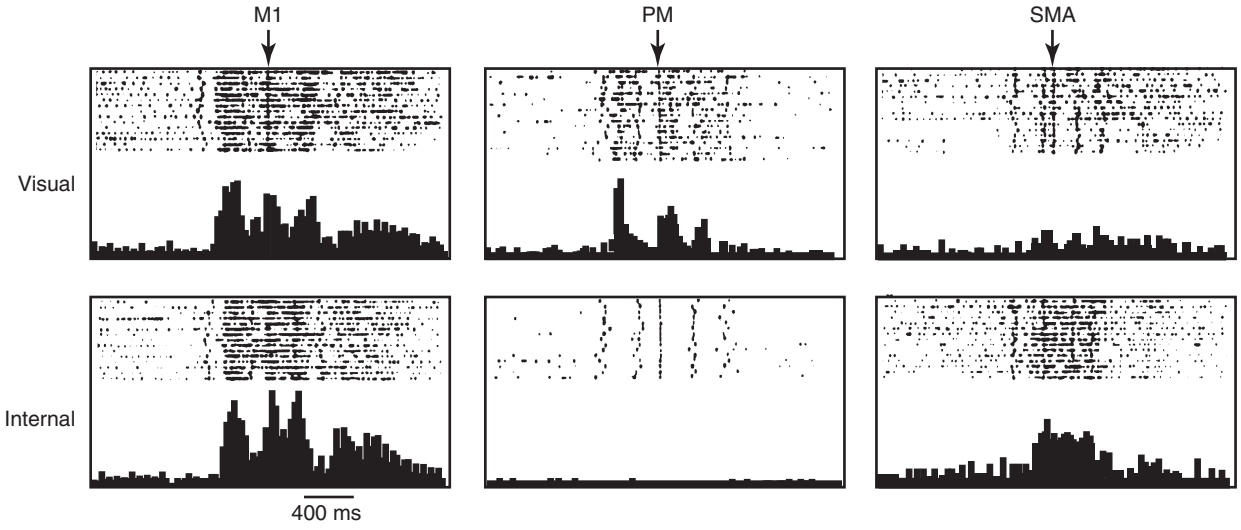

FIGURE 29.13 Activity of three neurons—one in M1, one in PM, and one in SMA—recorded as a monkey pressed three buttons in sequence. The sequence was first cued visually by lighting the buttons and was then cued internally. The M1 neuron showed similar activity whether the monkey performed from visual or internal cues. The PM neuron, however, was much more active in response to visual than internal cues, whereas the opposite was true for the SMA neuron. *Modified from Mushiake, Inase, and Tanji (1991).*

primary motor cortex, M1, but the somatotopic organization is limited by convergence and divergence in the corticospinal projection. Populations of M1 neurons are also in most direct control of movement kinematics and dynamics. Other cortical motor areas participate differentially in the selection of, and preparation for, voluntary movements based on a variety of internal and external cues.

SUMMARY

The motor cortex, the red nucleus, the pontomedullary reticular formation, and the vestibular nuclei each send major axonal projections descending from the brain to the spinal cord to control bodily movements. Although these pathways normally provide seamless movement control, different contributions of the medial and lateral descending pathways have been identified experimentally.

The medial system—vestibulospinal and reticulospinal—receives sensory input from the vestibular apparatus and mediates postural responses that keep the head and body stabilized for stance and gait. Additional visual and proprioceptive inputs that reach the vestibular and reticular nuclei via brainstem pathways or after processing in the cerebellum (Chapter 31) also influence postural control. Context-dependent strategies established via centers including the cerebellum and motor cortex further adapt postural responses to the needs of particular complex situations.

The lateral system—corticospinal and rubrospinal—receives, in addition to somatosensory inputs, information processed by the cerebellum (Chapter 31), the basal ganglia (Chapter 30), and association cortical areas to mediate voluntary movements of the face and extremities. Different cortical motor areas receive different portions of these inputs and therefore make different contributions to controlling voluntary movements. The most elaborate somatotopic representation is found in the primary motor cortex, M1. While the convergence, divergence and horizontal interconnections of the intrinsic organization of M1 result in considerably distributed activation during voluntary movements, the same substrates enable substantial plasticity. Whereas M1 neurons most directly control the kinematics and dynamics of movement execution, other cortical motor areas participate in selecting which movement(s) to make on the basis of external cues and internal states.

CHAPTER

30

The Basal Ganglia

The basal ganglia and the cerebellum are large subcortical components of the motor system. They act in parallel, influencing both cortical and brainstem motor areas to ensure efficient, focused, and well-coordinated movements. Although they communicate with the same areas of cerebral cortex and with each other, they have distinct functions and mechanisms of action. They communicate with motor areas of cerebral cortex privately using separate thalamic nuclei. The outputs have opposite signs: the basal ganglia output is inhibitory and the cerebellar output is excitatory. The cerebellum receives direct input from spinal cord ascending pathways and from the vestibular system, whereas the basal ganglia receives the bulk of its sensory information from cerebral cortex. In human diseases, basal ganglia dysfunction results in changes in the slow voluntary movements or the development of involuntary movements; cerebellar dysfunction results in impaired coordination. In addition to their motor functions, both basal ganglia and cerebellum play roles in nonmotor behavior, including cognition, emotion, and possibly others. The basal ganglia are discussed in this chapter and the cerebellum in the next (Chapter 31).

The basal ganglia comprise several interconnected nuclei in the forebrain, diencephalon, and midbrain (Fig. 30.1). They are an important part of the motor system, and motor control is a large part of basal ganglia function: (1) the largest portion of basal ganglia inputs and outputs are connected with motor areas; (2) the discharge of many basal ganglia neurons correlates with movement; and (3) basal ganglia lesions cause severe movement abnormalities. In view of these features, this chapter concentrates on the motor functions of the basal ganglia. Participation of the basal ganglia in nonmotor functions is discussed after the basic framework of basal ganglia function is presented for motor control. The anatomy of the basal ganglia is discussed first, since it is anatomy that provides the infrastructure for the physiology. Next we will consider the activity of the individual components of the basal ganglia during movement. Then we will review the effect of placing a lesion in one basal ganglia component while leaving the rest of the nervous system intact. The combined strategy of measuring the activity of a structure during movement and then determining the effect of a selective lesion on that movement has been fruitful in studying the function of the motor system and understanding the effects of human basal ganglia diseases. After presentation of current models of basal ganglia motor function, the chapter concludes with a discussion of basal ganglia participation in cognitive function.

ANATOMY OF THE BASAL GANGLIA

The basal ganglia receive a broad spectrum of cortical inputs. The information conveyed to the basal ganglia is processed to produce a focused output to areas of the frontal lobes and brainstem that are involved in the planning and production of movement. The basal ganglia output is inhibitory, which means that an *increase* in basal ganglia output leads to a *reduction* in the activity of its targets. The fact that the basal ganglia output is inhibitory to other motor mechanisms is key to understanding its normal function.

At first glance, the anatomy of the basal ganglia may seem confusing. There are several component nuclei at different levels in the brain, and two of the nuclei [substantia nigra (SN) and globus pallidus] are divided into functionally different components. The names of some structures are different in primates than in other mammals. Furthermore, the terminology has changed over the years so that

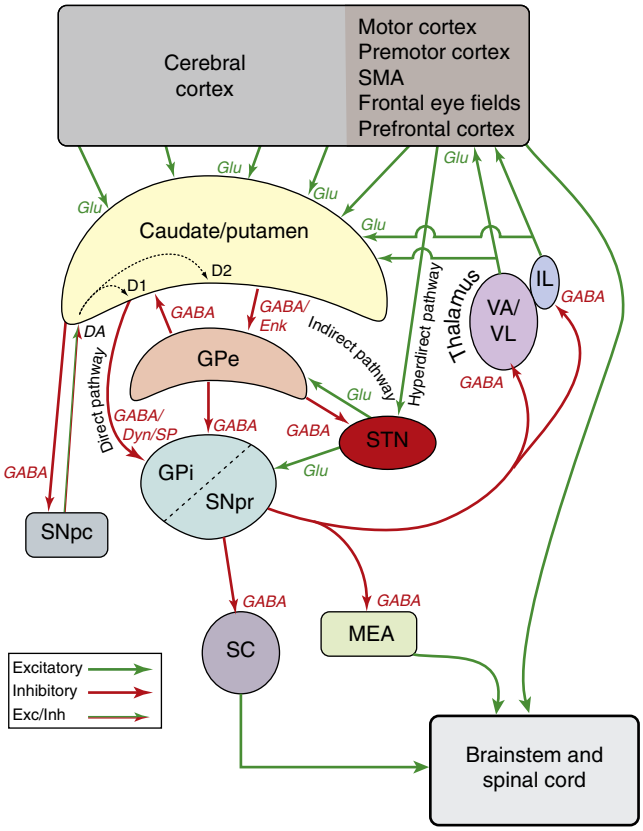

FIGURE 30.2 Simplified schematic diagram of basal ganglia circuitry. Excitatory connections are indicated by green arrows, inhibitory connections by red arrows, and the modulatory dopamine projection is indicated by a red and green arrow. GPe, globus pallidus, external segment; GPi, globus pallidus, internal segment; IL, intralaminar thalamic nuclei; MD, mediodorsal thalamic nucleus; MEA, midbrain extrapyramidal area; SC, superior colliculus; SNpc, substantia nigra pars compacta; SNpr, substantia nigra, pars reticulata; STN, subthalamic nucleus; VA, ventral anterior thalamic nucleus; VL, ventral lateral thalamic nucleus; DA, dopamine (with D1 and D2 receptor subtypes); Dyn, dynorphin; Enk, enkephalin; GABA, γ-aminobutyric acid; Glu, glutamate; SP, substance P.

historically an individual structure has been known by more than one name. However, with consistent use of modern terminology and a functional context in which to place the anatomy, the organization of basal ganglia can be learned readily. Once the organization is learned, many aspects of normal function and the response to injury become easier to understand.

The basal ganglia include the striatum (caudate, putamen, nucleus accumbens); the subthalamic nucleus (STN); the globus pallidus (internal segment—GPi; external segment—GPe; and ventral pallidum—VP); and the substantia nigra (pars compacta—SNpc; and pars reticulata—SNpr) (Fig. 30.2). The striatum and STN receive the majority of their inputs from outside the basal ganglia. Most of those inputs come from the cerebral cortex, but thalamic nuclei also provide strong inputs to striatum. There are no direct inputs from peripheral sensory or motor systems. The bulk of the outputs from basal ganglia arise from GPi and SNpr and are inhibitory to thalamic nuclei and to the brainstem. There are no direct outputs from basal ganglia to spinal motor circuitry.

The Striatum Receives Most of the Inputs to the Basal Ganglia

The striatum is located in the forebrain and comprises the caudate nucleus and putamen (neostriatum) and nucleus accumbens (ventral striatum). This section focuses on the neostriatum (see Box 30.3 and Chapter 41 for a discussion of the ventral system of the basal ganglia). Embryologically, the striatum develops from a basal region of the lateral telencephalic vesicle. It is named the striatum because axon fibers passing through the striatum give it a striped appearance. In rodents, the caudate and putamen form a single structure (caudatoputamen) with fibers of the internal capsule coursing through, but in carnivores and primates, the caudate and putamen are separated by the internal capsule (Fig. 30.1A).

Four major types of neurons have been described in the striatum, based on the size of the cell body, presence or absence of dendritic spines in individual neurons that have been stained with the Golgi technique or filled with horseradish peroxidase, and other staining properties. The first and by far the most numerous neuron type is the *medium spiny neuron* (Fig. 30.3). Medium spiny neurons make up 90 to 95% of the total number of striatal neurons. They utilize γ-aminobutyric acid (GABA) as a transmitter and constitute the output of the striatum, sending axonal projections to the GP and SN. Medium spiny neurons have large dendritic trees that span 200 to 500 μm. They also have extensive local axon collaterals that inhibit neighboring striatal neurons.

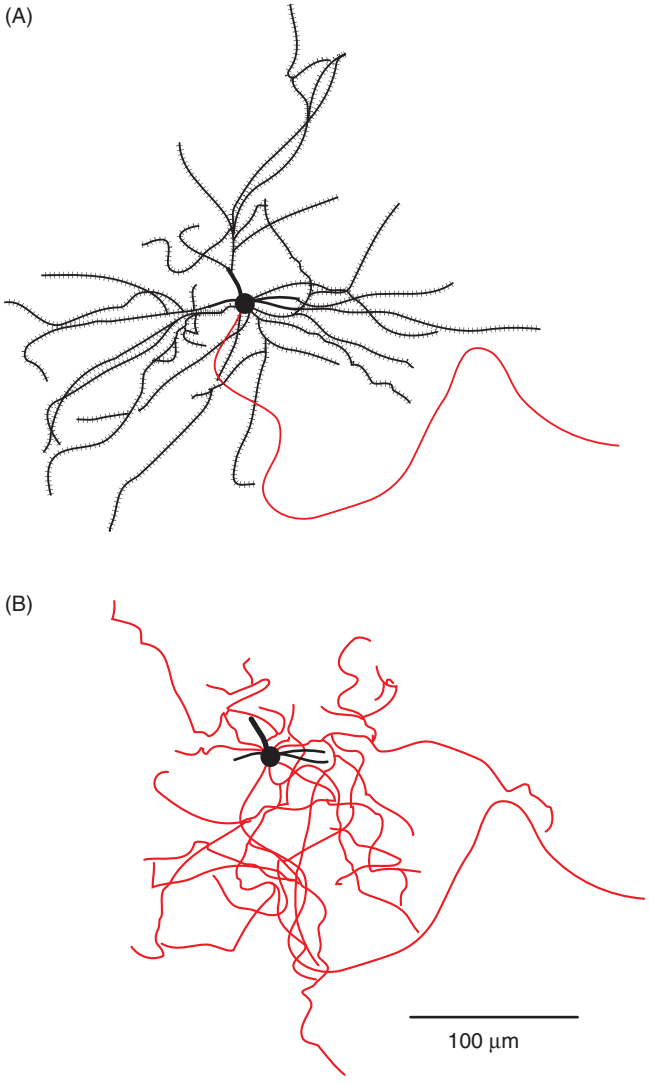

FIGURE 30.3 Two representations of a striatal medium spiny neuron that has been filled with HRP. (A) The soma and dendritic tree with numerous dendritic spines. The thin process is the axon, which has been drawn without its collaterals. (B) The same neuron drawn to show the axonal collaterals, which branch extensively within the same field as the dendritic tree. *From Wilson and Groves (1980).*

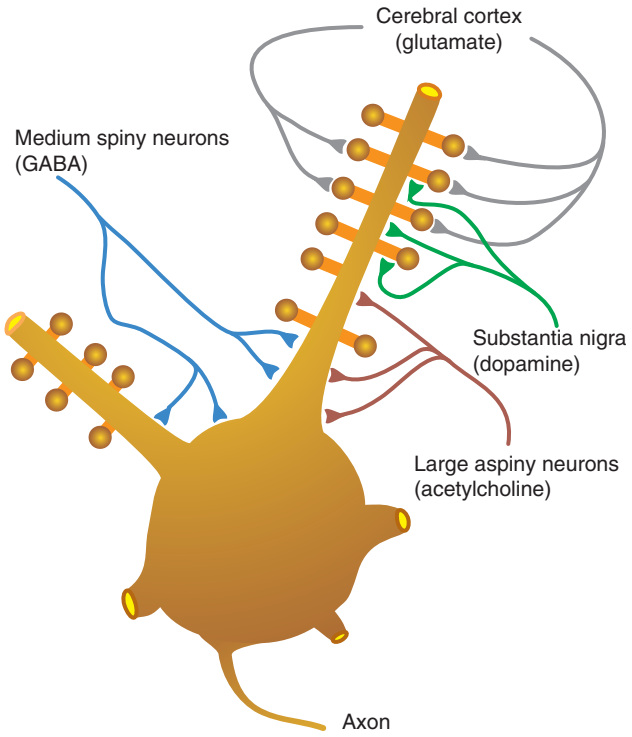

FIGURE 30.4 Pattern of termination of afferents on a medium spiny neuron. The soma and the proximal dendrites with their spines are shown.

The medium spiny neurons are morphologically homogeneous, but chemically heterogeneous, as discussed later. The second, *large aspiny neurons*, make up 1 to 2% of the striatal population. They are interneurons and use acetylcholine (ACh) as a neurotransmitter. They have extensive axon collaterals within the striatum that terminate on medium spiny neurons. The third type, *small aspiny neurons*, make up 2 to 5% of the striatal population. They stain positive for parvalbumin and use GABA as a neurotransmitter. The fourth type is the *medium aspiny neuron*. These are also interneurons and are thought to use somatostatin as a neurotransmitter.

The striatum receives excitatory input from nearly all of the cerebral cortex. The cortical input uses glutamate as its neurotransmitter and terminates largely on the heads of the dendritic spines of medium spiny neurons (Fig. 30.4). The projection from the cerebral cortex to the striatum has a roughly topographical organization. For example, the somatosensory and motor cortex project to the posterior putamen and the prefrontal cortex projects to the anterior caudate. Within the somatosensory and motor projection to the striatum, there is a preservation of somatotopy. It has been suggested that the topographic relationship between the cerebral cortex and the striatum provides a basis for the segregation of functionally different circuits in the basal ganglia (Kelly & Strick, 2004) (Fig. 30.5). These circuits include

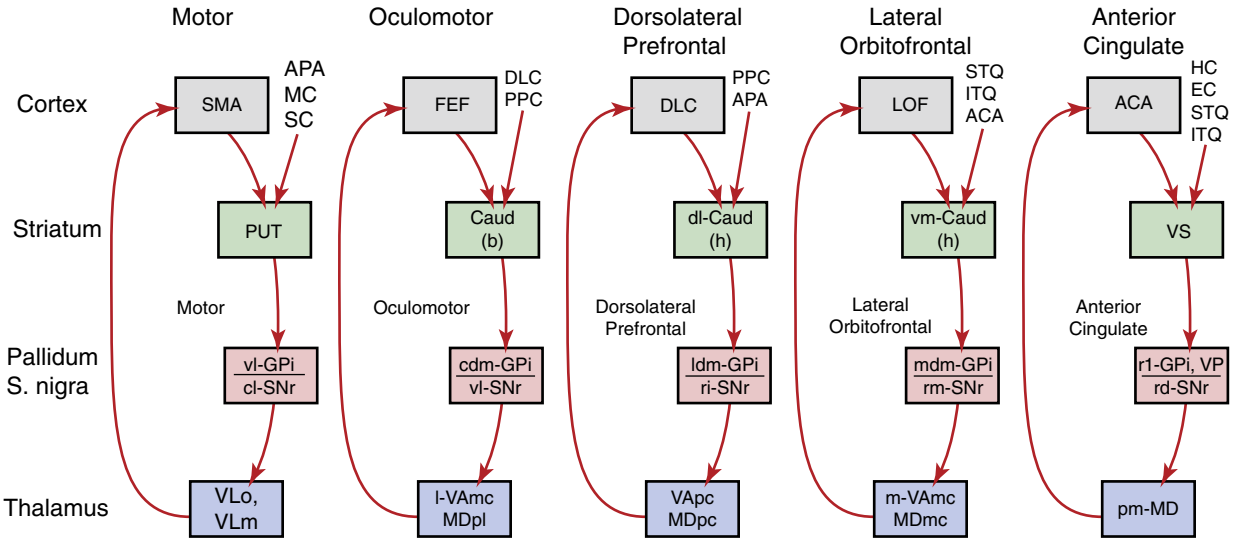

FIGURE 30.5 Hypothetical parallel segregated circuits connecting the basal ganglia, thalamus, and cerebral cortex. The five circuits are named according to the primary cortical target of the output from the basal ganglia: motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate. ACA, anterior cingulate area; APA, arcuate premotor area; CAUD, caudate; b, body; h, head; DLC, dorsolateral prefrontal cortex; EC, entorhinal cortex; FEF, frontal eye fields; GPi, internal segment of globus pallidus; HC, hippocampal cortex; ITG, inferior temporal gyrus; LOF, lateral orbitofrontal cortex; MC, motor cortex; MDpl, medialis dorsalis pars paralarnellaris; MDme, medialis dorsalis pars magnocellularis; MDpc, medialis dorsalis pars parvocellularis; PPC, posterior parietal cortex; PUT, putamen; SC, somatosensory cortex; SMA, supplementary motor area; SNr, substantia nigra pars reticulate; STG, superior temporal gyrus; VAmc, ventralis anterior pars magnocellularis; Vapc, ventralis anterior pars parvocellularis; VLm, ventralis lateralis pars medialis; VLo, ventralis lateralis pars oralis; VP, ventral pallidum; VS, ventral striatum, cl, caudolateral; cdm, caudal dorsomedial; d1, dorsolateral; 1, lateral; 1dm, lateral dorsomedial; m, medial; mdm, medial dorsomedial; pm, posteromedial; rd, rostrodorsal; rl, rostrolateral; rm, rostromedial; vm, ventromedial; vl, ventrolateral.

somatomotor, oculomotor, cognitive, and limbic connections. Within each circuit there appear to be subcircuits such that the primary motor cortex and premotor cortex have nonidentical connections with basal ganglia structures. Likewise, dorsolateral and orbitofrontal circuits have distinct connectivity patterns.

Although the topography and somatotopy imply a certain degree of parallel organization, there are also convergence and divergence in the corticostriatal projection. The large dendritic fields of medium spiny neurons allow them to receive input from adjacent projections, which arise from different areas of cortex. Inputs from more than one cortical area overlap, and input from a single cortical area projects divergently to multiple striatal zones (Fig. 30.6). This convergent and divergent organization provides an anatomical framework for the integration and transformation of information from several areas of the cerebral cortex.

In addition to cortical input, medium spiny striatal neurons receive a number of other inputs, including (1) excitatory glutamatergic inputs from intralaminar and ventrolateral nuclei of the thalamus; (2) cholinergic input from large aspiny neurons; (3) GABA, substance P, and enkephalin input from adjacent medium spiny striatal neurons; (4) GABA input from small interneurons; and (5) a large input from dopamine (DA)-containing neurons in the SNpc. The DA input is of particular interest because of its role in Parkinson disease (see Box 30.1).

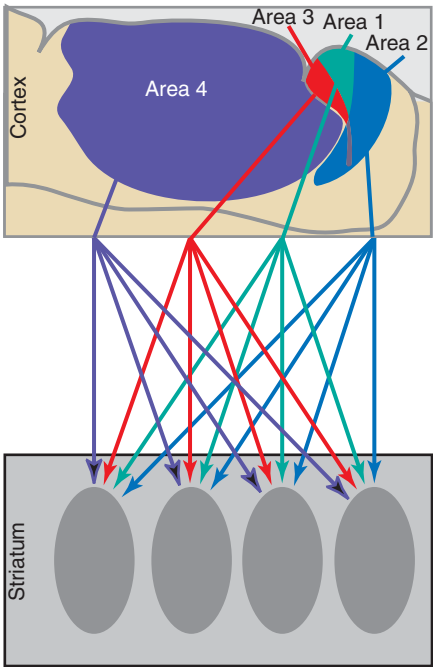

FIGURE 30.6 Schematic representation of the sensorimotor cortical projection to the striatum from arm areas in the somatosensory cortex (areas 1, 2, and 3) and motor cortex (area 4). Note that each cortical area projects to several striatal zones and several functionally related cortical areas project to a single striatal zone. *After Flaherty and Graybiel (1991).*

BOX 30.1

PARKINSON'S DISEASE

Parkinson's disease (PD) is the second most common progressive neurodegenerative disorder. Patients with PD experience slowness of movement, rigidity, a low-frequency rest tremor, and difficulty with balance. These major motoric features of PD are due to the degeneration of dopamine (DA) containing neurons in the substantia nigra pars compacta (SNC) with an accompanying loss of DA and its metabolites in the striatum. PD patients may exhibit other symptoms, including cognitive dysfunction, depression, anxiety, autonomic problems, and disturbances of sleep, which may be due to the degeneration of non-DA-containing neurons. PD is characterized pathologically by the cytoplasmic accumulation of aggregated proteins with a halo of radiating fibrils and a less defined core known as Lewy bodies. Measures of increased oxidative stress are also seen, including glutathione depletion, iron deposition, increased markers of lipid peroxidation, oxidative DNA damage and protein oxidation, and decreased expression and activity of mitochondrial complex 1 in the SNC. This mitochondrial complex 1 defect is specific to the SNC, as it has not been observed in other neurodegenerative diseases. Thus, in sporadic PD, oxidative stress and mitochondrial dysfunction appear to play prominent roles in the death of DA neurons. The majority of PD appears to be sporadic in nature, but an estimated 10% of cases are familial, with specific genetic defects. The identification of these rare genes and their functions has provided tremendous insight into the pathogenesis of PD and opened up new areas of investigation.

Several genes have been clearly linked to PD. The best studied are α-synuclein and parkin. α-Synuclein is a presynaptic protein and a primary component of Lewy bodies. Very rare missense mutations at A53T and A30P cause autosomal-dominant PD. How derangements in α-synuclein lead to dysfunction and death of neurons is not known. However, aggregation and fibrillization are thought to play a central role, perhaps leading to a dysfunction in protein handling by inhibiting the proteasome. The second "PD gene" parkin is an E3 ligase for the ubiquitination of proteins. Mutations in parkin include exonic deletions, insertions, and several missense mutations and result in autosomal recessive PD. Parkin mutations are now considered to be one of the major causes of familial PD. Substrates for parkin include the synaptic vesicle–associated protein CDCrel-1, which may regulate synaptic vesicle release in the nervous system. Whether CDCrel-1 is involved in the release of dopamine is not yet known. Synphilin-1 is a protein of unknown function that was identified as an α-synuclein interacting protein. It is a synaptic vesicle-enriched protein and is present in Lewy bodies. Synphilin-1 is a target of parkin, and expression of synphilin-1 with α-synuclein results in the formation of Lewy body–like aggregates that are ubiquitinated in the presence of parkin. Parkin is upregulated by unfolded protein stress, and expression of parkin suppresses unfolded protein stress-induced toxicity. The unfolded putative G-protein-coupled transmembrane receptor, the parkin-associated, endothelial-like receptor (Pael-R), is a parkin substrate. When over-expressed, Pael-R becomes unfolded, insoluble, and causes unfolded protein-induced cell death. Parkin ubiquitinates Pael-R, and coexpression of parkin results in protection against Pael-R-induced cell toxicity. Pael-R accumulates in the brains of autosomal-recessive Parkinson's disease patients and thus may be an important parkin substrate.

Ultimately, it would be of interest to link all the multiple genes and the sporadic causes of PD into a common pathogenic biochemical pathway. Derangements in protein handling seem to be central in the pathogenesis of familial PD. Oxidative stress seems to play a prominent role in sporadic PD, and oxidative stress leads to synuclein aggregation and/or proteasomal dysfunction. Data suggest that there may be selective derangements in the proteasomal system in the substantia nigra of sporadic PD. Thus, protein mishandling may be central to the pathogenesis of PD.

In contrast to most other neurodegenerative disorders, there is effective temporary symptomatic treatment for PD consisting of DA replacement with levodopa or DA agonists and adjunctive medications or surgical approaches. Because the neurodegeneration in PD is progressive and there is no proven preventative, restorative, or regenerative therapy, patients eventually become quite disabled. Ultimately, to affect a true cure, the underlying mechanisms of neuronal cell death need to be understood, strategies for enhancing neuronal survival and regrowth need to be developed, and consideration needs to be made toward the replacement of cells lost during the degenerative process. If these goals can be obtained, a full recovery could be achieved.

Valina L. Dawson and Ted M. Dawson

Adapted from Dawson T. M. (2000). New animal models for parkinson's disease. *Cell, 101*(2), 115–118.

Adapted from Zhang Y., Dawson V. L., & Dawson T. M. Oxidative stress and genetics in the pathogenesis of parkinson's disease. *Neurobiology of Disease, 7*(4), 240–250.

The DA input to the striatum terminates largely on the shafts of the dendritic spines of medium spiny neurons (Fig. 30.4). The location of dopaminergic terminals puts them in a position to modulate transmission from the cerebral cortex to the striatum. The action of DA on striatal neurons depends on the type of DA receptor involved. Five types of G-protein-coupled DA receptors have been described (D1–D5). These have been grouped into two families based on their response to agonists. The D1 family includes D1 and D5 receptors, and the D2 family includes D2, D3, and D4 receptors. D1 receptors stimulate adenylate cyclase activity and potentiate the effect of cortical input to striatal neurons. D2 receptors inhibit adenylate cyclase activity and decrease the effect of cortical input to striatal neurons (see Chapters 5, 7, and 8).

Medium spiny neurons contain the inhibitory neurotransmitter GABA. In addition, medium spiny neurons have peptide neurotransmitters that are co-localized with GABA. Based on both the type of neurotransmitters and the type of DA receptor they contain, medium spiny neurons can be divided into two populations. One population contains GABA, dynorphin, and substance P and primarily expresses D1 receptors. These neurons send axons to GPi and to SNpr and constitute the "direct pathway" (Fig. 30.2). The predominant effect of these neurons is inhibition of their targets. The second population contains GABA and enkephalin and primarily expresses D2 receptors. These inhibitory neurons project to GPe and form the first limb of the "indirect pathway" (Fig. 30.2). The two populations of medium spiny neurons are morphologically indistinguishable and are not segregated topographically within the striatum (Fig. 30.7). This comingling of neurons suggests that they receive similar input and thus they may convey similar information to their respective targets. However, the different targets and transmitter types of the two populations provides the substrate for functional segregation within the striatum.

Although there are no apparent regional differences in the striatum based on cell morphology, an intricate internal organization has been revealed with special stains. When the striatum is stained for acetyl-cholinesterase (AChE), there is a patchy distribution of lightly staining regions within more heavily stained regions. The AChE-poor patches have been called *striosomes* and the AChE-rich areas have been called the extrastriosomal *matrix*. The matrix forms the bulk of the striatal volume and receives input from most areas of the cerebral cortex. Within the matrix are clusters of neurons with similar inputs that have been termed *matrisomes*. The bulk of the output from cells in the matrix goes to both segments of the GP and to SNpr. The striosomes receive input from the prefrontal cortex and send output to SNpc. Immuno-histochemical techniques have demonstrated that several chemicals, including substance P, dynorphin, and enkephalin, have a patchy distribution that may be partly or wholly in register with the striosomes. The striosome-matrix organization provides the substrate for another level of functional segregation within the striatum.

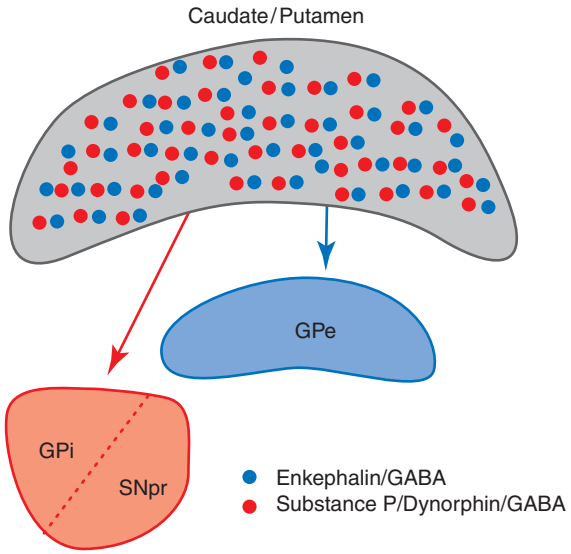

FIGURE 30.7 The two chemically different populations of striatal medium spiny neurons are intermixed. One population (blue) projects to the globus pallidus external segment (GPe) and contains GABA and enkephalin. The other population (red) projects to the globus pallidus internal segment (GPi) and substantia nigra pars reticulata (SNpr) and contains GABA, dynorphin, and substance P (red).

The Subthalamic Nucleus Receives Inputs from the Frontal Lobe

The STN is located at the junction of the diencephalon and midbrain, ventral to the thalamus and rostral and lateral to the red nucleus. Embryologically, it develops from the lateral hypothalamic cell column. The STN receives an excitatory, glutamatergic input from the frontal cortex with large contributions from motor areas, including the primary motor cortex, premotor and supplementary motor cortex, and frontal eye fields. The STN also receives an inhibitory GABA input from GPe. The output from the STN is excitatory and glutamatergic. STN projects to GPi and SNpr as well, projecting back to GPe.

Although the STN receives input from the neocortex and projects to both segments of GP and to SNpr, it is different from striatum in several ways. Unlike striatum, the cortical input to the STN is predominately from the frontal lobe. The output from STN is excitatory, whereas the output from striatum is inhibitory. Of the two routes from the cortex to GPi, GPe, and SNpr, the excitatory route through STN (5–8 ms) is faster than the inhibitory route through striatum (15–20 ms).

Globus Pallidus, Internal Segment and Substantia Nigra, and Pars Reticulata Are the Basal Ganglia Output Nuclei

GP lies medial to the putamen and rostral to the hypothalamus. Embryologically, it arises from the lateral hypothalamic cell column. In primates, GP is separated into an internal segment (GPi) and an external segment (GPe) by a fiber tract called the internal medullary lamina. In rodents and carnivores, the internal segment lies within the internal capsule and is called the entopeduncular nucleus.

The GPi is composed primarily of large neurons that project outside of the basal ganglia. The dendritic trees of GPi neurons radiate from the cell body in a disc-like distribution and are oriented so that the faces of the disc are perpendicular to incoming axons from the striatum. The dendrites of an individual GPi cell can span up to 1 mm in diameter, and therefore GPi neurons have the potential to receive a large number of converging inputs.

The principal inputs to GPi are from striatum and the STN. These two types of inputs differ in the neurotransmitters used, in their physiological action, and in their pattern of termination. As noted earlier, neurons projecting from striatum to GPi contain GABA, substance P, and dynorphin and are inhibitory. Each axon from the striatum enters GPi and sparsely contacts several neurons in passing before ensheathing a single neuron with a dense termination (Fig. 30.8). The excitatory, glutamate projection from STN to GPi is highly divergent such that each axon from the STN ensheathes many GPi neurons (Fig. 30.8). The cortico-STN-GPi pathway has been called the "hyperdirect" pathway. Thus, the striatal and STN inputs to GPi form a pattern of slow, focused, convergent inhibition from striatum ("direct pathway") and fast, widespread, divergent excitation from STN ("hyperdirect pathway") (Fig. 30.2).

The output from GPi is inhibitory and uses GABA as its neurotransmitter. The majority (70%) of the GPi output is sent via collaterals to both the thalamus and the brainstem. In the thalamus, axons from GPi terminate in the oral part of the ventrolateral nucleus (VLo) and in the principal part of the ventral anterior nucleus (VApc). In turn, these thalamic nuclei project to the motor, premotor, supplementary motor, and prefrontal cortex. They also project back to striatum in a potential feedback loop. An individual GPi neuron sends output via the thalamus to just one area of the cortex (Hoover & Strick, 1993). Thus, just as there are parallel inputs from the cortex to striatum, there appear to be functionally parallel outputs from GPi.

Collaterals of the axons projecting from GPi to the thalamus project to an area at the junction of the midbrain and pons near the pedunculopontine nucleus, which has been termed the "midbrain extrapyramidal area." The midbrain extrapyramidal area projects in turn to the reticulospinal motor system. Other GPi neurons (20%) project to intralaminar nuclei of the thalamus or to the lateral habenula. The specific role of these projections is not known.

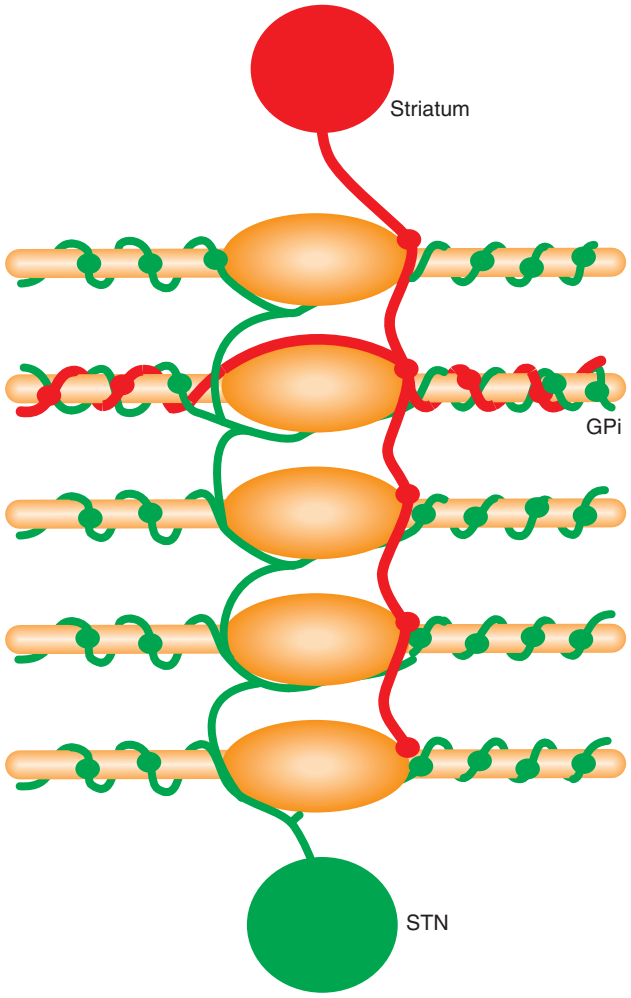

FIGURE 30.8 The two primary inputs to globus pallidus internal segment (GPi) have different patterns of termination. Axons from the subthalamic nucleus (green) are excitatory and terminate extensively on multiple GPi neurons. Axons from the striatum (red) contact several GPi neurons weakly in passing before terminating densely on a single neuron.

Like the GP, the SN is divided into two segments. One is sparsely cellular and is called the pars reticulata (SNpr), and the other is a densely cellular region called the pars compacta (SNpc). SNpr is similar to GPi in many ways, including cell size, histochemistry, and connectional anatomy. The pars compacta contains DA cells and is not a principal output nucleus of the basal ganglia.

Like GPi, the SNpr contains large neurons that project outside of the basal ganglia. Like GPi, SNpr receives inhibitory inputs from striatum that contain GABA, SP, and dynorphin and excitatory inputs from STN that contain glutamate and provides inhibitory, GABAergic outputs.

SNpr outputs are to the medial part of the ventro-lateral thalamus (VLm) and the magnocellular part of the ventral anterior thalamus (VAmc). These thalamic areas in turn project to the premotor and prefrontal cortex. Like the GPi output, SNpr sends collaterals to the midbrain extrapyramidal area and also has a projection to intralaminar nuclei of the thalamus. The primary difference in the outputs of GPi and SNpr is that the lateral portion of SNpr sends an inhibitory projection to the superior colliculus and to the paralaminar part of the medial dorsal thalamus (MDpl). MDpl projects in turn to the frontal eye fields. This lateral portion of SNpr is connected with cortical and brainstem areas which control eye movements (see Chapter 31).

GPe Is Connected to Several Other Basal Ganglia Nuclei

The GPe can be considered to be an intrinsic nucleus of the basal ganglia, as can the SNpc, which is considered in the next section. Both GPe and SNpc receive the bulk of their input from and send the bulk of their output to other basal ganglia nuclei.

The GPe is similar in some ways to GPi. Its inputs are an inhibitory projection from the striatum and an excitatory one from STN. The patterns of termination of the striatal and STN afferents are similar in that the striatal input is focused and convergent while the STN input is divergent (Parent & Hazrati, 1993). As noted earlier, GPe and GPi receive input from neighboring striatal neurons and thereby are likely to receive similar information. Unlike GPi, the striatal projection to GPe contains GABA and enkephalin but not substance P. However, the pathway taken by output of GPe is also quite different from that taken by the output of GPi, which undoubtedly has profound functional implications. The majority of the output of GPe projects to STN. The connections from striatum to GPe, from GPe to STN, and from STN to GPi thus are referred to as the "indirect" striatopallidal pathway to GPi (Alexander & Crutcher, 1990). In addition, there is a monosynaptic GABAergic inhibitory output from GPe directly to GPi and to SNpr and a recently described GABAergic projection back to striatum. Thus, GPe neurons are in a position to provide feedback inhibition to neurons in striatum and STN and feed-forward inhibition to neurons in GPi and SNpr. This circuitry suggests that GPe may act to oppose, limit, or focus the effect of the striatal and STN projections to GPi and SNpr, as well as focus activity in these output nuclei.

SNpc Provides DA Input to the Striatum

The SNpc is perhaps the most studied structure in the basal ganglia. The SNpc is made up of large DA-containing cells and it is these neurons that degenerate in PD (see later). DA neurons contain a substance called neuromelanin, which is a dark pigment that gives the SNpc a blackish appearance and appears to represent an oxidation product of DA. This is the basis for its name (substantia nigra = black substance). SNpc receives input from the striatum, specifically from the striosomes. This input is GABAergic and inhibitory. Other inputs to SNpc have been difficult to assess because the dendrites of SNpc and SNpr neurons overlap. The SNpc DA neurons project to all of caudate and putamen in a topographic manner. However, nigral DA neurons receive inputs from one striatal circuit and project back to the same and to adjacent circuits (Haber, Fudge, & McFarland, 2000). Thus, they appear to be in a position to modulate activity across circuits. The action of DA depends on the receptors located on target neurons, as was discussed earlier.

Summary of Basal Ganglia Circuitry

1. The striatum receives input from nearly all of the cerebral cortex such that several functionally related cortical areas project to overlapping striatal zones and an individual cortical area projects to several striatal zones. Cortical areas that are not functionally related project to separate zones of the striatum, although there may be some interaction between adjacent zones.
2. The striatum sends a focused and convergent inhibitory projection ("direct pathway") to the basal ganglia output nuclei, GPi and SNpr.
3. The STN receives input from the frontal lobe, especially from the motor, premotor, and supplementary motor cortex and from the frontal eye fields.
4. The STN sends a fast divergent excitatory projection ("hyperdirect pathway") to GPi and SNpr.
5. Reciprocal and loop-like connections among basal ganglia nuclei play a negative or positive feedback role and likely result in focusing of signals. These include the "indirect pathway" from striatum to GPe to STN to GPi and SNpr.
6. The output from the basal ganglia (GPi and SNpr) is inhibitory and projects to motor areas in the brainstem and thalamus.

The basal ganglia are sometimes viewed as a system with substantial convergence of information from the inputs to the outputs. In contrast, they have also been viewed as a system of multiple parallel functionally segregated loops through the basal ganglia, each with a separate output. In support of convergence are (1) the reduction of the number of neurons at each level from the cortex to striatum to GPi and SNpr, (2) the large number of synapses on each striatal neuron, (3) the large dendritic trees of striatal, GPi, and SNpr neurons, and (4) interaction across circuits mediated by SNpc and GPe neurons. In support of parallel segregated

loops are (1) the preserved somatotopy with separate representations of the face, arm, and leg in the cortex, striatum, and GPi/SNpr; (2) the relative preservation of topography through the basal ganglia; and (3) the finding that separate groups of GPi neurons project via the thalamus to separate motor areas of the cortex. It is likely that both views are correct with parallel organization of function circuits, but with convergence within circuits and interaction between adjacent (and functionally related) circuits.

SIGNALING IN BASAL GANGLIA

Although the anatomic organization may provide some clues as to what might be the function of basal ganglia circuits, inference of function from anatomy is speculative. One approach to studying the function of an area of the central nervous system is to record the electrical activity of individual neurons with an extracellular electrode in awake, behaving animals. Other approaches involve inferences of neuronal signaling from imaging studies of blood flow and metabolism, or of changes in gene expression. The activity of different regions can be correlated with performance of specific tasks. With electrophysiological studies, the timing of neural activity in one part can be compared to the timing of another and to the timing of the movement. This section will discuss movement-related signals in the basal ganglia that are correlated with the production or prevention of movement or with motor planning.

Striatal Output Neurons Have Low Spontaneous Activity That Increases With Movement

In awake animals, the majority of striatal neurons (80 to 90%) have low baseline discharge rates of 0.1 to 1 Hz (Fig. 30.9). These neurons project outside of the striatum and therefore are probably medium spiny neurons. In general, the activity of these neurons reflects the areas of cerebral cortex from which they receive inputs, though striatal neurons are less modality specific. Thus, neurons in areas of the putamen which receive input from the somatosensory and motor cortex have activity correlated with active and passive movement, but not with specific tactile modalities such as light touch, vibration, or joint position or with kinematic properties of movement such as amplitude, velocity, or force.

Striatal neurons related to movement have a distinct somatotopy with the face represented ventro-medially and the leg dorsolaterally. Neurons active in relation to eye movements are located in a longitudinal zone in the central part of the caudate nucleus. The striatum appears to be organized as clusters of neurons with similar discharge characteristics. These likely correspond to

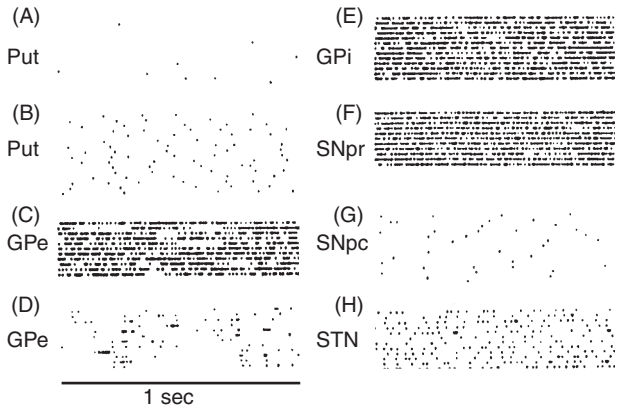

FIGURE 30.9 Representative neural discharge patterns from several basal ganglia nuclei. In the raster displays, each dot indicates the occurrence of an action potential. Each horizontal raster line represents a 1-s period of discharge. Several such periods are arranged vertically for each nucleus.

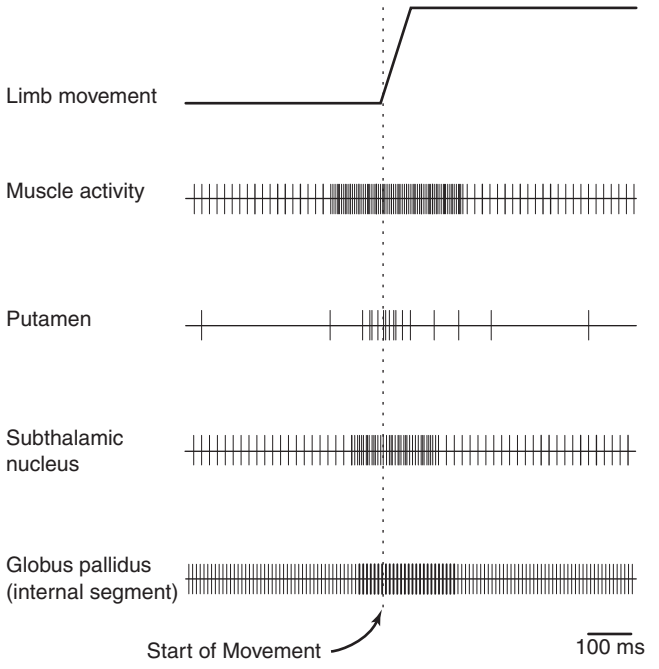

FIGURE 30.10 Schematic representation of the timing of neuronal activity in three nuclei of the basal ganglia in relation to limb movement and the muscle activity used to make the movement.

the anatomically defined matrisomes described earlier. Movement-related activity changes are typically increases above the very low baseline. On average, movement-related striatal neurons fire 20 msec prior to movement (Fig. 30.10). About half of these neurons fire in relation to the direction of movement. Some neurons fire in relation to the start of movement and others in relation to the stop. Some neurons in the putamen fire in relation to self-initiated movements, some in relation to stimulus-triggered

movements, and some in relation to both (Romo, Scarnati, & Schultz, 1992). Neurons in the anterior part of the putamen and in the caudate nucleus that receive input from the premotor or prefrontal cortex have activity during the preparation for movement. This activity is time locked to instructional cues but not to the movement itself. Some signals correlate with the instruction of whether to move ("set"). Other signals correlate with the signal to move ("go"). Although individual neurons may have signals that preferentially correlate with specific tasks or task parameters, as a whole the striatum is not exclusively involved in any one task type or parameter.

The timing of neuronal activity related to limb or eye movements is important to understanding the function of those neurons in the production of movement. In the putamen, most movement-related activity occurs relatively late, before the onset of movement but after the onset of muscle activity responsible for producing the movement. When compared to activity in the cerebral cortex, movement-related putamen neurons fire after those in the overlying motor cortex and supplementary motor area. Putamen neurons related to movement preparation also fire substantially later than cortical neurons involved in movement preparation. Caudate neurons related to eye movements fire late relative to oculomotor areas of cortex. The late timing of striatal discharge during movement and movement preparation relative to discharge in cortical areas suggests that the striatum is not involved primarily in the initiation of movement. Instead, it receives information from cortical areas that *are* responsible for movement generation and may use that information for facilitation, gating, or scaling of cortically initiated movement.

Two additional subsets of striatal neurons represent fewer than 10% of striatal neurons but are critical for basal ganglia function. One subset called the tonically active neurons (TANs) have a relatively broad action potential, are distributed throughout the striatum, and fire tonically but have no discharge correlated with movement. TANs are thought to be cholinergic interneurons which fire in relation to certain sensory stimuli that are associated with reward (Aosaki et al., 1994). It has been suggested that these neurons signal aspects of tasks that are related to learning and reinforcement. The other subset is the fast-spiking interneurons (FSIs) that are thought to be GABAergic interneurons. They have narrow waveforms, and do discharge in relation to movements. In particular, they have been shown to fire in a coordinated manner throughout striatum when animals initiate one chosen action while suppressing a highly trained alternative (Gage, Stoetzner, Wiltschko, & Berke, 2010).

Functional imaging studies using functional Magnetic Resonance Imagining (fMRI) in human subjects have shown signals in striatum related to several aspects of task performance. In addition to activity correlated with motor performance, several studies have suggested an important role of striatum in specific types of procedural memory and motor learning.

STN Has Moderate Spontaneous Activity That Increases during Movement

Neurons in the STN are tonically active with average baseline discharge rates of about 20 Hz (Fig. 30.9). They are organized somatotopically and change activity in relation to eye or limb movement. For 90% of these neurons, the change is an increase, occurring on average 50 msec prior to the movement (Fig. 30.10). The majority of movement-related neurons in STN have signals related to movement direction, but little is known about their relationship to physical parameters of movement. Functional imaging studies in human studies have demonstrated signals in STN that appear to be correlated with the stopping of ongoing movement or preventing the initiation of unwanted movements (see Box 30.8).

GPi and SNpr Have High Spontaneous Activity That Increases or Decreases after Movement Initiation

As described earlier, GPi and SNpr form the output of the basal ganglia. Neurons in these output structures fire tonically at average rates of 60 to 80 Hz (Fig. 30.9). They are organized somatotopically with the leg and arm in GPi and the face and eyes in SNpr. Due to the somatotopy, studies of limb movements have focused on GPi and studies of eye movements have focused on SNpr.

The discharge of many GPi neurons is related to the direction of limb movement, but most GPi activity is not correlated with other physical parameters of movement, including joint position, force production, movement amplitude, or movement velocity. Few GPi neurons have activity correlated with the pattern of muscle activity. Like striatum, some GPi neurons have activity related to movement preparation. During a reaching movement, 25% of GPi neurons are related to movement preparation and 50% are related to movement, but many neurons have more than one type of response. Approximately 70% of arm movement–related GPi neurons increase activity and 30% decrease activity from this tonic baseline during movement. Because the output from GPi is inhibitory, the large proportion of activity increases during movement translates to broad inhibition of thalamic and brainstem targets with more restricted facilitation during movement. GPi neurons are more likely to decrease discharge in stimulus-triggered movement and increase discharge in memory-guided movement. Thus, movement-related discharge is highly influenced by behavioral context.

The timing of movement-related GPi activity is late compared to the activation of agonist muscles. The average onset of GPi activity is after the onset of EMG but

before the onset of movement (Fig. 30.10). There is a tendency for GPi movement-related increases to occur earlier than decreases, which probably reflects the faster speed of the excitatory pathway from the cortex to GPi via STN compared with the slower inhibitory pathway from the cortex to GPi via striatum. The late timing of GPi movement-related activity suggests that the output of the basal ganglia is unlikely to initiate movement.

SNpr is the principal basal ganglia output for the control of eye movements, and most studies of SNpr activity have been in eye movement tasks (Hikosaka et al., 2000). Most saccade-related SNpr neurons fire in relation to the direction of the eye movements. Unlike GPi neurons during limb movements, virtually all saccade-related SNpr neurons decrease activity during the saccade. It is not known whether the fact that most GPi limb movement neurons increase and most SNpr saccade neurons decrease indicates a fundamental difference between eye and limb movement control or if it reflects task differences. Other differences between GPi limb movement neurons and SNpr saccade neurons have been noted. While GPi limb movement neurons have weak sensory responses, some SNpr neurons have strong responses to visual stimuli. For the visually responsive SNpr neurons, the spatial location of the stimulus seems to be the most salient feature.

Some SNpr neurons have their strongest relation to saccades made to remembered targets. If a visual target is presented and then removed and a monkey is trained to look to where the target had been, some SNpr cells will fire more in this condition as compared to when a saccade is made to a visible target. Thus, like GPi neurons, SNpr output neurons are strongly influenced by context.

GPe Has Irregular Activity That Increases or Decreases after Movement Initiation

Two types of neurons have been described in GPe based on their baseline activity patterns. Most fire at a high frequency (70 Hz) that is interrupted by long pauses. A smaller number fire at a low frequency (10 Hz on average) and have frequent spontaneous bursts of activity. Both types of neurons change activity in relation to limb movement and, for the majority, these changes are increases in activity. As has been described for GPi, GPe neurons weakly and inconsistently code for movement amplitude, velocity, muscle length, or force. Like the other structures of the basal ganglia, the activity of movement-related activity is late.

SNpc Has Low Spontaneous Activity That Does Not Change with Movement but Changes with Significant Environmental Stimuli

The activity of single neurons in the SNpc of trained animals is different from the activity of single neurons in the other basal ganglia structures. At baseline, SNpc neurons fire at a low rate (2 Hz on average). The activity of these neurons is not related to movement itself and there is no apparent somatotopy in SNpc. The neurons carry little specific information regarding sensory modality or spatial properties. The activity of SNpc neurons does change in relation to behaviorally significant events such as reward or the presentation of instructional cues. The responses to stimuli only occur if the stimulus is presented in the context of a movement task. Furthermore, the activity changes with conditioning. As an example, consider an SNpc neuron that fires in relation to an unexpected reward. If one records from this neuron over several trials while the reward is paired with a tone that precedes the reward, the SNpc neuron will gradually stop firing in relation to the reward and instead will begin to fire in relation to the tone that predicts the reward.

Thus, it appears that SNpc DA neurons can predict the occurrence of a behavioral event. In this way, SNpc neurons are similar to the TANs neurons described earlier. Remember that SNpc neurons also synapse extensively on medium spiny striatal neurons and that DA terminals are on the shafts of dendritic spines. It has been suggested that the DA input changes the sensitivity of striatal neurons to cortical inputs that terminate on the heads of dendritic spines. If so, the activity of SNpc neurons could modify the response of striatal neurons to cortical input that occurs in a specific behavioral context. Such influences may be related to the apparent ability of DA to mediate both long-term potentiation and long-term depression in striatal neurons, which in turn is likely to be an important mediator of learning and plasticity in the striatum.

Summary of Signaling in the Basal Ganglia

Several general statements about basal ganglia movement-related neuronal discharge can be made.

1. Movement-related neurons in the striatum, STN, GP, and SNpr are arranged somatotopically.
2. Medium spiny output neurons in the striatum are quiet at rest and increase during movement. Neurons in STN are tonically active and increase during movement. Recalling the anatomy, this means that GPi neurons receive a widespread, tonically active excitatory input and a focused, intermittent inhibitory input.
3. STN has increased activity when an ongoing movement is stopped suddenly or when initiation of movement is prevented.
4. Neurons in both GPe and GPi are tonically active. Most increase activity, but up to one-third decrease activity during limb movement.
5. Neurons in SNpr are also tonically active. Those that are related to saccadic eye movements decrease activity during the movement.

6. Neurons in SNpc discharge in relation to rewards and behaviorally relevant stimuli, but not to movement. They are likely to play a critical role in some types of motor learning.
7. Changes in the activity of basal ganglia occur at the onset of movement but after the muscles are already active. Thus, they are unlikely to initiate movement.
8. Movement-related activity throughout the basal ganglia is modulated by the behavioral context in which the movements are performed.

THE EFFECT OF BASAL GANGLIA DAMAGE ON BEHAVIOR

Valuable clues to the function of the basal ganglia have come from studying activity patterns during behavior. However, correlation of activity with an aspect of behavior does not necessarily mean that structure plays a causal role in that behavior. One approach to determining the precise roles of the basal ganglia in behavior is to selectively remove a specific component from an otherwise intact system. Certain human neurological diseases cause the loss of specific types of neuron in the basal ganglia. The movement disorders that result from basal ganglia damage are often dramatic. Depending on the site of the pathology, some basal ganglia diseases cause extreme slowness of movement and rigidity and others cause uncontrollable involuntary movements. Although human diseases are of great interest, they often affect more than one structure. This necessarily limits the power of functional models derived from the study of human basal ganglia diseases. In experimental animals, more selective lesions can be made with specific pharmacologic agents. More recently, mice have been genetically engineered to prevent development of specific neuron types.

Experimental Damage to the Striatum Causes Slow Voluntary Movements or Involuntary Postures and Movements

Lesions in the striatum produce variable results that depend on the location of the lesion, the lesion method, and what is measured. Many studies of unilateral striatal lesions have described only minimal deficits. If the putamen is inactivated pharmacologically with the GABA agonist muscimol unilaterally, the result is slightly slow movement of the contralateral limb. The slowed movement is associated with an increased activity of antagonist muscles. Despite slower movements after putamen lesions, reaction time is generally normal, indicating that movement initiation remains intact. Large bilateral lesions result in the paucity of movement, severe slowness of movement bilaterally, and postural abnormalities. In other studies, there appears to be little effect of bilateral electrolytic putamen lesions. The reason for this discrepancy is not clear, but it may be due to differences in lesion size.

Selective inactivation of striatal inhibitory interneurons (FSIs) results in abnormal involuntary movements (Gittis et al., 2011). The selective inactivation is thought to cause excessive firing of direct pathway striatal medium spiny neurons which, in turn, results in reduction of the inhibitory output from GPi and SNpr.

Huntington's disease (HD) is a genetically based, degenerative disease in humans that results in disabling involuntary movements (see Box 30.4). These movements are called chorea (Greek for "dance"). They are frequent, brief, sudden, random twitch-like movements that involve all parts of the body and resemble fragments of normal voluntary movement. The pathologic hallmark of HD is a marked loss of neurons in the striatum. Studies have shown that not all striatal neurons are equally affected in HD (Albin, Young, & Penney, 1989). In early adult-onset HD, the enkephalin-containing neurons that project to GPe are lost first. Clinically, this is associated with the presence of chorea. In late adult-onset and in juvenile-onset HD, both the enkephalin-containing and the substance P-containing striatal neurons that project to GPi and SNpr are lost. Clinically, this loss is associated with the presence of rigidity and dystonia (sustained, abnormal postures). Interestingly, experimental destructive lesions of the striatum in monkeys do not result in chorea. This is probably due to the nonselective destruction of both GPe-and GPi projecting striatal neurons. More selective disruption of the striatal–GPe pathway with a GABA antagonist administered into the GPe does produce chorea. The suggested mechanism for chorea is that disinhibition of GPe neurons (pharmacologically, or as a result of selective striatal cell death) causes inhibition of STN and GPi. This results in abnormal overactivity of motor cortical and brainstem mechanisms, resulting in chorea.

Damage to STN Causes Large-Scale Involuntary Movements

In monkeys and humans, lesions in the STN cause dramatic involuntary flinging movements of the contralateral arm and leg. These movements have been called hemiballismus. They resemble chorea in their brief, random, and sudden nature, but they tend to be much larger in amplitude. After a lesion in STN, the hemiballism lasts for days to weeks before gradually resolving. Animals and humans with hemiballism can still make voluntary movements and often the voluntary movements appear to be quite normal. It has been suggested that the mechanism underlying the hemiballism is a loss of excitatory input to GPi, resulting in decreased GPi activity and ultimately in the disinhibition of cortical and brainstem motor mechanisms.

Several lines of evidence support this. First, blocking the excitatory transmission from STN to GPi with a glutamate antagonist administered into GPi causes involuntary movements. Second, metabolic activity patterns as shown with 2–deoxyglucose uptake indicate decreased GPi output in hemiballism. Third, neuronal recording during stereotaxic surgical treatment of movement disorders has shown decreased GPi activity in patients with chorea or hemiballism. However, it is likely that chorea or hemiballism is due to abnormal patterns of basal ganglia output signals and not just tonically decreased activity. Thus, if hemiballism or chorea is produced by an STN lesion in monkeys, a second lesion placed in GPi abolishes the involuntary movements. Furthermore, in monkeys with STN lesions, the level of GPi activity is reduced even after the involuntary movements resolve. Finally, destruction of GPi in humans with hemiballism or chorea abolishes the involuntary movements and experimental lesions of GPi in monkeys do not cause chorea. Therefore, it seems likely that chorea and hemiballism reflect an abnormal fluctuating or bursting output from the basal ganglia rather than a simple reduction of output.

In rodent studies, involuntary movements are uncommon but STN lesions cause animals to respond prematurely to cues and impair the ability to prevent unwanted movements. Similar difficulties with impulse control occur in people with Parkinson disease who have been treated with Deep Brain Stimulation of STN (see Box 30.5).

Damage to GP Causes Slow Voluntary Movements and Involuntary Postures and Does Not Delay Movement Initiation

Lesions of the GPi result in slowing of movement but normal movement initiation. Because of their close proximity to each other, it is difficult to lesion GPi without including part of GPe or vice versa. Therefore, caution must be used in interpreting results of GP lesions. However, in most cases, combined GPe and GPi lesions have a similar effect to the lesion of GPi alone. Unilateral lesions of GPe and GPi result in slowness of movement, with abnormal cocontraction of agonist and antagonist muscles, but normal initiation of movement. Bilateral lesions of GPe and GPi result in even more severely abnormal flexed postures with an apparent inability to move out of them. Electrolytic lesions producing this severe abnormality have tended to be large, involving both GPe and GPi and part of the internal capsule. Similar abnormalities are seen with carbon monoxide or carbon disulfide poisoning, which results in neuron death in GPi and SNpr.

Lesions restricted to GPi result in slowness of movement of the contralateral limbs. After GPi lesions, reaction time is normal, which indicates that mechanisms involved in the initiation of movement are intact. In some studies, the slowness of movement is accompanied by a cocontraction of agonist and antagonist muscles, which results in abnormal postures similar to those that occur in dystonia, a basal ganglia movement disorder. In other studies, the slowing may depend on the context of the task. Monkeys with GPi lesions are more impaired when movements are made by turning off active muscles than when movements are made by further turning on active muscles (Fig. 30.11). Thus, lesions that remove the inhibitory output of the basal ganglia appear to interfere with the ability to turn off unwanted muscle activity.

Damage to SNpr Causes Involuntary Eye Movements

Due to its proximity to SNpc, it is difficult to produce electrolytic lesions exclusively in SNpr. However, with the use of the GABA agonist muscimol, it has been possible to inactivate neurons focally in SNpr. Injection of muscimol into the lateral SNpr inactivates neurons that are normally involved in saccadic eye movements. Inactivation in this area results in an inability to maintain visual fixation because of involuntary saccades (Fig. 30.12). The inability to suppress involuntary saccades appears to result from disinhibition of the superior colliculus. Injection of the GABA antagonist bicuculline into the superior colliculus mimics the effects of muscimol in SNpr. Thus, just as GPi inactivation results in abnormal excess limb and trunk muscle activity, SNpr inactivation results in abnormal excess eye movements.

Damage to SNpc Causes Symptoms of Parkinson's Disease

Lesions of SNpc are of particular interest because the DA neurons in this nucleus die in Parkinson's disease (PD). PD is a neurological disease that affects older adults (see Box 30.1). The main symptoms of PD are (1) tremor at rest that decreases during movement, (2) slowness of movement (bradykinesia), (3) paucity of movement (akinesia), (4) muscular rigidity, and (5) unstable posture. The primary pathology in PD is a progressive degeneration of neurons in the SNpc. Additionally, there is some degree of loss of DA neurons in the ventral tegmental area and of norepinephrine neurons in the locus coeruleus. Although PD has been recognized for over a century, it has only been since the early 1980s that a complete animal model has been available. As noted earlier, the interdigitation of SNpc and SNpr has made selective electrolytic lesions of SNpc or SNpr difficult to produce. In the 1960s, it was found that 6-hydroxydopamine (6-OHDA) produces specific lesions of catecholamine neurons. Therefore, injection of 6-OHDA into the rat SN bilaterally produces

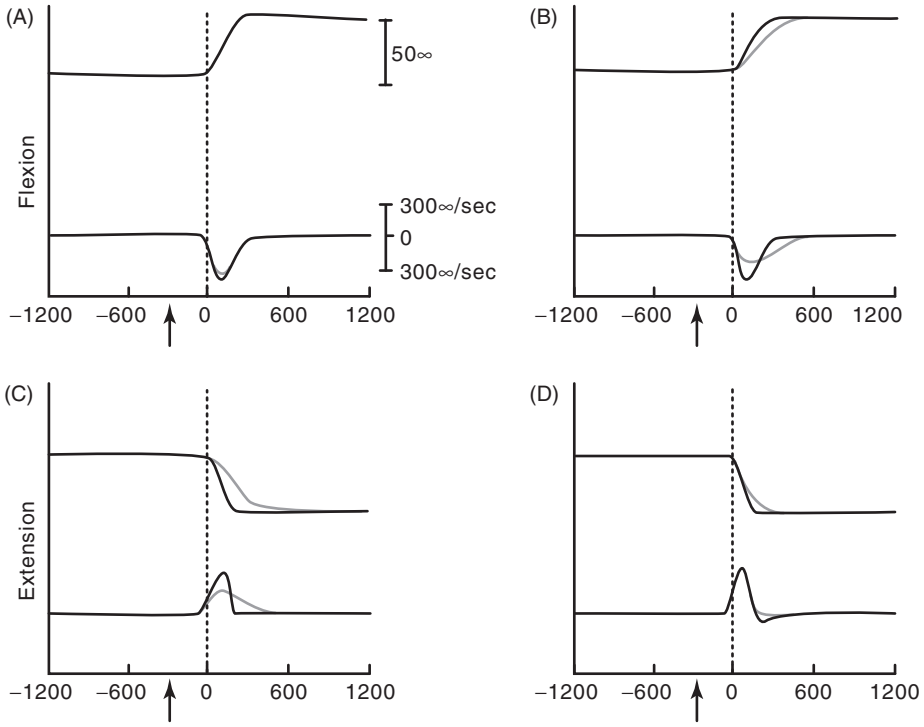

FIGURE 30.11 Wrist position and velocity in visually guided wrist movements before (black traces) and after (blue traces) a lesion of the globus pallidus internal segment. In each graph, the top traces represent wrist position, the lower traces represent wrist velocity. (A) Flexion with the flexor muscles loaded (movement made by further activating the loaded muscles). (B) Flexion with extensor muscles loaded (movement made by turning off the loaded muscles). (C) Extension with flexor muscles loaded (movement made by turning off the loaded muscles). (D) Extension with extensor muscles loaded (movement made by further activating the loaded muscles). After the lesion, the peak velocity was slower when the movements were made by decreasing the activity of the loaded muscle than when made by increasing the activity of the loaded muscle. *From Mink and Thach (1991).*

(A) The top line represents vertical eye position, and the bottom line represents horizontal eye position during attempted visual fixation. (B) Lines represent the trajectory of the involuntary eye movement when the monkey was instructed to maintain its gaze in the center dot. *From Hikosaka and Wurtz (1985).*

a selective loss of SNpc DA neurons. Lesions made in this way result in some of the abnormalities of PD—namely, the slowness of movement and rigidity, but they did not produce tremor. In the 1980s, a street drug contaminant called MPTP (see Box 30.2) was found to produce all of the symptoms of PD in humans and in certain species of monkeys. The MPTP monkey has proven an extremely valuable model with which to explore this disease.

Despite extensive investigation, the fundamental mechanism of the tremor in PD is not known. Some evidence suggests that it results from abnormal bursting of neurons in the thalamus. The slowness of movement in PD has been associated with a reduced magnitude and duration of muscle activity during movement. In monkeys that have been given 6-OHDA or MPTP, the activity of motor cortex neurons during arm movements is also reduced compared with normal monkeys. In the MPTP monkey model of PD, some animals have abnormally increased activity of STN and GPi and decreased activity of GPi. GPi neurons in the MPTP monkey have abnormal bursting activity and abnormally increased responses to somatosensory stimuli. It has been suggested that the increased activity of GPi causes an excess inhibition of motor mechanisms in the cortex and brainstem and that this excess inhibition causes movements to be slow (Albin et al., 1989). However, it has been argued that the abnormal patterns of GPi activity may be more important than the more modest increase in tonic activity.

The rigidity of PD has been attributed in part to hyperactivity of the transcortical stretch reflex. Normally, the

BOX 30.2

THE MPTP STORY

Until the early 1980s, the quest for a complete animal model of Parkinson's disease (PD) was largely unsuccessful. Although some of the abnormalities of PD could be caused by electrolytic lesion of SNpc or by injecting the neurotoxin 6-hydroxydopamine into SNpc, neither of these methods produced the full syndrome of PD. Then, in 1982 an unfortunate, but fortuitous, accident happened. Four young drug users in northern California developed symptoms of PD. Because PD is highly unusual in young adults, the neurologists caring for these patients began a search for the cause (Langston, Ballard, Tetrud, & Irwin, 1983). They discovered that each of the patients had recently obtained a "new" synthetic heroin. This "new heroin" contained an analog of the narcotic meperidine, 1-methyl-4-phenyl-proprionoxy-piperidine (MPPP), and a contaminant, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP). It turned out that MPTP was the agent responsible for the parkinsonism. MPTP is oxidized in the brain to MPP^+ by monoamine oxidase. MPP^+ is taken up by DA neurons where it inhibits oxidative metabolism in the mitochondria and ultimately leads to cell death.

Subsequently, it has been found that MPTP produces a Parkinson's-like syndrome in several species of monkeys. Unlike previous models, monkeys given MPTP had not only slowness of movement, paucity of movement, and rigidity, but also tremor. The Parkinson's-like syndrome in monkeys given MPTP is associated with a nearly complete degeneration of DA neurons in SNpc and the ventral tegmental area and variable degeneration in the locus coeruleus. MPTP monkeys improve when given the DA precursor L-DOPA and have side effects of chorea when they are given too much L-DOPA, similar to what happens in people with PD. Hence, by behavioral, pharmacological, and pathological measures, the MPTP monkey is an excellent model of human PD. It is currently used to study the pathophysiology and pharmacology of PD and it has lead to new ideas about possible causes of PD. One such idea is that environmental toxins may play a role in the etiology of PD. In this regard, it is important to note that paraquat and rotenone, two compounds that are used commonly as pesticides and/or herbicides, both have MPTP-like structures and have also been shown to damage DA neurons.

transcortical stretch reflex is active to resist displacement from an actively held posture. It is inhibited when subjects are instructed not to resist the displacement. People with PD have abnormally increased transcortical stretch reflexes and are unable to suppress them in response to instruction. The inability to inhibit long-loop reflexes may also account for the postural instability of PD. Patients with PD have an inappropriate cocontraction of leg and back muscles in response to perturbation from an upright stance. When the same subjects perturbed from a sitting position, they are not able to inhibit the postural reflexes that were active during stance. This suggests that the mechanism of rigidity and postural instability may be similar and that they reflect an inability to suppress unwanted reflex activity.

Paradoxically, it is known that lesions of GPi or STN can ameliorate many or all of the signs and symptoms of PD without producing the abnormalities associated with lesions in these areas in normal animals or humans. This is particularly paradoxical for GPi lesions that can produce the signs of PD (flexed posture, slow movement, rigidity) in normal monkeys and in some rare human diseases, but can reduce or eliminate those signs in monkeys and humans with preexisting lesions of the DA system. Why this is the case is not known, but it may relate to long-term changes in basal ganglia physiology that result from chronic DA depletion. Chronic, high-frequency stimulation of the STN or GPi has been found to be effective for the treatment of symptoms in advanced PD. This has been called deep brain stimulation (DBS; see Box 30.5). The mechanisms by which DBS works are not well understood, but it is thought that high-frequency stimulation disrupts neural signaling and thus mimics a lesion in the stimulated area. The growth of neurosurgical treatment of PD is a direct result of knowledge about basal ganglia circuitry.

Summary

1. Damage to any basal ganglia structure may cause slowness of voluntary movement, involuntary movements, involuntary postures, or a combination of these.
2. Damage to the striatum causes voluntary movements to be slow and may produce involuntary movements or postures depending on the mechanism of damage.

3. Damage to the STN causes large amplitude involuntary limb movements.
4. Damage to the GP causes slowness of movement, abnormal postures, and difficulty relaxing muscles, but does not delay movement initiation.
5. Damage to SNpr causes abnormal eye movements, but does not delay the initiation of eye movements.
6. Damage to SNpc causes tremor at rest, slowness of movement, rigidity, and postural instability, which are the main features of PD.

PRINCIPLES OF BASAL GANGLIA OPERATION FOR MOTOR CONTROL

How do the basal ganglia participate in motor control? Several hypotheses have been advanced over the past century. A growing consensus suggests that models based on human disease states may not be sufficient to explain normal basal ganglia function. Nonetheless, the models based on human disease have been useful in developing new treatments for movement disorders and for the development of testable hypotheses relating to basal ganglia function.

An old model of basal ganglia function is that the basal ganglia initiate movement. This model was based in large part on the manifestation of basal ganglia diseases. The paucity and slowness of movement in PD were attributed to an inability to initiate movements, whereas the involuntary movements of chorea and hemiballism were attributed to a release of normal motor systems from basal ganglia control. This model gained support from the fact that much of the output from the basal ganglia goes to parts of the thalamus that project to the premotor and motor cortex. It was argued that motor programs are stored in the basal ganglia and are called up and sent to the motor cortex for execution. This model is no longer widely accepted because it is now apparent that basal ganglia are active relatively late in relation to movement and to the activation of those brain mechanisms that are known to be involved in initiation. Furthermore, lesions of basal ganglia output do not delay the initiation of movement.

If basal ganglia do not initiate movement, what do they do? We consider three current hypotheses. One hypothesis states that although basal ganglia do not initiate movement, they contribute to the automatic execution of movement sequences. This hypothesis suggests that other mechanisms initiate the first component in a sequence, but that basal ganglia contain the programs for completion of the sequence. The second hypothesis states that the basal ganglia circuitry is made up of opposing parallel pathways that adjust the magnitude of the inhibitory GPi output in order to increase or decrease movement. According to this hypothesis, increased GPi output slows movements and decreased GPi output increases movement. The third hypothesis states that basal ganglia act to permit desired movements and to inhibit unwanted competing movements.

Do Basal Ganglia Automatically Generate Learned Movement Sequences?

A popular hypothesis states that basal ganglia are responsible for the automatic execution of learned movement sequences (Marsden, 1987). It has been pointed out that patients with PD have difficulty moving several body parts simultaneously or sequentially, and that this difficulty is more than one would expect from a simple addition of the deficits of each component of the movement. An example of an apparent problem with sequential movements in PD is the phenomenon of micrographia (or small writing). A patient begins to write a sentence with nearly normal-sized writing, but within several letters, the writing begins to get smaller so that by the end of the sentence, it may be illegible. It has been emphasized that the early components of the sequence are larger and faster than are the subsequent components. One experiment compared the performance of elbow flexion and hand grip individually or in sequence (Benecke, Rothwell, Dick, Day, & Marsden, 1986). Patients with PD performed each movement more slowly than normal subjects. However, when the movement was part of a sequence, it was slowed to an even greater degree than when it was performed separately. Another experiment involved recording the activity of GPi neurons in monkeys trained to perform two successive prompt wrist movements. It was found that some GPi neurons fired after the first component of the movement but before the second component. Proponents of the sequencing hypothesis speculate that the loss of this GPi output signal in PD is responsible for the relatively greater difficulty in producing sequential movements than in producing individual movements.

Do Basal Ganglia Produce or Prevent Movement by Using Opposing Direct and Indirect Parallel Pathways?

This hypothesis emphasizes the two major paths of information flow from the striatum to GPi and SNpr that were described earlier (Fig. 30.2). To recapitulate, one is an inhibitory "direct" pathway from striatum to GPi/SNpr and the other is a net excitatory "indirect" pathway from striatum to GPe (inhibitory), from GPe to STN (inhibitory), and from STN to GPi/SNpr (excitatory). In this hypothesis, the two pathways are in balance in such a way that increased activity in the "direct" pathway causes decreased GPi/SNpr output and increased activity in the "indirect" pathway causes increased GPi/SNpr output. By adjusting the balance, cortical targets of the basal ganglia can be

facilitated or inhibited. The hypothesis predicts that abnormally decreased output results in excessive movements (chorea) and abnormally increased output results in a decreased movement (PD). The "direct/indirect pathway" model has been useful for understanding and developing certain treatments of movement disorders, but it has several shortcomings when it comes to explaining normal basal ganglia function and the mechanism of treatments for involuntary movements. Despite the shortcomings, this has been a central hypothesis in the field of basal ganglia research for over 20 years. If the success of a model can be measured by the amount of research it stimulates, this one has been highly successful.

Do Basal Ganglia Select and Inhibit Competing Motor Patterns?

The output of the basal ganglia is inhibitory to posture and movement pattern generators in the cerebral cortex (via thalamus) and in the brainstem. The inhibitory output neurons fire tonically at high frequencies. In this hypothesis, the motor output of the basal ganglia is analogous to a brake (Mink, 1996). The hypothesis states that when a movement is initiated by a particular motor pattern generator, GPi neurons projecting to that generator decrease their discharge, thereby removing tonic inhibition and "releasing the brake" on that generator. GPi neurons projecting to other movement pattern generators increase their firing rate, thereby increasing inhibition and applying a "brake" on those generators. Thus, other postures and movements are prevented from interfering with the one selected.

How might this mechanism work (Fig. 30.13)? When one makes a voluntary movement, that movement is initiated by the prefrontal, premotor, and motor cortex and by the cerebellum. The premotor and motor cortex send a corollary signal to STN, exciting it. STN projects to GPi in a widespread pattern and excites GPi. In parallel, signals are sent from the cortex to the striatum, which inhibits GPi focally via a direct pathway. Striatum can also disinhibit GPi via two indirect pathways (striatum → GPe → GPi and striatum → GPe → STN → GPi). The indirect pathways further focus the effects of the fast excitatory cortico-STN pathway and the slower inhibitory cortico-striatal pathway to GPi. The net result is to release the "brake" from the selected voluntary movement pattern generator and to apply the "brake" to potentially competing posture-holding pattern generators (transcortical, vestibular, tonic neck, and other postural reflexes; see Chapter 28). The result is the focused selection of desired motor patterns and surround inhibition of competing patterns. Disruption of the ability to facilitate desired movements and inhibit unwanted movements results in slow voluntary movements (parkinsonism), abnormal involuntary movement (chorea, dystonia, tics), or both (Mink, 2003).

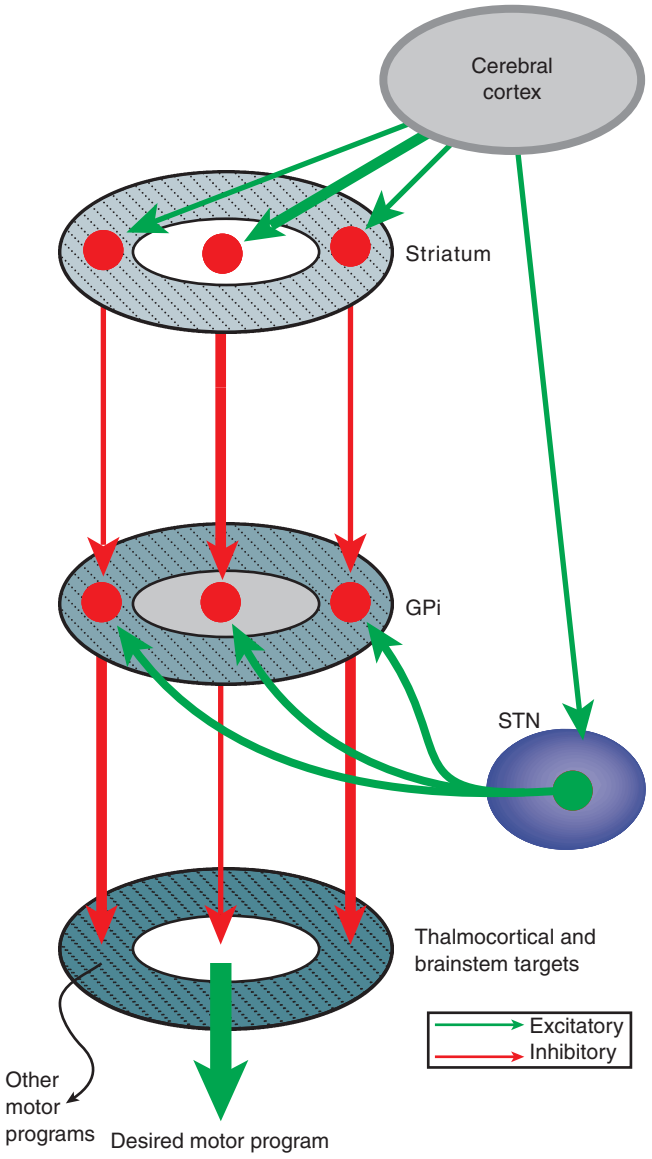

FIGURE 30.13 Relationship of proposed center-surround organization of GPi to inputs from the striatum and subthalamic nucleus. During voluntary movement, excitatory subthalamo-pallidal neurons increase the activity of the pallidal neurons in the surround territory. Inhibitory striatopallidal neurons inhibit the functional center in a focused manner. Pallidal activity changes are conveyed to the targets in the thalamus and midbrain brainstem, causing disinhibition of neurons involved in the desired motor program and inhibition of surrounding neurons involved in competing motor programs. Excitatory projections are indicated with green arrows; inhibitory projections are indicated with red arrows. The relative magnitude of activity is represented by line thickness.

BASAL GANGLIA PARTICIPATION IN NONMOTOR FUNCTIONS

Although the focus of this chapter has been on motor control, it has become increasingly clear that the basal ganglia participate in a variety of nonmotor functions. These include functions of the limbic system (see Box 30.3) and

cognitive functions. The anatomy of basal ganglia circuits has revealed outputs to all areas of frontal cortex, placing the basal ganglia in a position to influence a wide variety of behaviors. As discussed earlier, specific areas of the basal ganglia are connected preferentially with specific areas of the cerebral cortex. This provides the anatomic substrate for the localization of different functions in the basal ganglia circuits. It is known that focal lesions of the striatum tend to produce deficits similar to those seen after lesions of afferent areas of the cortex. Thus, lesions of posterior putamen cause movement deficits, lesions of inferior caudate produce deficits similar to lesions of the orbitofrontal cortex, and lesions of the dorsolateral caudate produce deficits similar to lesions of dorsolateral prefrontal cortex. The basal ganglia have been implicated in a variety of nonmotor disorders, including depression, obsessive-compulsive disorder (see Box 30.6), attention deficit hyperactivity disorder, and schizophrenia. It is becoming clear that the basic underlying principles of basal ganglia function are similar. Thus, the intrinsic circuitry is the same for cognitive and motor parts of the basal ganglia, the basic neurophysiology appears to be the same, and the effects of lesions are analogous. For example, chorea is characterized by excessive involuntary movements, and obsessive-compulsive disorder is characterized by excessive involuntary thoughts and complex behaviors. The hypothesis of focused selection and surround inhibition has been applied to non-motor basal ganglia functions (Redgrave, Prescott, & Gurney, 1999) and data support each hypothesis from cognitive science and psychiatric research.

Increasing evidence points to a role for the basal ganglia in procedural learning. Much of the research has focused on the learning of tasks or of sequential behavior. There is evidence for a role of the basal ganglia in procedural learning that leads to the formation of habits and the performance of behavioral routines once they are learned (Jog, Kubota, Connally, Hillegart, & Graybiel, 1999). As described earlier, TANs and SNpc DA neurons fire in relation to behaviorally significant events. The activity patterns of these neurons change as the task becomes learned and when novel stimuli or events are introduced. There is also growing evidence for DA-mediated long-term potentiation and long-term depression in striatal neurons that is likely to play an important role in learning. It has been shown that non-TAN striatal neurons also change activity in relation to learning. In rats performing a T-maze task, striatal neurons changed activity patterns as the task became learned and more automatic (Jog et al., 1999). In monkeys performing a discrimination learning task, striatal neurons changed activity as the animal learned new associations between stimuli and reward (Tremblay, Hollerman, & Schultz, 1998). Functional imaging studies have also shown basal ganglia activity correlated with the learning of new tasks. Striatal lesions or focal striatal DA depletion impairs the learning of new movement sequences, and procedural learning has been shown to be impaired in people with PD. These findings together support a role for the basal ganglia in certain types of procedural learning. However, other brain structures have also been implicated in procedural learning, including the cerebellum (see Chapter 31). Just as the cerebellum and basal ganglia play different roles in motor control, they are likely to play different, but complementary, roles in procedural learning. The exact nature of those different roles is the subject of current research.

BOX 30.3

VENTRAL SYSTEM OF THE BASAL GANGLIA

There are nuclei in the brain that historically have not been included with the basal ganglia, but that are analogous to the traditional components. These lie ventral to the neostriatum and GP and are called the ventral striatum (nucleus accumbens and olfactory tubercle) and the ventral pallidum. The ventral striatum receives input from limbic and olfactory areas of the cortex, including the amygdala and hippocampus. Like the neostriatum, the ventral striatum receives a *DA* input, but it is from the ventral tegmental area (VTA), which lies medial to the SN. The ventral striatum sends a projection back to VTA and to the adjacent SNpr. The ventral pallidum is analogous to both GPe and GPi. It receives input from the ventral striatum and possibly from STN. Unlike the GP, the ventral pallidum receives direct input from the amygdala. The output of the ventral pallidum projects to the dorsomedial nucleus of the thalamus (DM) and from there to limbic areas of the cortex. By virtue of its inputs and outputs, the ventral system is closely linked to the limbic system. This linkage has led to the suggestion that the ventral system is involved to some degree in motivation and emotion (see Chapter 41). The exact nature of this role is not known, but it may be analogous to the motor role of the basal ganglia, with the inhibitory output of the ventral pallidum acting to suppress or select potentially competing limbic mechanisms.

Lesions of the ventral pallidum lead to an inability to inhibit incorrect responses in an odor discrimination task, supporting the hypothesis.

BOX 30.4

HUNTINGTON'S DISEASE

Huntington's disease (HD) is an inherited progressive neurodegenerative disorder that affects about 1 in 10,000 people. Symptoms include abnormal movements (comprising both involuntary movements termed chorea or dystonia and motor incoordination), cognitive difficulties, and emotional difficulties, including depression, apathy, and irritability. Onset is usually in midlife, but can range between childhood and old age. HD is generally fatal within 15 to 20 years after onset. The disease is caused by an expanded CAG repeat coding for polyglutamine in the HD gene product, termed the "huntingtin" protein. CAG repeat lengths between about 10 and 25 are normal, whereas those above 36 cause HD. Within the expanded range, the longer the repeat, the earlier the age of onset. The normal function of huntingtin is poorly understood, but it may be involved with cytoskeletal function, or cellular transport.

Pathologically, HD is characterized by selective neuronal vulnerability. The caudate and putamen of the corpus striatum are most affected in early stages, but as the disease progresses, other areas of the brain also become affected. Within the striatum, medium spiny GABA neurons are severely affected, with up to 95% loss in advanced cases, whereas large interneurons are relatively spared. In addition, there are intranuclear inclusion bodies and perinuclear and neuritic aggregates of huntingtin in HD neurons.

The pathogenesis of HD is still incompletely understood and represents a challenge for neuroscience. The huntingtin protein is widely expressed throughout the brain and is expressed at lower levels in other regions of the body as well. HD, like other neurodegenerative diseases, involves abnormal protein folding and aggregation. The inclusions themselves appear not to be directly toxic, but they likely represent a late stage of an abnormal process, whose earlier steps are pathogenic. The study of the disease has been facilitated by the generation of cell models, invertebrate models, and mouse models. Chaperone proteins can ameliorate the pathology, perhaps by refolding abnormally folded huntingtin. Huntingtin may normally be degraded by intracellular proteolytic machinery, termed the proteasome, and inhibition of the proteosome may be one of the toxic effects of the abnormally expanded polyglutamine.

A number of lines of evidence have pointed to a possible role for abnormal gene transcription in HD. Several studies have suggested that targeting of huntingtin to the nucleus enhances toxicity. Huntingtin may normally have a role in regulation of gene transcription, although this is poorly understood. Expression array studies show that mouse and cell models have an alteration of normal gene expression patterns. Abnormal intereactions with coactivator and corepressor complexes may contribute.

Whatever the initial mechanisms, symptoms appear to be caused by both cell dysfunction and cell death, with cell death correlating best with functional disability. Thus, preventing cell death is a major goal of experimental therapeutics in HD and other neurodegenerative disorders. Cell death may partly involve apoptotic mechanisms with activation of caspases and may also involve mechanisms such as excitotoxicity, metabolic, or free radical stress. Therapeutic strategies under investigation include protection of neurons with neurotrophins, altering abnormal gene transcription patterns, and reducing cell death with inhibitors of caspase activation or blockers of excitotoxicity.

BOX 30.5

DEEP BRAIN STIMULATION

Ablative neurosurgery has been used for treating movement disorders, epilepsy, and pain for over 80 years. In ablative procedures, a lesion is placed in the brain in order to disrupt a dysfunctional circuit. Ablative neurosurgery is still used, but increasingly deep brain stimulation (DBS) is replacing ablations to treat disorders associated with neural circuit dysfunction. This is particularly true for movement disorders related to basal ganglia dysfunction.

The idea of treating neurologic disorders with chronic electrical stimulation emerged in the 1960s. By the 1990s, technological advances provided the possibility of a system that could be implanted with no external components that could provide continuous stimulation for years without battery replacement. DBS involves stereotaxic surgical placement of electrodes into specific brain targets, fixing the electrodes to the skull, passing the electrode wires under the skin and ultimately connecting to a pacemaker-like device that is implanted under the skin in the chest, back, or abdomen. The pacemaker device can be programmed telemetrically to deliver desired stimulation by

BOX 30.5 (*cont'd*)

adjusting voltage, pulse width, frequency, and electrode configuration.

DBS was used initially for treating tremor associated with Essential Tremor or Parkinson disease, with electrodes placed in the cerebellar-receiving thalamic nucleus (ventral intermediate nucleus; VIM). By the end of the 1990s, DBS was used increasingly for treating other symptoms of Parkinson disease including bradykinesia and rigidity (targets: STN or GPi) and for treating dystonia (target: GPi). DBS can be dramatically effective for these movement disorders.

The mechanism by which DBS works is a subject of investigation. Although the effects are similar to the effect of ablation of the brain target in which the electrodes are placed, DBS does not appear to work simply by inactivating the target nucleus. In fact, there is evidence that DBS activates the efferent axons from that target. Regardless of the mechanism, there is no controversy regarding the efficacy of DBS for specific disorders. Investigations are under way to determine whether other neuropsychiatric disorders such as depression, OCD, and Tourette Syndrome, can be treated safely and effectively with DBS.

BOX 30.6

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is a chronic disorder characterized by recurrent intrusive thoughts and ritualistic behaviors that consume much of the afflicted individual's attentional and goal-directed processes. Among the more agonizing illnesses in clinical medicine, OCD is classified as an anxiety disorder because of the marked tension and distress produced by resisting the obsessions and compulsions. Common obsessions involve thoughts of harming oneself or others, of being afflicted by various illnesses, or of being contaminated by germs. Compulsions may be a response to obsessive thoughts (e.g., repetitive hand washing following skin contact with any object due to obsessive worries of having contacted germs) or may instead reflect cognitive-behavioral rituals performed according to stereotyped rules (e.g., counting one's footsteps to avoid ending on certain numbers). Although individuals with OCD recognize that such thoughts and behaviors are irrational, they feel irresistibly compelled to engage in them.

The onset of OCD usually occurs between late childhood and early adulthood. Without treatment, OCD is often disabling. However, chronic treatment with drugs that potently inhibit serotonin reuptake can reduce the amount of time engaged in obsessions and compulsions and the magnitude of the associated anxiety. In addition, behavioral therapy involving repeated *in vivo* exposure and response prevention (e.g., having patients touch a toilet seat and subsequently preventing them from hand washing) may facilitate extinction of the anxiety responses generated by resisting obsessive thoughts and compulsive behaviors.

The etiology and pathophysiology of OCD are unknown. Converging evidence from analysis of the lesions that result in obsessive-compulsive symptoms, functional neuroimaging studies of OCD, and observations regarding the neurosurgical interventions that can ameliorate OCD implicate prefrontal cortical-striatal circuits in the pathogenesis of obsessions and compulsions. The neurological conditions associated with the development of secondary obsessions and compulsions include lesions of the globus pallidus and putamen, Sydenham chorea (a poststreptococcal autoimmune disorder associated with neuronal atrophy in the caudate and putamen), Tourette disorder (an idiopathic syndrome characterized by motoric and phonic tics that may have a genetic relationship with OCD, see Box 30.7), chronic motor tic disorder, and lesions of the ventromedial prefrontal cortex. Several of these conditions are associated with complex motor tics (repetitive, coordinated, involuntary movements occurring in patterned sequences in a spontaneous, unpredictable, and transient manner). Complex tics and obsessive thoughts may thus both reflect aberrant neural processes originating in distinct portions of the cortical-striatal-pallidal-thalamic circuitry that are manifested within the motor and cognitive-behavioral domains, respectively. Compatible with this hypothesis, neurosurgical procedures that interrupt the white matter tracts carrying projections between the frontal lobe, basal ganglia, and thalamus are effective at reducing obsessive-compulsive symptoms in OCD cases that prove intractable to other treatments.

BOX 30.6 (*cont'd*)

Functional neuroimaging studies have also implicated prefrontal cortical-striatal circuits in the pathophysiology of OCD. In primary OCD, "resting" cerebral blood flow and metabolism are increased abnormally in the orbitofrontal cortex and the caudate nucleus, and increase further during symptom provocation in these areas, as well as in the putamen, thalamus, and anterior cingulate cortex. During effective pharmacotherapy, orbital metabolism decreases toward normal, and both drug treatment and behavioral therapy are associated with a reduction of caudate metabolism. In contrast, imaging studies of obsessive-compulsive syndromes arising in the setting of Tourette syndrome or basal ganglia lesions have found reduced metabolism in the orbital cortex in such subjects relative to controls. Differences in the functional anatomical correlates of primary versus secondary OCD suggest that dysfunction arising at multiple points within the ventral prefrontal cortical-striatal-pallidal-thalamic circuitry may result in pathological obsessions and compulsions.

This circuitry in general appears to be involved in the organization of internally guided behavior toward a reward, switching of response strategies, habit formation, and stereotypic behavior. Electrophysiological and lesion analysis studies indicate that parts of the orbitofrontal cortex are specifically involved in the correction of behavioral responses that become inappropriate as reinforcement contingencies change. Such functions could potentially become disturbed at the level of this cortex itself or within the circuits conveying projections from the ventral PFC through the basal ganglia, conceivably giving rise to the perseverative patterns of nonreinforced thought and behavior that characterize the cognitive-behavioral state of OCD.

BOX 30.7

TOURETTE SYNDROME

A "tic" is a sudden, rapid, recurrent, nonrhythmic, stereotyped movement or sound. Individuals with Tourette syndrome (TS) exhibit prominent and persistent motor tics and at least one phonic tic, beginning in childhood. Current estimates of TS prevalence range between 0.1 and 1.0%, with a 3:1 male:female ratio. Symptoms wax and wane; roughly half of all TS patients experience a significant symptom decline in their early 20s, whereas others experience lifelong symptoms.

Tics differ in complexity (simple, complex) and domain of expression (motor, phonic). In addition to their outward manifestations, a variety of sensory and mental states are associated with tics. "Simple" sensory tics are rapid, recurrent, and stereotyped, and are sensations at or near the skin. "Premonitory urges" are more complex phenomena, which often include both sensory and psychic discomfort that may be momentarily relieved by a tic. The full elaboration of tics, therefore, can include a sequence: (1) a sensory event or premonitory urge, (2) a complex state of inner conflict over if and when to yield to the urge, (3) the motor or phonic production, and (4) a transient sensation of relief.

Functional impairment in TS often results from comorbid conditions. More than 40% of individuals with TS experience symptoms of obsessive-compulsive disorder (OCD), and a comparable number have symptoms of attentional deficits and hyperactivity (ADHD).

Limited neuropathological evidence suggests four locations of potential pathology within cortico-striato-pallido-thalamic (CSPT) circuitry in TS: (1) intrinsic striatal neurons (increased neuronal packing density); (2) diminished striato-pallidal "direct" output (reduced dynorphin-like immunoreactivity in the lenticular nuclei); (3) increased dopaminergic innervation of the striatum (increased density of dopamine transporter sites); and (4) reduced glutamatergic output from the STN (reduced lenticular glutamate content).

BOX 30.7 (*cont'd*)

Volumetric neuroimaging studies report an enlarged corpus callosum, reduced caudate volume, or diminished striatal and lenticular asymmetry; these changes are subtle and are not replicated uniformly. Metabolic neuroimaging studies in TS report a reduced glucose uptake in the orbitofrontal cortex, caudate, parahippocampus, and midbrain regions and reduced blood flow in the caudate nucleus, anterior cingulate cortex, and temporal lobes. Regional glucose uptake patterns suggest distributed CSPT dysfunction, based on covariate relationships between reduced glucose uptake in striatal, pallidal, thalamic, and hippocampal regions. Tic suppression is associated with increased right caudate activation, measured by functional MRI, and by bilaterally diminished activity in the putamen, globus pallidus, and thalamus. Neurochemical imaging studies have reported relatively subtle abnormalities in the levels of dopamine receptors, dopamine release, DOPA decarboxylase, and dopamine transporter in the striatum of some individuals with TS. A report of greater caudate D2 receptor binding among more symptomatic TS identical twins may be relevant to factors contributing to heterogeneity of the TS phenotype.

There are a number of reported subtle abnormalities in the levels of major neurotransmitters, precursors, metabolites, biogenic amines, and hormones in blood, cerebrospinal fluid (CSF), and urine of TS subjects compared to controls. One qualitatively different finding is that of approximately 40% elevations of serum antiputamen antibodies in TS children. This finding may have particular importance, based on growing evidence for autoimmune contributions to at least some forms of TS.

Converging evidence for CSPT pathology in TS comes from neuropsychological and psychophysiological studies. Some forms of TS appear to be accompanied by abnormalities in sensorimotor gating, oculomotor functions, and visuospatial priming consistent with mild corticostriatal dysfunction.

Treatments for TS focus on education, comorbid conditions, and direct tic suppression. Education is a critically important intervention for both family members and affected individuals. Treatments for comorbid conditions, particularly OCD and ADHD, are highly effective and can provide significant relief. Dopamine antagonists, particularly high potency, D2 preferential blockers, are the most potent and rapid acting tic-suppressing agents, but have important, undesirable side effects. Newer, "atypical" antipsychotics are better tolerated, and some are effective in suppressing tics. The DA depleter tetrabenazine also offers significant tic suppression. α_2-Adrenergic agonists are often used as anti-tic agents; compared to dopamine antagonists, these drugs have relatively weaker anti-tic abilities and their benefit generally evolves more gradually. New therapeutic avenues for TS are being explored in controlled studies, including dopamine D1 antagonists, Δ^9-tetrahydro-cannabinol, and deep brain stimulation. Intractable, localized tics have also been treated successfully with injections of botulinum toxic. An effective nonpharmacologic therapy, habit reversal therapy, involves the application of cognitive and behavioral therapy principles to TS, analogous to the successful use of these therapies in the treatment of OCD. Behavioral therapy for tics is as effective as most currently employed pharmacologic therapies.

BOX 30.8

THE ROLE OF THE SUBTHALAMIC NUCLEUS IN STOPPING

You are sitting astride your bicycle at an intersection and just about to press down on the pedal when all of a sudden a motorist runs the light. This requires the rapid cancellation of an initiated action. Recent studies suggest that rapid stopping of this kind is implemented by a "hyperdirect" pathway between the frontal cortex and the subthalamic nucleus.

The broader sequence of events that engages this pathway is as follows. Sensory information about the stop signal (in this case, the car) is quickly relayed to the prefrontal cortex, where the stopping command must be generated. Two broad regions of the prefrontal cortex are apparently critical for stopping behavior: the right inferior frontal cortex and the dorsomedial frontal cortex

BOX 30.8 (*cont'd*)

(especially the presupplementary motor area). These two regions appear to work together to send a stop command to intercept the Go process, via the subthalamic nucleus. To appreciate how, first consider the Go process (the initiated pedal press). This is likely generated by premotor areas that project via the direct pathway of the basal ganglia (through striatum, pallidum, and thalamus), eventually exciting primary motor cortex and generating corticospinal volleys to the foot. An important point of interaction for Stop and Go processes could be the globus pallidus. Whereas the Go process activates the striatum and inhibits part of the globus pallidus pars interna, the Stop process activates the subthalamic nucleus which then excites the globus pallidus pars interna, which reduces thalamocortical excitability, leading to increased GABAergic inhibition in primary motor cortex. The consequence is a cessation of the corticospinal volleys for the Go process.

Interestingly, recent studies show that rapidly stopping the hand leads to suppression of foot motor representations and rapidly stopping the voice leads to suppression of hand motor representations. This shows that stopping has very broad effects on the motor system (a "global stop command"). While not proven, this could relate to the fact that the subthalamic nucleus appears to have a very broad effect on multiple neurons in the globus pallidus pars interna (Fig. 30.8).

Although rapid stopping has only so far been explored in the action domain, note that the subthalamic nucleus has different territories, including sensorimotor, associative and limbic, which connect to motor/premotor cortical, lateral prefrontal and cingulate/orbital frontal regions, respectively. It is an open question whether the kind of stopping discussed here could extend, for example, to the limbic domain of the subthalamic nucleus to enable emotional and motivational control. Notably, the limbic domain of the subthalamic nucleus is now a target for deep brain stimulation in obsessive compulsive disorder, and some studies have reported that inadvertent stimulation of this area in Parkinson's patients induces hypomania.

Other research points to the importance of neural oscillations in the beta frequency band for the stopping system. Successfully stopping action is associated with increased beta power in the subthalamic nucleus, as well as the presupplementary motor area and the right inferior frontal cortex. It is possible that stopping is implemented via long-distance synchronization in the beta band in the overall cortico-basal ganglia network.

Summary

It is appropriate to consider the basal ganglia as part of the motor system because the largest portion of the basal ganglia is devoted to motor control and the most prominent deficits resulting from basal ganglia damage are motor. However, it has become clear that the basal ganglia play substantial roles in nonmotor function and in more cognitive aspects of movement. These roles are the subject of active research. Ultimately there may be a unifying theory of basal ganglia function that will encompass all of the subdivisions, but at this point one can only say that it is likely that the different circuits employ similar mechanisms.

CHAPTER

31

Cerebellum

The cerebellum is a softball-sized structure located at the base of the skull. Grab the back of your head just above where it meets your neck: your hand is now cupped around your cerebellum. As with most brain systems, much of what we know about the cerebellum stems from symptoms of damage or pathology and from its connectivity with the rest of the brain. From such evidence it has long been clear that the cerebellum is an important component of the motor system. Severe abnormalities of movement are produced by pathologies of the cerebellum. Cerebellar output influences systems that are unambiguously motor, and inputs to the cerebellum convey information known to be essential for movement such as joint angles and loads on muscles. Recently it has become equally clear that the role of the cerebellum is not limited to movement. This is indicated by its interconnections with nonmotor structures; by the more subtle, nonmotor deficits seen with cerebellar lesions; and by functional imaging studies where regions of the cerebellum show activation during nonmotor tasks. A deeper understanding of the cerebellum will require identification of the common aspects or computational demands that these motor and nonmotor functions share.

Research on the anatomy, physiology, and function of the cerebellum is complemented by computational analyses of the rules for input/output transformations and the means by which the cerebellar circuit implements such transformations. This interdisciplinary approach was made possible by the seminal work of Eccles, Ito, and Szentágothai, who in 1967 published *The Cerebellum as a Neuronal Machine*, which described most of the essential aspects of the cellular and synaptic organization of the cerebellum. Two years later, David Marr published a remarkable paper in which he inferred some basic computational properties of the cerebellum solely on the basis of the wiring diagram that Eccles and associates had elucidated. The relative clarity of the cerebellar circuit and the close interconnections between cerebellar activity and motor output have enabled rigorous experimental and computational analyses of the relationship between brain and behavior, and even between circuit plasticity and learning.

CEREBELLAR ANATOMY AND CIRCUIT

The anatomical, circuit, and physiological characteristics of the cerebellum suggest that it carries out a different type of computation than the cerebral cortex. One indication of this distinction is that Purkinje cells, which provide the only output of the cerebellar cortex, are inhibitory (GABAergic) and fire about 50 action potentials every second, even in the absence of sensory input. Their downstream target neurons in the vestibular and cerebellar nuclei, which comprise the sole output of the entire cerebellum, are also spontaneously active. High tonic firing rates enable these cerebellar cell types to respond rapidly, precisely, and bidirectionally to input signals. As a result, the cerebellum can exert tight temporal control over its diverse downstream target regions. This chapter first discusses cerebellar anatomy, circuit, and development, and then examines the cellular and synaptic specializations that underlie cerebellar function. The last section demonstrates the relationship between circuit and function during behavior and learning.

Phylogenetic Development

The cerebellum is present in all vertebrates. In agnathans (lampreys and hagfish), it is a rudimentary structure that assists the functions of the well-developed vestibulo-ocular, vestibulospinal, and reticulospinal systems. The cerebellum is somewhat larger in fishes, where, on the input side, it processes sensory information from the vestibular,

© 2013 Elsevier Inc. All rights reserved.

lateral line, and to a lesser extent proprioceptive and somatosensory systems. On the output side it is connected to the vestibular and reticular nuclei. In amphibians the region of the cerebellum that receives proprioceptive and other sensory information is expanded, and it increases still further in reptiles, birds, and most mammals, where it constitutes the largest portion of the cerebellum. A diverse range of brain regions send inputs to or receive outputs from the cerebellum. In primates and dolphins, the hugely expanded lateral hemispheres are connected with the enlarged cerebral cortex via the thalamus and pons.

Gross Anatomy

The cerebellum consists of a three-layered cortex folded repeatedly, accordion-style, around the three pairs of cerebellar nuclei buried in the middle. Each fold of the cerebellar cortex is called a folium (leaf), and in most species the folia run roughly transverse to the long axis of the body, from ear to ear. The folia are grouped into lobules, numbered I to X; lobulation is fairly consistent across individuals of the same species and even across species, despite great variation in cerebellar development. The lobules in turn are grouped into three lobes. The flocculonodular lobe (also known as the vestibulocerebellum) is the phylogenetically oldest portion and is located on the inferior surface. Above the posterolateral fissure sit the anterior and posterior lobes, separated from each other by the primary fissure (Fig. 31.1). If the entire human cerebellar cortex were unfolded and flattened, it would have about the same area as a sheet of paper, but arranged in a long thin strip.

The cerebellar cortex influences the rest of the brain exclusively via projections to neurons in the vestibular and cerebellar nuclei (also termed the "deep cerebellar nuclei"). From medial to lateral, the cerebellar nuclei comprise the fastigius, the interpositus (further divided into the globose and emboliform in humans), and the dentate. The cerebellar cortex, excluding the flocculonodular lobe, can be divided into three longitudinal (parasagittal) zones based on the projection of the cortex onto the three cerebellar nuclei (Fig. 31.2). The medial zone receives information from a wide range of sensory systems, including vestibular, visual, somatosensory, and auditory. The medial zone also processes signals relating to autonomic, visceral, cardiovascular, and immune function. It projects to the fastigial nuclei, which in turn send outputs to the vestibular and reticulospinal systems, as well as the thalamus and superior colliculus. The intermediate zone of the cerebellar cortex receives proprioceptive and somatosensory information from the spinal cord, as well as information from the motor cortex via the pontocerebellar nuclei. Its axons target the interpositus nuclei, which in turn have a major

projection to the red nucleus, with some axons continuing to the contralateral thalamus (VL). There are also a sparser number of collaterals projecting to the spinal cord and pons. The lateral zone receives diverse types of information from the pontine nuclei, which carry signals from the widespread regions of the cerebral cortex. The lateral zone projects to the dentate nuclei, whose predominant output is to the thalamus (VL) and reticular formation, with lesser outputs to the red nucleus and spinal cord (Fig. 31.2). Finally, the flocculonodular lobe receives vestibular, visual, and motor information, and sends its output exclusively to the brainstem vestibular nuclei. In addition to the premotor outputs shown in Figure 31.2, each ouput nucleus also sends inhibitory outputs to subregions of the inferior olive: vestibular and fastigial nuclei to

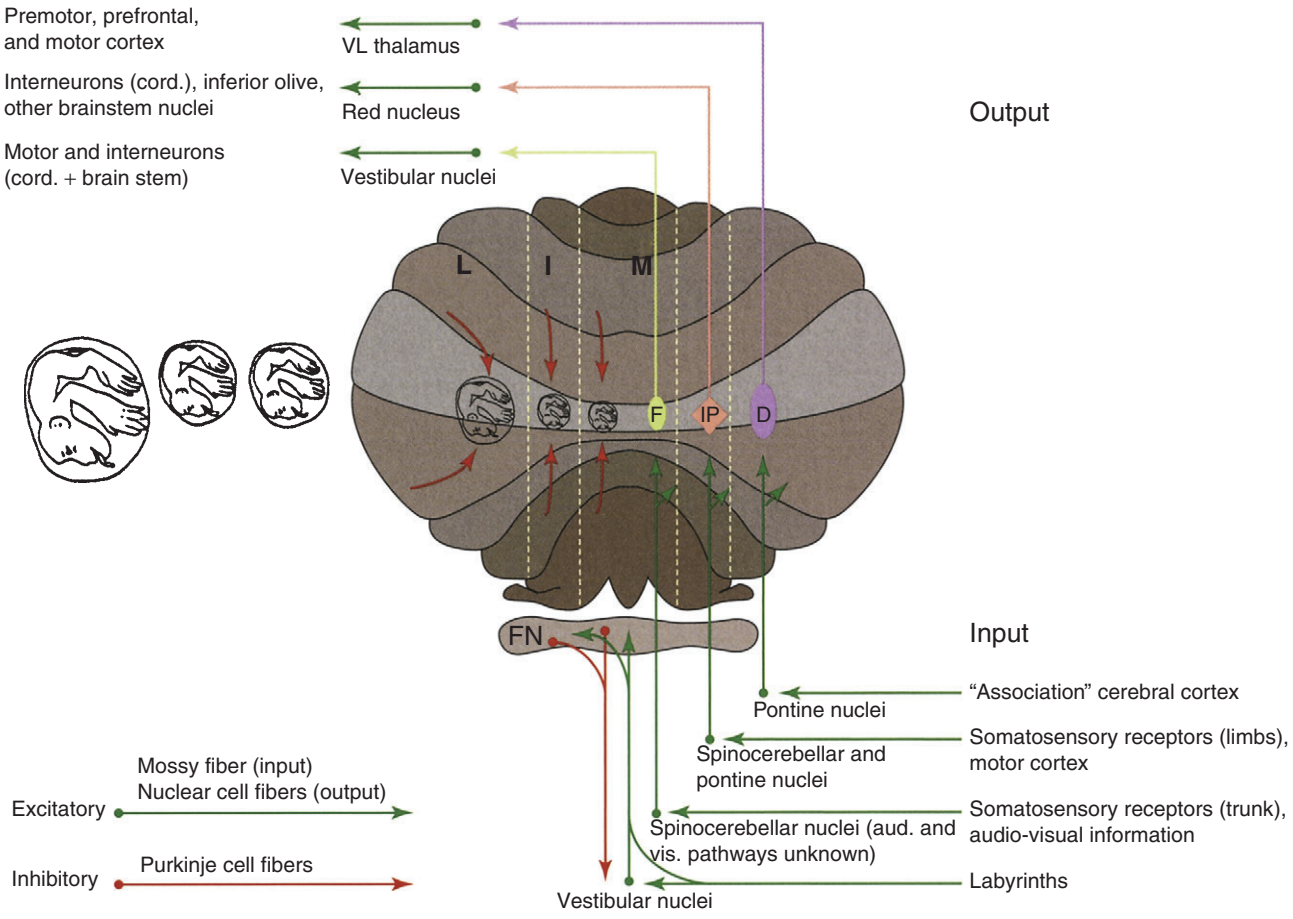

FIGURE 31.2 Cerebellar inputs and outputs. The cerebellum is shown schematically with the flocculonodular (FN) lobe unfolded and represented at the inferior surface. the dorsal cap of Kooy, the beta nucleus, and weakly to the medial accessory olive; interpositus to the dorsal and medial accessory olive, with a weaker projection to the cap of Kooy; and the dentate to the principal olive.

Mapping studies reveal that the cerebellum is not organized purely somatotopically like the sensory cerebral cortices. Part of the difficulty in defining cerebellar organizing principles is that the cerebellum combines diverse sensory inputs to create and refine motor commands. Thus, neither sensory nor motor mapping individually may square exactly with cerebellar organization. Sensory mapping studies reveal a "fractured somatotopy," in which the regions of cerebellum that respond to touch of paw sites, for example, are located close to each other, but sensation for forelimb is represented elsewhere. The cerebellum can also be partitioned into parasagittal zones that may represent distinct motor control modules (see Box 31.1).

Two different schema have been proposed to account for cerebellar organization. In the first, each major subdivision of the cerebellum controls all parts of the body, but during different behavioral requirements: the flocculonodular lobe and medial cerebellum modulate vestibular-driven behaviors and eye movements; the intermediate zone controls somatic reflexes; and the lateral zone concerns itself with movements under voluntary control. In a second schema, the medial zone primarily controls musculature of the trunk, the intermediate zone that of the proximal limbs, and the lateral zone the distal limbs. Both of these organizing principles are supported by experimental and clinical studies in which the different cerebellar nuclei are lesioned or inactivated (Fig. 31.3). Neither accounts for the role of the cerebellum in regulating autonomic, emotional, or cognitive functions. The inputs and outputs of the cerebellum are diverse, and the outputs are relatively poorly characterized to date. A unifying view of cerebellar function that draws on analyses of neuronal activity, circuits, and behavior remains to be established.

Basic Cerebellar Circuit

The structure of the cerebellar circuit is highly stereotyped (Fig. 31.4; though see Box 31.2). Mossy fiber inputs,

BOX 31.1

PARASAGITTAL STRIPES: THE BASIS OF CEREBELLAR MICROCIRCUITS?

One of the greatest unknowns about the cerebellar circuit is whether the prototypical olivocerebellar loop, from olive → Purkinje cells → cerebellar nuclei → back to olive, is actually organized so that an *individual* olivary neuron receives inhibitory feedback from the same inhibitory nucleus neurons that it influences indirectly via Purkinje cells. In other words, does the microcircuit (at the level of individual neurons) reflect the macrocircuit (at the level of entire structures)? The most suggestive work on this question comes from anatomical studies on the parasagittal zones of the cerebellum. Histological experiments have revealed that many proteins, including aldolase C, acetylcholinesterase, calbindin, and parvalbumin, are expressed differentially in parasagittal stripes that run the length of each longitudinal zone. These stripes, which have been given names (1+, 1−, 2+, 2−, etc.), are constant in their presence and location within a species and to some extent across species (Pakan, Graham, Gutiérrez-Ibáñez, & Wylie, 2011).

Recent work has highlighted the potential significance of these stripes in organization of microcircuits in the cerebellum. Each olivary neuron gives rise to 7 to 10 climbing fibers in the cortex; all of the Purkinje cells that receive input from one olivary neuron are located within a stripe defined by aldolase C staining. Even in cases where the olivary axon diverges to different cerebellar lobules, the climbing fibers in both lobules obey the pattern established by aldolase C stripes: either all branches are in positive stripes or all in negative stripes. Furthermore, a group of Purkinje cells that are innervated by a small cluster of olivary neurons typically exhibit converging axon arbors in the cerebellar nuclei as well, within a subregion that is also defined by aldolase C staining (Sugihara, 2011). This convergence holds true even when the Purkinje cells are located in separate lobules. The axon collaterals of olivary neurons, which extend into the cerebellar nuclei, also form small clusters of terminals suggestive of microcircuit targeting. In turn, a cluster of nuclear neurons appears to target the same olivary region from which it receives input. Even cortical interneurons may respect the boundaries defined by aldolase stripes (Sillitoe & Joyner, 2007). Together these data are strongly suggestive of a closed loop olivo-cortical-nuclear microcircuit.

These findings are exclusively anatomical, but some experiments have extended these concepts to physiology and function as well. For example, muscle injection of a rabies virus tracer, which can travel retrogradely across many synapses, reveals one or more longitudinal stripes of Purkinje cells bounded by aldolase C compartments. Physiologically, Purkinje cells in aldolase positive and negative stripes express different complements of glutamate transporters, some of which are more effective than others. As a result, it is easier to trigger metabotropic glutamate receptor activity, and the consequent cascade leading to long-term depression of the parallel fiber → Purkinje cell synapse, in aldolase-negative than in aldolase-positive compartments (Wadiche & Jahr, 2001). In sum, the parasagittally organized stripes of the cerebellum are highly significant for both circuit and function.

which are excitatory, arise from a wide variety of pontine, medullary, and spinal areas (Fig. 31.2). Mossy fibers diverge to send axon collaterals to the cerebellar nuclei before ascending to the inner, granular layer of the cerebellar cortex; they typically synapse bilaterally but in some cases are restricted ipsilaterally. In each folium of the cortex, a mossy fiber makes up to 50 large glomerular synapses with a relatively large presynaptic specialization known as a *rosette*, which excites one dendrite from each of ~20–30 granule cells. Granule cells typically have 3 to 5 short dendrites, each of which terminates in a glomerulus; thus, each granule cell receives input from 3 to 5 mossy fibers. Granule cells are the most common cell type in the entire brain (~50 billion in humans), providing an unparalleled capacity for combinatorial and sparse coding of inputs. The axons of granule cells ascend radially, making a few synaptic contacts on Purkinje cells on their way to the outer molecular layer, where they bifurcate into a T shape and extend long, unmyelinated branches termed the parallel fibers (so named because they run transversely, parallel to the folia). Each parallel fiber reaches up to 1 cm through the cortex and releases glutamate onto the

BOX 31.2

DIFFERENCES BETWEEN THE VESTIBULAR AND NONVESTIBULAR PORTIONS OF THE CEREBELLUM

Phylogenetically, the vestibular and fastigial (medial) cerebellar nuclei predate the interpositus and dentate. Perhaps as a result, the vestibular and fastigial cerebellar circuits exhibit some distinctive properties compared to their relatively younger neighbors:

1. Unipolar brush cells are present in highest densities in the granule cell layer of the flocculonodular lobe. These excitatory neurons receive mossy fiber input, like granule cells, but synapse locally onto granule cells. Golgi cells feed back to unipolar brush cells with mixed glycinergic and GABAergic synapses, in contrast to the purely GABAergic feedback to granule cells (Dugue, Dumoulin, Triller, & Dieudonne, 2005). The role of these neurons in the vestibular circuit is unclear.
2. Olivary neurons in the dorsal cap of Kooy, to which both the vestibular and fastigial nuclei project, have different intrinsic electrical properties than those in the principal and accessory olive. Neurons in the dorsal cap exhibit an approximately linear relationship between injected current and resulting firing rate, tonically firing at up to 35 Hz during a current step. In contrast, neurons in the rest of the olive exhibit significant subthreshold oscillations, usually only fire a couple of spikes at a maximum of 10 Hz in response to depolarization, and are relatively insensitive to depolarizing current injection (Urbano, Simpson, & Llinas, 2006).
3. In a similar vein, the GABAergic feedback from the vestibular cerebellum to the dorsal cap of Kooy is phasic and time-locked to presynaptic firing. The comparable feedback from nonvestibular cerebellum to the principal and accessory olive is slow, aphasic, and appears to be mediated by asynchronous release of GABA (Best & Regehr, 2009).
4. The vestibular and fastigial nuclei contain two major types of premotor projection neurons: glutamatergic neurons that project to contralateral targets, and glycinergic neurons that project to ipsilateral targets. Premotor projection neurons in the interpositus and dentate are exclusively contralateral-projecting and glutamatergic (although the dentate nucleus contains in addition some nucleocortical glycinergic neurons of unknown role) (Bagnall et al., 2009; Shin et al., 2011; Uusisaari & Knopfel, 2010).
5. Some projection neurons in the vestibular nuclei synapse directly onto motor neurons, whereas projection neurons in the nonvestibular cerebellum influence behavior less directly via synapses onto thalamus, pons, medulla, and colliculi.

As a result of these differences, it is not known whether computations carried out by one portion of the cerebellum are necessarily the same as those carried out by the other. The generally homologous structures of the vestibular and nonvestibular parts of the cerebellum may mask significant underlying dissimilarities in the nature of their information processing. This distinction may be related to the need for high-speed processing in the vestibular system, or perhaps to the relatively tight coupling between vestibular signaling and motor output.

Martha Bagnall and Michael Mauk

dendritic spines of ~75 Purkinje cells. The parallel fibers in any one region of the cortex may arise from granule cells in the medial, intermediate, and lateral zones of the cerebellum. Thus, each Purkinje cell may receive information about sensory conditions, internal states, and the plans of the organism. It is notable that while the synapse from mossy fiber to granule cell is robust, each parallel fiber synapse on Purkinje cells is quite small (1 nS measured at soma). Therefore, it is assumed that the convergent activity of many parallel fibers is required to modulate the simple spike firing rate of Purkinje cells. Approximately 150,000 parallel fibers contact a given Purkinje cell.

The second major input to the cerebellum is the climbing fiber, which originates from inferior olivary neurons in the contralateral brainstem. Climbing fibers branch in the sagittal plane and make contact with 7 to 10 Purkinje cells, often in more than one lobule. After a developmental pruning period, each Purkinje cell receives input from only one climbing fiber, which makes about 300 synaptic contacts onto its soma and dendrites. The simultaneous release of multiple vesicles of glutamate from each of these contacts results in a powerful postsynaptic current that drives an unusual action potential termed a "complex spike." The complex spike consists of an action potential followed by several spikelets riding on the back of a larger plateau depolarization (Fig. 31.5). Two to four of these spikelets are sufficiently large to drive axonal action potentials, so that a downstream neuron in the cerebellar or vestibular nuclei is thought to see a short, high-frequency burst of Purkinje input after each complex spike. Olivary neurons fire at about 1 Hz and increase firing as an animal encounters novel conditions or tries to adapt its movement.

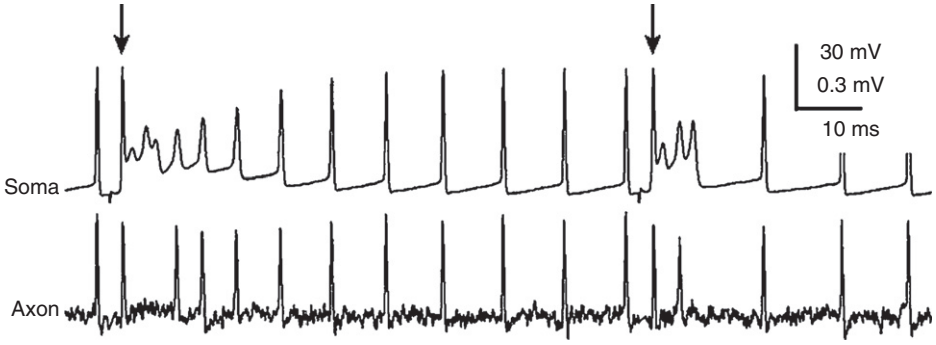

FIGURE 31.5 Whole-cell recording of a Purkinje cell at the soma (top) and cell-attached recording from its axon (bottom). The Purkinje cell fires "simple spikes" spontaneously, all of which are transmitted down the axon. At the times indicated by arrows, a complex spike is elicited by climbing fiber stimulation. Two to three of the spikes associated with the complex spike drive axonal spiking. *Adapted from Khaliq and Raman (2005).*

Most climbing fiber axons also emit collaterals in the cerebellar nuclei, but these synaptic connections have only been studied to date at the anatomical, not physiological, level.

Purkinje cell output is inhibitory and targets exclusively the neurons of the cerebellar and vestibular nuclei. The axon of a Purkinje cell projects ipsilaterally to one of these nuclei, where it diverges onto three main types of neurons: (1) GABAergic neurons that project back to the inferior olive, closing an inhibitory feedback loop; (2) large projection neurons, most of which are excitatory; and (3) short-axon inhibitory neurons of unknown function. The large projection neurons serve as the sole output of the cerebellar circuit and send their axons to regions of the brain as diverse as the thalamus, superior colliculus, and pons. A small subset project back to the cerebellar cortex, with unknown functional consequences (Gould & Graybiel, 1976; Uusisaari & Knopfel, 2010). Surprisingly, given their role as sole output of the large and computationally intense cerebellum, cerebellar and vestibular nucleus neurons are few in number, approximately 1/30 as many as Purkinje cells (Palkovits, Mezey, Hamori, & Szentagothai, 1977). Similar to Purkinje cells, they fire spontaneously at high rates *in vivo* and *in vitro* (~30 Hz, with significant variation), with their firing rates modulated during various types of behaviors.

Complete Cerebellar Circuit

Five other cell types make up the complete cerebellar circuit (Fig. 31.4). Inhibitory Golgi cells reside in the upper portion of the granule cell layer. Their ascending dendrites extend to the outer molecular layer, where they receive excitatory inputs from parallel fibers; their basal dendrites remain in the granule cell layer, where they receive excitatory inputs from mossy fibers. Each Golgi cell synapses onto several thousand granule cells, enabling it to provide both feedforward and feedback inhibition, depending on whether its activity is driven more by mossy fibers or parallel fibers, respectively. Golgi cells also appear to make direct inhibitory synapses on each other (Hull & Regehr, 2012).

Also in the granule cell layer are Lugaro cells, located just below the Purkinje cell layer. Lugaro cells form inhibitory synaptic contacts onto Golgi cells as well as basket and stellate cells in the outer molecular layer (see below). A distinguishing characteristic is that Lugaro cells, unlike Golgi cells, are sensitive to serotonin. Serotonergic activation of Lugaro cells may indirectly activate other circuit elements by inhibiting inhibitory Lugaro cells (Geurts, De Schutter, & Dieudonne, 2003).

The third identified member of the granule cell layer is the glutamatergic unipolar brush cell (Mugnani, Sekerková, & Martina, 2011), which is found in highest densities in vestibular regions (the nodulus and flocculus) of the cerebellum. Like granule cells, they receive excitatory inputs from mossy fibers, but their axons branch locally within the granule cell layer and form excitatory synapses onto granule cells. They are inhibited by Golgi cells at glycinergic or mixed glycinergic/GABAergic synapses. *In vitro* studies have shown that unipolar brush cells respond to brief bursts of excitatory input with prolonged bursts of output that far outlast the stimulus. The influence of this cell type on network computation is far from understood.

Two types of GABAergic interneurons, basket and stellate cells, reside in the outer molecular layer. Both are excited by parallel fibers and inhibit Purkinje cells; basket cells target the soma and perisomatic region of the Purkinje cell, whereas stellate cells contact Purkinje dendrites. Thus, both basket and stellate cells provide feedforward inhibition from granule cells to Purkinje cells. Both cell types also receive weaker, nonsynaptic excitation from climbing fibers. Basket cells, but not stellate cells, are inhibited by Purkinje cell axon collaterals that ramify near the Purkinje cell layer, creating an inhibitory loop. Because the basket cell axons traverse along parasagittal strips, this inhibitory loop may provide a way for each Purkinje cell in a parasagittal strip to entrain the firing of its sister Purkinje cells via disinhibition (inhibition of inhibition). Classically, these outer molecular layer interneurons are thought to provide a type of "off-beam" inhibition, wherein the parallel fibers excite Purkinje cells directly in their path, but Purkinje cells located to either side are inhibited by basket and stellate cells. Thus, the net effect of activity in a small cluster of granule cells would be an increase in firing in the transverse strip of Purkinje cells directly above

and a decrease in firing in the strips of Purkinje cells on either side of the "on-beam" activity. Whether this occurs outside of the context of experiments stimulating beams of parallel fibers and whether basket and stellate cells contribute equally to this phenomenon are both unclear.

Finally, in addition to the mossy fiber and climbing fiber inputs to the cerebellum, there is a third type of modulatory input with a widespread, nonlaminar distribution. These afferents originate in the locus ceruleus, raphe nuclei, and other brainstem and hypothalamic nuclei. They innervate the cerebellar and vestibular nuclei and all cortical layers, with some preference from the molecular layer. Modulatory inputs synapse onto Purkinje cells as well. Afferents from the locus ceruleus release norepinephrine, those from the raphe release serotonin, those from the brainstem release acetylcholine, and those from the hypothalamus release histamine. Synapses of nonlaminar afferents have been difficult to define at the electron microscopic level because of their sparseness and lack of distinctive structural characteristics. As a result, little is known about the specifics of their connectivity or their functional roles in modulating cerebellar activity (Ito, 2009).

Development

Cerebellar cell types develop at different times and at different places. First to be formed are the neurons of the cerebellar nuclei. They are followed soon after by Purkinje cells, which originate in the ventricular epithelium and migrate to their ultimate location in the cortex. Golgi cells, basket cells, stellate cells, astrocytes, and Bergmann glia also originate at the ventricular epithelium and migrate to their final positions after the migration of the Purkinje cells. The Bergmann glia later guide the descent of the granule cells from the external granule cell layer.

Once the Purkinje, Golgi, basket, and stellate cells have formed, climbing fibers enter the cerebellum from the inferior olive and begin to innervate the Purkinje cells. Much later, after the Purkinje cells have begun to receive synapses from parallel fibers, most of the climbing fiber contacts with Purkinje cells are eliminated. Mossy fibers also enter the cerebellum and grow to the level just below the Purkinje cell layer. They will ultimately synapse on granule cells, which have yet to arrive.

The granule cells first develop at a very distant site, posterior and lateral in the anlagen at the rhombic lip. They then crawl over the Purkinje cells to form an external granule cell layer. Some granule cells may cross the midline to the other side of the cerebellum as they make this migration. The granule cells extend their axons, which branch to form parallel fibers that run as coronal beams through the dendrites of the Purkinje cells. Only then do the granule cells descend, guided by the Bergmann glia, to form the internal granule cell layer. Each granule cell is connected by the proximal portion of its axon to the branch point of its parallel fibers, which remain in the external granule cell layer. In the internal granule cell layer, each granule cell dendrite is contacted by the terminals of the mossy fibers and gradually forms synaptic connections with them. Synapses are also made between granule cells and the intrinsic cortical inhibitory neurons—the Golgi, stellate, and basket cells. Notably, the output side of the cerebellar circuit (vestibular and nuclear neurons and Purkinje cells) forms first, the input side (mossy fibers) then arrives, and the "matrix" that connects the two (the granule cells and intrinsic inhibitory neurons) is the last to develop (Ray & Dymecki, 2009; Sillitoe & Joyner, 2007).

In humans, the first cerebellar structures develop at approximately 32 days after fertilization, and development is not completed until after birth. The cerebellar cortex of the early embryo has six distinct layers, but this number is ultimately reduced to three. The cortex begins to differentiate slightly earlier in the vermis, flocculus, and median sections of the hemispheres than in the lateral hemispheres. By 7 months after fertilization, the cerebellar nuclei have attained the shape and location they will have in the adult. At birth, the cerebellar cortex consists of four uneven layers, and the Purkinje cells and basket cells are weakly developed. The fourth layer (the external granule cell layer) disappears within the first postnatal year. In humans, full myelination of cerebellar connections is not complete until the second year of life (Brody, Kinney, Kloman, & Gilles, 1987; Wang and Zoghbi, 2001).

Summary

The cerebellum is a prominent structure in the nervous systems of most vertebrates. The cerebellum receives inputs from many parts of the nervous system but predominantly influences motor circuits and the cerebral cortex. This suggests that many different kinds of information are brought together to coordinate and adaptively control movement and certain cognitive functions. The intrinsic structure is relatively simple and very stereotyped throughout the cerebellum, very different from that of the cerebrum. The ontogenetic development is conspicuously late: cell migrations and fiber connections continue to occur after birth and the development of the rest of the motor nervous system.

CELLULAR AND SYNAPTIC PERFORMANCE OF THE CEREBELLAR CIRCUIT

Distinctive Properties of Cerebellar Neurons

The continuous high firing rates of both Purkinje cells and vestibular/nuclear neurons are unusual in comparison to most other brain regions. These cerebellar neurons

are not only active during behaviors, but they also play critical roles in the induction and expression of long-term memories. These constraints pose a distinct set of challenges for the underlying cellular and synaptic physiology. This section examines the adaptations and performance of several aspects of the cerebellar circuit: high spontaneous firing rates, four distinctive synaptic connections, and multiple forms of synaptic and intrinsic plasticity.

Spontaneous, Continuous High Firing Rates

The advantage of the high firing rates of Purkinje and nuclear/vestibular neurons is thought to be the resulting rapid, bidirectional modulation of firing rate that enables tight temporal control over movement and planning. However, high firing rates incur a significant metabolic cost. Each time a neuron fires an action potential, sodium and calcium enter the neuron and potassium exits. These ions must be pumped back across the membrane with ATP-driven ion exchangers to regain their balance. Purkinje and cerebellar/vestibular nucleus cells express a specific complement of ion channels that help minimize this cost and maintain the cell's spontaneous rate. They are enriched for Kv3 potassium channel subtypes, which have rapid kinetics that speed cell repolarization. As a result, action potentials are brief in duration, limiting the window for sodium and calcium entry, so that fewer of these ions will have to be pumped back outside. Rapid repolarization together with specialized sodium channels (Bant & Raman, 2010; Raman & Bean, 1991) minimizes the inactivation of sodium channels that typically occurs during each action potential (Carter & Bean, 2011; Gittis et al., 2010). These biophysical properties are critical for enabling cerebellar neurons to rapidly and precisely modify their downstream targets.

Mossy Fiber Glomerulus

The mossy fiber axon terminates in glomerular structures in the granule cell layer, each of which can contain a dendritic terminus from each of ~20 to 30 granule cells and one Golgi cell basal dendrite. Each mossy fiber forms 15 to 50 such glomeruli per folium, so that it directly influences as many as 1000 granule cells and 50 Golgi cells in one folium. Mossy fiber firing patterns vary across the cerebellum, depending on the source of the fiber, and can range from prolonged firing at tens of Hz to short bursts at instantaneous frequencies upwards of 200 Hz. The mossy fiber to granule cell synapse achieves reliable transmission of high bursts by rapid recycling and reloading of a large pool of available vesicles (Saviane & Silver, 2006). It is thought that the conjunctive activity of several mossy fiber inputs is required to trigger granule cell firing *in vivo*, but it is possible that just one is sufficient. The small size and close quarters of granule cells make it technically challenging to record the spiking of individual neurons, leaving this question open to further study.

Climbing Fiber Synapse

The climbing fiber that arises in the inferior olive makes an intricate, ivy-like connection with each of its Purkinje cell targets, synapsing along the entire dendritic arbor at ~2–3 μm intervals. Ascending axonal branches also have contact points with molecular layer interneurons, although the dominant mode of transmission appears to be through spillover of glutamate from nearby release sites (Szapiro & Barbour, 2009). While the climbing fiber ascending synapse onto Purkinje cells is the best studied, the axon also makes a number of transverse branches of unknown function, with few conventional synapses (Nishiyama, Fukaya, Watanabe, & Linden, 2007).

Each synaptic contact between the climbing fiber and Purkinje cell is ensheathed by glial processes, deriving from Bergmann glia, that reduce the spillover of glutamate from the synaptic cleft to other sites. This specialization may be due to the large amount of glutamate released by the climbing fiber: not only does each axon make hundreds of contacts with one Purkinje cell, each contact is able to release multiple vesicles of glutamate at a time (Wadiche & Jahr, 2001). Furthermore, inferior olive neurons can fire complex spikes as well, in which a high-frequency burst (3–4 spikes at 100–200 Hz) is successfully transmitted down the axon, leading to an even larger glutamate release (Mathy et al., 2009). The result of all this glutamate release is the Purkinje cell complex spike. Each complex spike causes ~2 to 3 spikes to propagate down the Purkinje cell axon, at instantaneous rates of up to ~400 Hz (Fig. 31.5). However, the specific waveform of the complex spike, and thus the number of action potentials that propagate down the Purkinje cell axon, is determined by the characteristics of climbing fiber synaptic transmission and is subject to change. Interestingly, the ~50 Hz simple spike activity in a Purkinje cell is often suppressed for tens of ms after the complex spike, so that the net effect of this synapse is a burst-pause. The flood of calcium triggered by climbing fiber activity is a critical signal for parallel fiber plasticity (see below).

Purkinje Cell to Cerebellar Nuclear Neuron Synapse

Purkinje cells fire simple spikes spontaneously at ~50 Hz, modulate their firing up to 100–200 Hz, and can achieve instantaneous frequencies of up to 400 Hz in response to climbing fiber input. How do the output neurons of the cerebellar circuit respond? The Purkinje cell synapse onto cerebellar nucleus neurons is robust. Each axon terminal is large (~3–4 μm diameter) and contains around 10 individual release sites (Telgkamp, Padgett, Ledoux, Woolley, & Raman, 2004). Furthermore, each

Purkinje cell axon makes several synaptic contacts onto a single cerebellar nucleus neuron, providing a total of 100 to 200 release sites at a unitary connection. Although the probability of transmitter release is low at each site, the sheer number of release sites guarantees that a given Purkinje cell can reliably release transmitter to a cerebellar nucleus neuron even at high rates of presynaptic firing.

The high spontaneous rates of cerebellar nucleus neuron firing enable Purkinje cell inhibition to sculpt postsynaptic responses in several different ways. Dozens of Purkinje cell axons converge onto individual nuclear neurons. Synchrony in the firing of converging Purkinje cells enables inhibition to produce precise delays in postsynaptic firing with little effect on overall rate; conversely, asynchronous firing of Purkinje cells results in a reduction in nuclear neuron firing rates (Person & Raman, 2012). Most nuclear neurons respond to the *offset* of hyperpolarization with a transient increase in firing rate, termed *rebound firing*, before settling into a new, elevated rate relative to the inhibited state. Whether Purkinje cell inhibition is sufficiently strong to engage rebound firing remains unclear. One working hypothesis is that the relief of Purkinje cell inhibition, evoked by a synchronized pause in Purkinje cell firing, serves as a precisely timed signal to increase cerebellar nuclear neuron firing and modulate downstream behavior. In this scenario, the timing of the Purkinje cell pause would be controlled by temporal coding provided by granule cell inputs so that learned Purkinje cell responses can be temporally specific.

Cerebellar Nuclear to Olivary Input

GABAergic neurons in the cerebellar and vestibular nuclei give rise to thin axons that project to the inferior olive, closing the feedback loop of the cerebellum. Little is known about the firing rates of these GABAergic neurons with respect to behavior, because of the difficulty in identifying these neurons during *in vivo* recordings. However, the connection is clearly required for extinction of learned reflexes (as described below). Nuclear and vestibular neurons make synapses on olivary dendrites. *In vivo* studies have shown that stimulation of the nucleo-olivary tract causes a slow, long-lasting inhibition of olivary firing. Recent work has revealed that the sluggishness of this response derives from asynchronous release of GABA, yielding a barrage of miniature synaptic events. The resulting synaptic current is small in amplitude but lasts tens of milliseconds (Best & Regehr, 2009). Interestingly, inputs from vestibular nuclei to the olive do not share this characteristic: they are phasic and rapid in time course (Box 31.2). Nuclear synapses onto olivary dendrites occur preferentially close to the gap junctions that interconnect olivary neurons (De Zeeuw et al., 1998). This localization suggests that nuclear input might selectively weaken olivary coupling (Lang, Sugihara, & Llinas, 1996).

Long-Term Depression and Potentiation at the Parallel Fiber to Purkinje Cell Synapse

The cerebellum is the site of certain types of memory formation and storage. Activity-dependent plasticity has been found in synapses and neurons throughout the cerebellar circuit (Carey, 2011). The following section describes two forms of cerebellar plasticity that have been long hypothesized to mediate cerebellar-dependent learning.

Marr first proposed the existence of plasticity at the parallel fiber to Purkinje synapses whose induction is controlled by the climbing fiber input (Marr, 1969). Later, Masao Ito and colleagues demonstrated climbing fiber-controlled induction of long-term depression (LTD) at these synapses (Ito, Sakurai, & Tongroach, 1982; Ito, 1996). This plasticity and the related implication that the climbing fibers provide a "teaching" input to the cerebellum are at the core of theories of cerebellum function (Ito, 2001).

The strength of the granule cell to Purkinje cell synapse can be studied over the period of several hours in slice preparation (or more rarely, *in vivo*). Classic early studies showed that when a set of parallel fibers is stimulated repeatedly and in conjunction with the other major input to a Purkinje cell, the climbing fiber, the amplitude of the parallel fiber synapse is reduced. This depression is maintained for the duration of recording and thus is termed *parallel fiber long-term depression* (Fig. 31.6A). Somatic depolarization of the Purkinje cell can substitute for climbing fiber activity. Subsequent studies revealed more about the relative timing required between parallel fiber and climbing fiber activation to induce parallel fiber LTD: best induction of LTD requires parallel fiber activation 100–250 ms prior to the climbing fiber input. This agrees well with *in vivo* studies suggesting that climbing fiber inputs modify synapses onto Purkinje cells that were active 100–200 ms prior (Raymond & Lisberger, 1996). In contrast, repeated stimulation of the parallel fiber pathway by itself, in the absence of climbing fiber activity, leads to potentiation of the stimulated inputs (*long-term potentiation*) (Fig. 31.6B) (Coesmans, Weber, De Zeeuw, & Hansel, 2004). Mechanistic analyses reveal that paired parallel and climbing fiber input produces an mGluR-driven signaling cascade in Purkinje cells (Linden et al., 1991), leading to the removal of AMPA-type glutamate receptors from the parallel fiber synapse (Wang & Linden, 2000). However, the requirement of parallel fiber LTD for cerebellar motor learning is unclear. Using genetically modified mice in which the mechanisms responsible for the expression of LTD are specifically impaired, some authors have found impairments in motor learning while others see no changes (De Zeeuw et al., 1998; Schonewille et al., 2011).

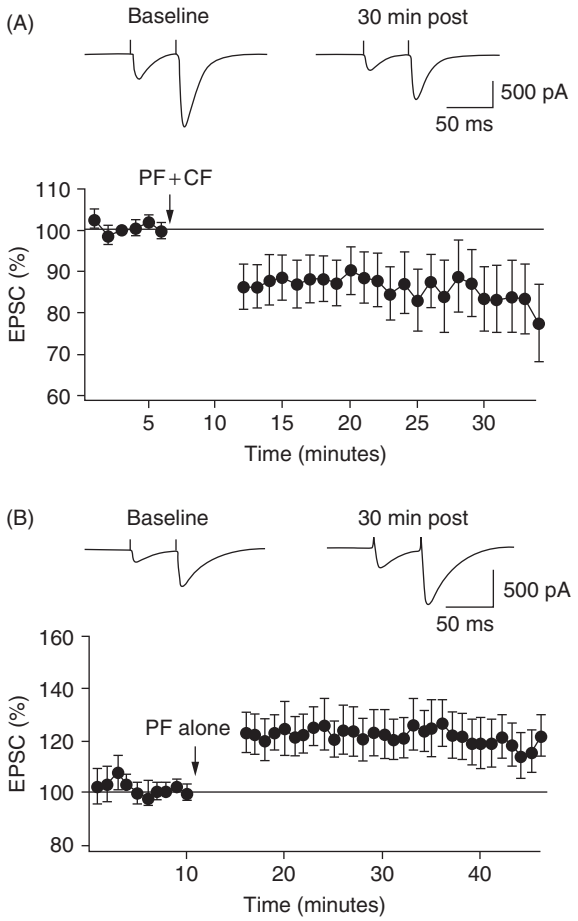

FIGURE 31.6 Whole-cell recordings from Purkinje cells showing the synaptic result of parallel fiber stimulation over time. (A) After a baseline period, parallel fiber stimulation is paired with conjunctive climbing fiber stimulation every 1 s for 5 min (arrow). Afterwards, the parallel fiber synaptic amplitude is depressed (LTD). (B) The parallel fiber is stimulated as in A, but in the absence of climbing fiber input potentiated (LTP). *Adapted from Coesmans et al. (2004).*

Synaptic and Intrinsic Forms of Plasticity in Vestibular and Cerebellar Nucleus Neurons

Miles and Lisberger proposed the hypothesis that cerebellar learning is mediated by plasticity downstream of Purkinje cells, at synapses onto cerebellar and vestibular nucleus neurons (Miles & Lisberger, 1981). They proposed that an "error signal" is calculated in the cerebellar cortex and the result of that calculation is conveyed by the Purkinje cells to their target neurons, where it serves as a teaching input to control the induction of plasticity. *In vivo* recording studies provided strong evidence for this hypothesis during adaptation of the VOR and during eyelid conditioning.

Recent work has found two major forms of plasticity in Purkinje cell target neurons. The first is changes in intrinsic excitability. Target neurons in the vestibular and cerebellar nuclei can modify their intrinsic input-output functions, so that a synaptic input of a given size that once elicited a modest response (as evaluated by postsynaptic spiking) now elicits a strong one, or vice versa (Shadmehr, Smith, & Krakauer, 2010; Zhang & Linden, 2003). This type of plasticity might be useful for generalized changes of behavioral gains—the magnitude of the response to a given stimulus.

The second type of plasticity is synaptic. The strength of synapses from excitatory mossy fibers onto their postsynaptic targets in the cerebellar or vestibular nuclei can be bidirectionally modified. The learning rules, inspired by ideas from Lisberger and Miles applied to eyelid conditioning (Mauk & Donegan, 1997), are distinctive. Long-term potentiation (LTP) and LTD of the mossy fiber to nuclear neuron synapse are controlled by Purkinje cell inhibition in conjunction with afferent synaptic stimulation. Afferent input combined with release from hyperpolarization is required to trigger an increase in synaptic strength, whereas afferent input without release from hyperpolarization triggers decreases in synaptic strength (McElvain, Bagnall, Sakatos, & du Lac, 2010; Pugh & Raman, 2009; Zhang & Linden, 2003). Increases and decreases in Purkinje cell firing rate are the most obvious potential sources of cerebellar nuclear hyperpolarization and release, respectively. Each of these forms of plasticity is a candidate substrate of cerebellar learning, and their relative roles are under active debate and investigation.

CEREBELLAR FUNCTION

The stereotyped circuitry and cellular mechanisms of signaling and plasticity within the cerebellar cortex and nuclei suggest a common role for diverse regions of the cerebellum. But what exactly is that role? Dysfunction of the cerebellum leads to a variety of clinical manifestations (see Box 31.3). As described in the following sections, the cerebellum is thought to adaptively modify downstream circuits, optimizing performance in the face of changes in the external and internal environments. To optimize circuit function and behaviors effectively, the cerebellum requires information from sensory, motor, and cortical systems. Each region of the cerebellum exerts its influence via cerebellar or vestibular nucleus neurons that themselves influence a variety of downstream circuits and behaviors.

Mossy Fibers and Climbing Fibers Convey Distinct Types of Information to Cerebellar Circuits

Precerebellar mossy fiber neurons distributed throughout the midbrain (red nucleus), pons, medulla, and spinal cord convey signals that inform the cerebellum about the

BOX 31.3

CLINICAL TESTING CAN REVEAL CEREBELLAR DAMAGE

In the early 1900s, Gordon Holmes carefully described the movement deficits associated with discrete cerebellar lesions caused by gunshot wounds (Holmes, 1939). Lesions caused by cerebellar infarct also provide information about the role of portions of the cerebellum, although interpretation of these data can be difficult because of the frequent spread of damage to extracerebellar regions. The common theme through these studies is that cerebellar damage does not impair sensory perception, but instead causes deficits in motor coordination and adaptation. These deficits are consistent with a role for the cerebellum in producing a *forward model* of movement, which predicts the expected sensory result of a movement and updates the forward model if errors occur (Shadmehr & Krakauer, 2008). Several types of cerebellar deficits are seen in human patients:

Ataxia is a condition that involves lack of coordination between movements of body parts. The term often is used in reference to gait or movement of a specific body part, as in "ataxic arm movements." Ataxia of posture, stance, and rhythm can derive from damage to vestibular and fastigial nuclei and vestibulocerebellum, while the intermediate and dentate nuclei and associated cortex appear more responsible for limb placement and multisegmental coordination. **Asynergia** is an inability of cerebellar patients to correct their movements for the interaction torques between multiple joints, leading to inaccurate reaching or stepping movements.

Dysmetria is an inability to make a movement of the appropriate distance. Hypometria is undershooting a target, and hypermetria is overshooting a target. Patients with cerebellar damage tend to make hypermetric movements when they move rapidly and hypometric movements when they move more slowly and wish to be accurate.

Dysdiadochokinesia is an inability to make rapidly alternating movements of a limb. It appears to reflect abnormal agonist-antagonist control. It is thought to be due to damage to the interpositus and/or dentate nuclei and resulting perturbation of muscle stretch reflexes.

Action tremor, or **intention tremor**, is an involuntary oscillation that occurs during limb movement and disappears when the limb is at rest. Cerebellar action tremor is generally of high amplitude and low frequency (3–5 Hz). **Titubation** is a tremor of the entire trunk during stance and gait. Lesions of cerebellar target structures (e.g., the red nucleus and the thalamus) often result in cerebellar outflow tremor, or postural tremor. Most prominent when a limb is actively held in a static posture, postural tremor attenuates during limb movement and disappears when the limb is at rest. Like dysdiadochokinesia, these tremors are also thought to be caused by deficient stretch reflexes.

Hypotonia is an abnormally decreased muscle tone. It is manifest as a decreased resistance to passive movement, so that a limb swings freely upon external perturbation. Hypotonia often is limited to the acute phase of cerebellar disease.

Nystagmus is an involuntary and rhythmic eye movement that usually consists of a slow and a fast phase. In a unilateral cerebellar lesion, the fast phase of nystagmus is toward the side of the lesion.

Patients with cerebellar damage are impaired both in normal motion and during motor adaptation. For example, a normal subject can adapt to wearing prism eyeglasses that shift the world to one side. After the prisms are removed, the subject shows a slow return to normal behavior, indicating that learning took place. In contrast, a cerebellar patient shows neither adaptation to the prisms, nor any sign of learning afterwards. Saccade learning is similarly impaired in cerebellar patients.

There is some promise for rehabilitation of cerebellar patients. Recent work suggests that these patients can learn to correct for small errors, either by using remaining functional circuits or through other brain circuits entirely. Cumulative learning of small adjustments can produce an overall large change in the resulting behavior, suggesting that compensation may be possible for certain types of deficit (Bastian, 2011).

Martha Bagnall and Tom Thach

sensory world, movements, and cortical plans for action (including, perhaps, cognitive plans that do not result in overt movements). Each type of mossy fiber neuron conveys a specific type of information to the cerebellum (Kolkman, McElvain, & du Lac, 2011). Neurons in the vestibular and external cuneate nucleus and in Clarke's column in the spinal cord transmit sensory signals to the cerebellum (vestibular, somatosensory, and proprioceptive). Sensory information about internal state and autonomic function are handled by neurons in the lateral reticular nucleus. "Efference copy" signals (which inform the brain about commands for movement sent to motor neurons) are conveyed to the cerebellum by neurons in the nucleus prepositus and pontine reticular formation. Neurons in the pons mediate the connections between the cerebral cortex and the cerebellum. Some mossy fiber neurons fire

high-frequency bursts of action potentials, while others fire tonically and modulate their firing rates in response to inputs, thus providing the cerebellum with continuous streams of information.

In contrast, neurons in the inferior olive fire rarely and convey discrete signals to the cerebellum. Each of several subdivisions of the inferior olive comprises neurons that encode unexpected signals, or errors, in a particular domain. For example, neurons in the caudal portion of the dorsal cap of the olive increase their firing rates (from 1 to 2 Hz) under only one condition: when images move horizontally across the retina. Neighboring neurons in the rostral dorsal cap fire when images move vertically. Some olivary neurons are activated in response to head motion and somatosensory, proprioceptive, nociceptive, or viscerosensory signals, while others appear to be activated when movements are planned or initiated by the superior colliculus or cerebral cortex.

Cerebellar and Vestibular Nuclei Influence Several Neural Circuits and Behaviors

Vestibular Nucleus

The vestibular nuclei comprise several subdivisions (see Chapter 29) and are important for several different behaviors. The vestibulo-ocular reflex (VOR) is the simplest and most extensively studied behavior under cerebellar control. The VOR enables clear vision during head movements by producing compensatory eye movements (see Chapter 32). A simple form of motor learning—adaptation—occurs whenever images move persistently during head movement. Adaptation can either increase or decrease the gain of reflexive eye movements. The flocular lobe of the cerebellum is required to induce adaptive changes in the VOR. Remarkably, although the VOR is mediated by as few as two muscles, Purkinje cells in the flocculus synapse onto at least five different cell types in the vestibular nucleus (Shin et al., 2011). The relative contribution of plasticity in the flocculus versus these vestibular nucleus neurons to motor learning in the VOR remains to be elucidated.

Cerebellar inputs to lateral vestibular nucleus are critical for coordinating and calibrating postural movements (see Chapter 29). Caudal vestibular nucleus neurons, which convey information about head tilt and gravity to autonomic brainstem regions (Holstein et al., 2011), are responsible for increasing blood pressure rapidly during the transition from lying down to standing up.

Fastigius (Medial Cerebellar Nucleus)

The fastigius controls all musculature involved in stance and gait. It receives input from the vermal cortex, vestibular complex, lateral reticular nucleus, and (indirectly) spinocerebellar pathways. Ablation of the fastigius dramatically impairs movements requiring control of equilibrium, such as unsupported sitting, stance, and gait. Single-unit recordings in the fastigius and vermal cortex of decerebrate cats, but not the interpositus or dentate, have shown neural discharge that is correlated with both walking and scratching movements. Rostral fastigial neurons are critical for the regulation of blood pressure and other autonomic functions. The caudal portion of the fastigius contains neurons that project to midline nuclei of the thalamus (Steriade, 1995), as well as neurons responsible for maintaining the accuracy of saccadic eye movements.

Interpositus (Intermediate Cerebellar Nucleus)

Inactivation of both the interpositus and the dentate with cooling probes elicits tremor that depends on proprioceptive feedback but is also influenced by vision. Inactivation of the interpositus causes a large-amplitude, 3- to 5-Hz action tremor as animals reach for food but has minimal effects on gait. Neurons in the interpositus fire when the holding position of a limb is perturbed. Their activity appears to control antagonist muscles that check the reflex movement of the limb to its position. Interpositus neurons also modulate their activity in relation to sensory feedback, including that from tremor accompanying movement, consistent with its role in controlling the antagonist muscles to dampen the tremor. Other evidence suggests that the interpositus is important in determining whether the pattern of activity in muscles acting at a joint represents reciprocal activation or co-contraction. During behaviors that involve co-contraction, interpositus neurons fire as if activating both agonist and antagonist muscles, and Purkinje cells are silent. In behaviors where agonists and antagonists are reciprocally active, both interpositus cells and Purkinje cells fire in similar patterns. One interpretation of these results is that alternating firing in Purkinje cells creates (through inhibition) a similar pattern of activity in the interpositus cells, which in turn produces the alternation between agonist and antagonist muscles. Other work suggests that the interpositus contributes to stretch reflex excitability by controlling the discharge of gamma motor neurons (Chapter 28). The interpositus also houses neurons required for classical conditioning of the eyelid response, as described below.

Dentate (Lateral Cerebellar Nucleus)

Neuronal activity in the dentate precedes the onset of movement and may also precede firing in the motor cortex. Dentate neurons fire preferentially at the onset of movements that are triggered by mental associations. Single-unit recordings in the motor cortex, dentate, and interpositus can be correlated with electromyograms as monkeys make wrist movements in response to stimuli. In tasks where movements are triggered by light, the order of activity is dentate, motor cortex, interpositus, and muscles. When a transient force perturbs the wrist, however, the firing order is muscles, interpositus, motor cortex,

and dentate. These results suggest that the dentate influences movements triggered by stimuli that are mentally associated with the movement, whereas the interpositus is more involved in compensatory or corrective movements initiated via feedback from the movement itself. In other studies, the dentate responded strongly when movements were triggered by either visual or auditory signals but not proprioceptive signals. Firing in both dentate and interpositus neurons is thought to relate more closely to movements involving multiple joints than to those involving single joints. Neither nucleus codes for any specific parameter (e.g., velocity, amplitude, or duration) during single-jointed movements. In sum, the dentate plays a role in initiating movements that require a mental interpretation of the visual or auditory signal, and both the dentate and the interpositus are increasingly active during multijointed movements.

Theories of Cerebellar Function

With the knowledge available about cerebellar anatomy, cellular and synaptic physiology, interconnectedness with the rest of the brain, and effects of cerebellar damage on behavior, research has been strongly influenced by a variety of computationally oriented ideas about cerebellar function. Pronounced deficits in muscle tone following cerebellar damage led to early ideas that the cerebellum could serve to reinforce tone. Other theories emphasized the importance of the cerebellum in motor coordination. The organization of parallel fibers and their relatively slow conduction times were incorporated into an influential model, proposed by Braitenberg and colleagues, which postulated that the cerebellar circuit produces precise timing. Behavioral experiments in patients with cerebellar damage have lent support to the notion that the cerebellum is critical for specifying motor timing (Spencer, Zelaznik, Diedrichsen, & Ivry, 2003). The 10-Hz tremor produced by damaging inferior olive neurons with the drug harmaline and observations that olivary neurons can emit 8- to 10-Hz bursts of firing led Llinas, Welsh, and others to suggest that the cerebellum provides clock-like timing signals to the rest of the brain.

The wealth of sensory and cortical information conveyed to the cerebellum, the indirect influence of cerebellar output nuclei on motor neurons, and the extensive interconnection to nonmotor regions of the cerebral cortex (Strick, Dum, & Fiez, 2009) suggest that the primary role of the cerebellum may not be motor *per se* but instead may be to evaluate sensory or cortical information in the context of ongoing movements or plans. The hypothesis that the cerebellum predicts the consequences of movements is supported by behavioral studies in patients with cerebellar damage (Bastian, 2011; Shadmehr, Smith, & Krakauer, 2010). Cerebellar involvement in certain aspects of cognitive and emotional processes is consistent with a prominent role for prediction in cerebellar function (Box 31.4).

BOX 31.4

COGNITION, EMOTION, AND THE CEREBELLUM

It no longer is viable to consider the function of the cerebellum as being confined to the control of voluntary movement, speech, and equilibrium. Considerable evidence suggests that the cerebellum is critical also for cognition and emotion. Anatomical studies demonstrate that the cerebellum is an important part of the distributed neural circuitry that subserves cognitive processing. The frontal, association, and paralimbic cerebral cortices known to subserve higher-order functions are linked with the cerebellum in a precisely organized system of feedforward and feedback loops, and physiological studies indicate that these pathways are functionally relevant (Strick et al., 2009). Cerebellar ablation and stimulation experiments in animals have demonstrated cerebellar influences on many nonmotor functions, including classical conditioning, navigational skills, cognitive flexibility, sham range, predatory attack, and aggression. Functional neuroimaging investigations of the morphologic correlates of cognitive processing using PET and fMRI in humans have revealed sites of activation in the cerebellum in a number of cognitive tasks. These include linguistic processing, verbal working memory, shifting attention, mental imagery, classical conditioning, motor learning, sensory processing, and modulation of emotion. Furthermore, there appears to be a topographic organization of the sites within the cerebellum activated by these different cognitive processes.

Clinical investigations of adults and children with diseases confined to the cerebellum have defined a cerebellar cognitive affective syndrome characterized by impairments of executive processing, working memory, visual spatial reasoning, language disturbances (ranging from mutism to agrammatism), and a flattened or inappropriate affect. The net effect of these deficits is a lowering of overall intellectual ability. The posterior lobe of the cerebellum appears particularly important in the generation of this syndrome, and the vermis is consistently involved when the affective component is pronounced. Elements of this clinical syndrome have also been noted in patients with developmental cerebellar

BOX 31.4 (*cont'd*)

anomalies, cerebellar degeneration, autism, and fragile X syndrome. In addition, cerebellar abnormalities, particularly in the vermis, have been observed in patients with schizophrenia.

The relationship between the cerebellum and nonmotor function has been conceptualized as follows.

1. The cerebellum is able to subserve cognitive and emotional functions because it is anatomically interconnected with the associative and paralimbic cortices.
2. The convergence of inputs from multiple regions of the cerebral cortex to adjacent areas within the cerebellum facilitates cerebellar regulation of supramodal functions.
3. The cerebellar contribution to cognitive and emotional processes is one of modulation rather than generation.
4. The cerebellum performs computations for cognitive functions similar to those for the sensorimotor system—but the nature of the information being modulated is different.
5. The disruption of the cerebellar influences on higher functions can lead to dysmetria of thought or impairment of mental agility.
6. The cerebellum may play an important role in the development of cognitive and emotional function.

The potential for further discovery in this field places the cerebellum, previously thought of as a motor control device, in the forefront of current behavioral neuroscience research.

Sascha du Lac and Jeremy D. Schmahmann

The most influential theory, which implicated the cerebellum in motor learning, was proposed more than four decades ago by Marr (1969). At that time, the basic cerebellar circuit had been recently identified; from it, Marr inferred the essential learning attributes of the cerebellum including plasticity at the granule cell to Purkinje cell synapses and the role of climbing fibers as a teaching input to control the induction of this plasticity. These ideas inspired Masao Ito's demonstration, in the context of the VOR, of climbing fiber controlled LTD (and much later the demonstration of the induction of LTP when granule to Purkinje synapses are active without a climbing fiber input; Fig. 31.6). An early link between circuit and behavior came from experiments showing changes in Purkinje cell simple and complex spikes during the course of motor learning (Fig. 31.7). The importance of learning in the cerebellum and how it may contribute to cerebellar computation and function remain actively investigated issues.

Computation as a Unifying Theme

What computations does the cerebellum perform on its inputs? Like all brain systems, the essence of what the cerebellum does is this: it receives inputs from other parts of the brain, acts on these inputs with rules determined by its connectivity and synaptic and cellular properties, and produces output to other brain systems. Given that the synaptic organization of the cerebellum is relatively uniform, it is likely that the same computational principles apply qualitatively for cerebellar regions involved in motor, autonomic, and cognitive functions.

Analyses of what (and how) the cerebellum computes have been facilitated greatly by the advantages provided by a limited number of experimental preparations amenable to quantitative behavioral analyses. These include adaptation of the vestibulo-ocular reflex, saccadic eye movements, and reaching, as well as motor learning in smooth pursuit eye movements. Insights from these behaviors have been complemented by the analysis of classical associative (Pavlovian) conditioning of eyelid responses.

Cerebellum and Eyelid Conditioning

The procedures of eyelid conditioning are relatively straightforward: an animal is presented with training trials that involve a relatively neutral stimulus such as a tone paired in time with a reinforcing "unconditioned stimulus" such as a puff of air or mild electrical stimulation near the eye; we will use "puff" for convenience. In an untrained subject the puff elicits a reflex eye blink response, but the tone elicits no response. After a sufficient number of training trials, the tone comes to elicit learned eyelid responses (Fig. 31.8A; sample eyelid sweeps). Remarkably, the timing of these learned eyelid responses precisely anticipates the timing of the puff onset: animals can be trained using a range of temporal intervals between tone and air puff onsets and are capable of learning responses appropriate for each interval: the learned responses peak just before the air puff occurs (Fig. 31.8B). This learning is bidirectional: presenting the tone without the air puff to an already trained animals results in extinction of the learned eyelid responses (Fig. 31.8C).

Support for the conclusion that eyelid conditioning is mediated by cerebellar learning comes from lesion studies and from experiments employing electrical stimulation and reversible pharmacological inactivation. Lesions of either the cerebellar cortex or the cerebellar nucleus

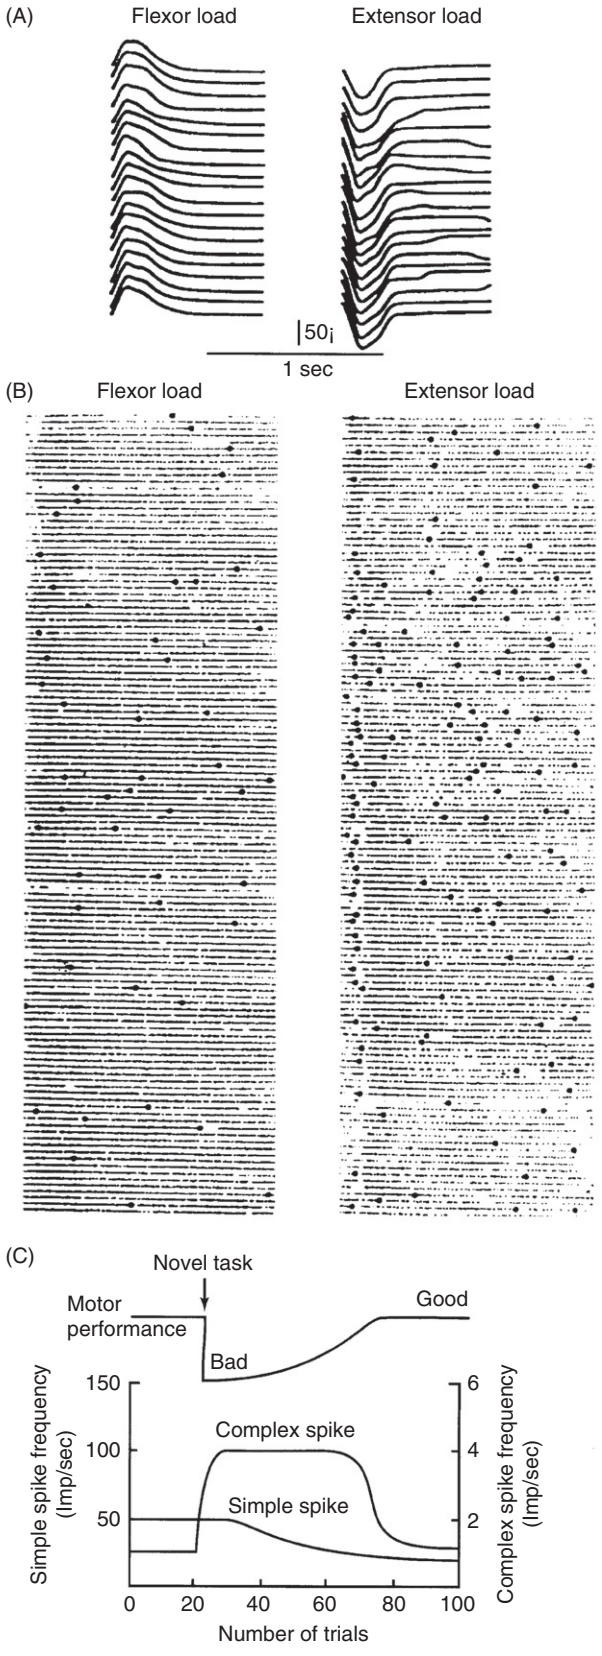

FIGURE 31.7 Simple and complex spikes recorded during motor learning task. *Adapted from Ito; original reference Gibert & Thach (1977).*

(anterior interpositus) prevent naive animals from acquiring learned eyelid responses (Garcia, Steele, & Mauk, 1999). Robust eyelid conditioning can be induced by direct electrical stimulation of mossy fibers, which can substitute for the tone, combined with stimulation of climbing fibers, which can substitute for the air puff. Reversible inactivation studies provide complementary evidence for a critical role of the cerebellum: pharmacological inactivation of the red nucleus (which receives inputs from the interpositus cerebellar nucleus) during training precludes expression of responses, but learned responses are present in the first trials after removal of the block. This indicates that the plasticity responsible for learning happens upstream of the red nucleus. Such studies demonstrate that eyelid conditioning is mediated by neuronal plasticity within the cerebellar cortex, the cerebellar nuclei, or both (Fig. 31.9).

Behavioral analyses suggest differential roles for the cerebellar cortex and nuclei in eyelid conditioning. Lesions to the cerebellar cortex disrupt the learned timing of the conditioned responses. In intact animals, learned responses peak at the time that the air puff was presented. In contrast, animals with cerebellar cortex lesions are unable to learn appropriately timed responses and instead respond at a short, fixed latency. Subsequent work using stimulation and reversible inactivation studies has shown that these short-latency responses are mediated by plasticity in the cerebellar nucleus. Together, these findings suggest (1) cerebellar learning is mediated by plasticity in both the cerebellar cortex and the cerebellar nuclei, (2) the cerebellar cortex is necessary for the learned and adaptive timing of the conditioned responses, and (3) consistent with the Miles and Lisberger theory, the cerebellar cortex provides the teaching signal for the induction of plasticity in the cerebellar nuclei.

Eyelid conditioning studies have revealed a role for the inhibitory feedback from cerebellar nuclei to the inferior olive (Medina, Nores, & Mauk, 2002). This portion of the cerebellar circuit has been particularly difficult to examine because olivary-projecting neurons are intermingled with other cerebellar nucleus neurons and because the olive itself is a tiny structure located deep in the brainstem. Pharmacological blockade of synaptic receptors implicates the inferior olive in memory storage. Learned eyelid responses are extinguished (a form of forgetting) if the tone conditioned stimulus is presented repeatedly by itself, without the air puff. Eventually, animals cease to emit appropriately timed eyelid responses to the tone. In previously trained animals, infusion of GABAergic synaptic blockers into the olive during tone-alone training completely prevents extinction. Conversely, infusion of excitatory synaptic antagonists causes extinction, even when the animals are being presented with the normal training stimulus of tone together with the air puff.

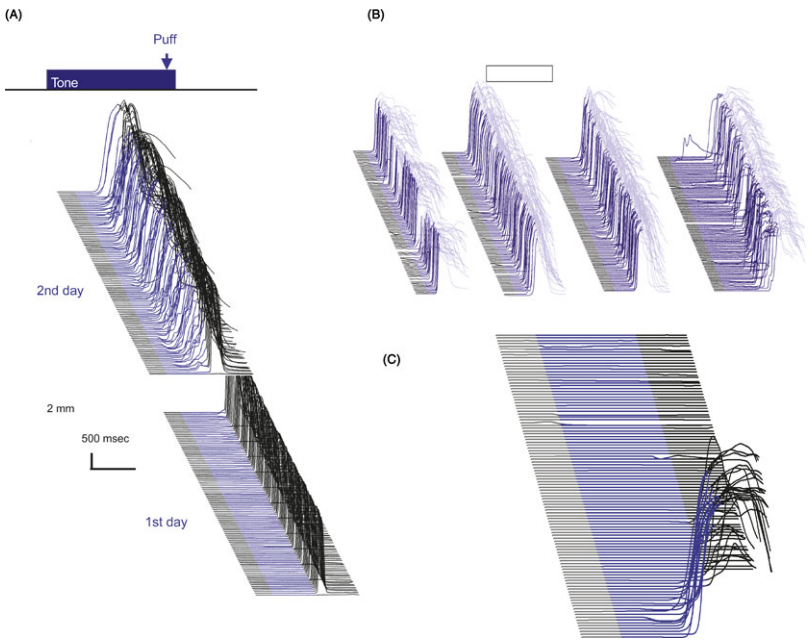

FIGURE 31.8 Eyelid conditioning. (A) Top, schematic of the training procedure. A tone is presented for a brief duration (usually ~500 ms), coterminating with a brief air puff to the eye. Bottom, traces of eyelid movement during training. Each line represents one trial; the period in blue is the tone presentation. On the first day of training, animals only blink in response to the air puff; by the second day, the eyelid begins to move before the end of the tone, eventually reaching peak movement that is well timed to block the air puff. (B) Animals can learn a range of tone durations, with appropriately timed blinks regardless of the interval between tone onset and air puff. (C) Extinction of prior learning. A well-trained animal blinks at the appropriate time even when the air puff is not presented, but after repeated trials with no air puff, the animal ceases to blink in response to the tone alone.

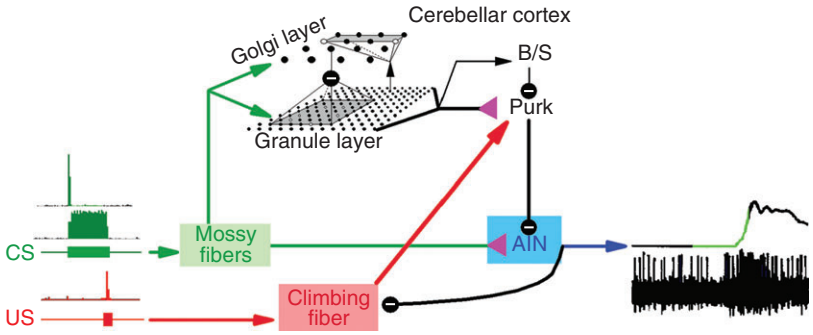

FIGURE 31.9 Circuit underlying eyelid conditioning. The conditioned (CS; tone) and unconditioned stimuli (US; air puff) activate mossy and climbing fibers, respectively. Some mossy fibers fire throughout the duration of the tone, while others fire only at the onset (green). Mossy fibers diverge to granule and Golgi cells in the granule layer, and to neurons in the anterior interpositus nucleus (AIN). The granule cells influence basket/stellate (B/S) and Purkinje cells, which in turn modulate AIN firing. Plasticity at the granule cell to Purkinje synapse, as well as the mossy fiber to nucleus synapse, appears to occur during learning. As a result, AIN neurons are thought to see a powerful barrage of Purkinje inhibition during the beginning of the tone. The relief of inhibition combined with mossy fiber excitation at the appropriate time triggers AIN firing, which (via the red nucleus; not shown) causes motor neuron firing to close the eyelid.

Feedforward Prediction Contributes to Cerebellar Coordination, Timing, and Learning

Analyses of eyelid conditioning and other behaviors suggest a common computational framework that ties together many of the functions proposed for the cerebellum. In all behaviors, sensory information can be used to coordinate, guide, and adjust movements. But most sensory systems are too slow to provide signals that can be used effectively to coordinate and control fast movements. The solution provided by the cerebellum is elegant: instead of using sensory signals to adjust ongoing movements, the cerebellum learns how to optimize subsequent movements. The computation performed by the cerebellum is thus a form of feedforward prediction.

In principle there are two ways to use sensory input to guide appropriate output: feedback and feedforward. Feedback is familiar and simple—for example, a thermostat. The measured temperature (sensory input) is compared to a target, and differences are translated into turning on the heater or cooler. Feedback systems of this sort can be accurate and reliable, but they cannot be fast. Attempts to make a feedback system fast result in

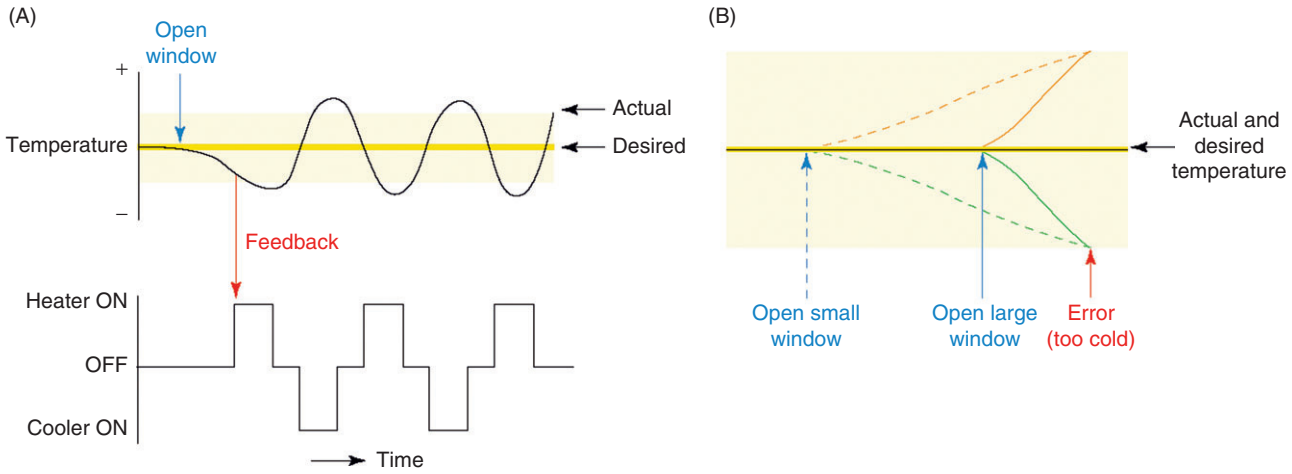

FIGURE 31.10 Feedback and feedforward control. (A) An example of a feedback-regulated thermostat. Though simple and accurate, feedback regulation tends to be slow, and attempts to speed it up cause oscillations. In this example, an attempted correction by a powerful heating system (in response to a decrease in temperature caused by opening a window) overshoots the mark, forcing another attempted adjustment by a powerful cooling system that also overshoots the mark, and so on. The upper and lower boundaries of the yellow area indicate the thresholds for detecting temperature change. (B) An example of a feedforward thermostat, which counteracts (orange lines) the changes in temperature predicted by the opening of windows (green lines). Though much quicker than feedback control, feedforward control is more complicated, requiring the ability to detect error-predicting stimuli (windows opening) and to delay anticipatory responses appropriately. Here, the opening of a large window (unbroken green line) predicts a faster decrease in temperature than does the opening of a small window (broken green line). The anticipatory response (increasing room temperature; broken or unbroken orange lines) must therefore be appropriately delayed in response to the predictive stimulus (opening a large or small window). This type of calibration requires associative learning that is temporally specific. *Modified from Ohyama et al. (2003).*

oscillations as, in the thermostat example, small deviations from the target produce alternating activations of the heater and cooler as each output causes overshoot of the target temperature (Fig. 31.10). Feedforward control can be faster because it involves anticipation of errors from previous experience. A hypothetical feedforward thermostat would be outfitted with a variety of sensory devices for temperature, humidity, number of people in the room, position of the sun, number of windows open, and so on. When a rapid change in room temperature is required, this hypothetical feedforward thermostat would predict, from previous experience, the burst of hot or cold air required to produce the rapid change.

If the thermostat's response yields the wrong outcome, then a feedforward thermostat should learn from this mistake so that subsequent predictions in similar circumstances are better. The properties required of this learning, as instantiated in the cerebellum, are fairly specific. Learning should produce changes in cerebellar signals that are timed to occur just before the error occurred (since that was the errant output). Cerebellar learning is thus expected to be associative: it should only modify the future output of the system for inputs that are similar to the ones that were present just before the error. In addition, learning should show temporal flexibility. The learned changes in output should not be time locked to the onset of any given mossy fiber input, but should be delayed after their onset so that the changed responses fix the errant prediction—namely, the one that occurred just before the arrival of the error signal. In other words, the error signal should correct the output that just occurred.

Eyelid conditioning studies reveal precisely these properties in cerebellar learning (Ohyama, Nores, Murphy, & Mauk, 2003). It is associative in that it takes mossy fiber inputs predicting climbing fiber inputs to occur. Moreover, the timing of the responses is precisely as described above. Pairing a mossy fiber input with a climbing fiber input produces a change in cerebellar output that is not time locked to the onset of the mossy fiber input but is instead timed to peak just before the input from the climbing fiber. This shows that cerebellar learning can develop predictions, through trial and error learning with climbing fiber error signals, that improve the prediction about the proper cerebellar output for a given mossy fiber input.

These considerations may tie together many key ideas about cerebellar function. Motor coordination is improved by feedforward predictions, which must be learned. This learning requires associative learning with quite specific temporal properties. It requires motor learning with timing. An important challenge for the future will be to determine how feedforward prediction contributes to the various motor, cognitive, and autonomic behaviors that engage the cerebellum.

Summary

Ideas about cerebellar function have been driven by analyzing the effects of lesions or dysfunction of the

cerebellum, by considering the nature of cerebellar inputs and outputs, and by examining the properties of cells and synapses within the cerebellar circuit. Analyses of cerebellar function that incorporate behavioral analyses, neuronal recordings, and computational perspectives are providing a framework for unifying a wide range of experimental results. The cerebellum appears to optimize downstream circuits by learning to predict the consequences of intended actions.

CHAPTER

32

Eye Movements

As we learned in Chapter 26, the photoreceptor mosaic of the vertebrate retina transduces light energy in the form of photons into neural activity, ultimately in the form of action potentials. The spatial resolution of this transduction system is limited by the mosaic of photoreceptors and the optics of the eye, but only if the eye is held stationary with respect to the objects of interest in the external world. Thus, stabilizing the eyes with regard to the outside world and aiming the eyes toward moving or stationary targets are critical challenges to effective vision. Evolutionary pressures have shaped the eye movement systems of animals to meet this challenge in ways that are tailored to the visual structures and behavioral needs of each species. In this chapter we examine the behavioral and neural systems used by vertebrates to control eye movements in the support of vision.

As we shall see, the control of eye movements provides a window into several fundamental aspects of neuroscience. Because the eyes are a relatively simple mechanical system, eye movements provide an excellent system for investigating the neural mechanisms of motor control, and also offer some of the clearest views of other complex processes, such as sensory-motor interactions, and the higher-order control of behavior.

EYE MOVEMENTS ARE USED TO STABILIZE GAZE OR TO REDIRECT GAZE

Similar to the handling of a camera, the images that fall on the retina depend on how the eyes are held and moved. The orientation of the eyes in the head and the orientation and position of the head in space together determine the gaze direction (i.e., gaze = eye + head) and, consequently, control the retinal image. These spatial arrangements underlie the two general classes of eye movements in vertebrates. One class is responsible for *stabilizing gaze*. When animals move with respect to their surroundings, they risk degrading their visual acuity, because moving the head necessarily moves the eyes, and can cause images to streak across the retina. Gaze stabilization mechanisms have evolved to solve this problem. They maintain visual acuity during self-motion by stabilizing the retinal image of the world with rotations of the eyes that exactly compensate for head and body movements. The neural mechanisms for gaze stabilization are highly conserved across vertebrates, reflecting the widespread need to stabilize visual inputs despite other sensory and motor differences between species. The second class is responsible for *redirecting gaze*. When animals visually inspect their surroundings, they may use these eye movements to aim the line of sight at objects or features of particular interest, even when those items move. In contrast to stabilizing gaze, the process of redirecting gaze involves selectively sampling the animal's visual environment, because tracking one visual object often causes the retinal images of other objects to become blurred. Accordingly, the mechanisms for redirecting gaze are found only in animals that have retinal specializations, such as the primate fovea, that can be used to examine a limited region of visual space at a higher spatial resolution.

Stabilizing Gaze

There are two types of mechanisms for stabilizing gaze (Fig. 32.1): the *vestibulo-ocular reflex* (VOR) and the *optokinetic response* (OKR). The VOR uses signals from the vestibular labyrinth to counterrotate the eyeballs to keep retinal images stable during head movements. The *rotational VOR* is driven by head-rotation signals from the semicircular canals and represents a phylogenetically old reflex present in all vertebrate species. The fast transduction properties of the vestibular

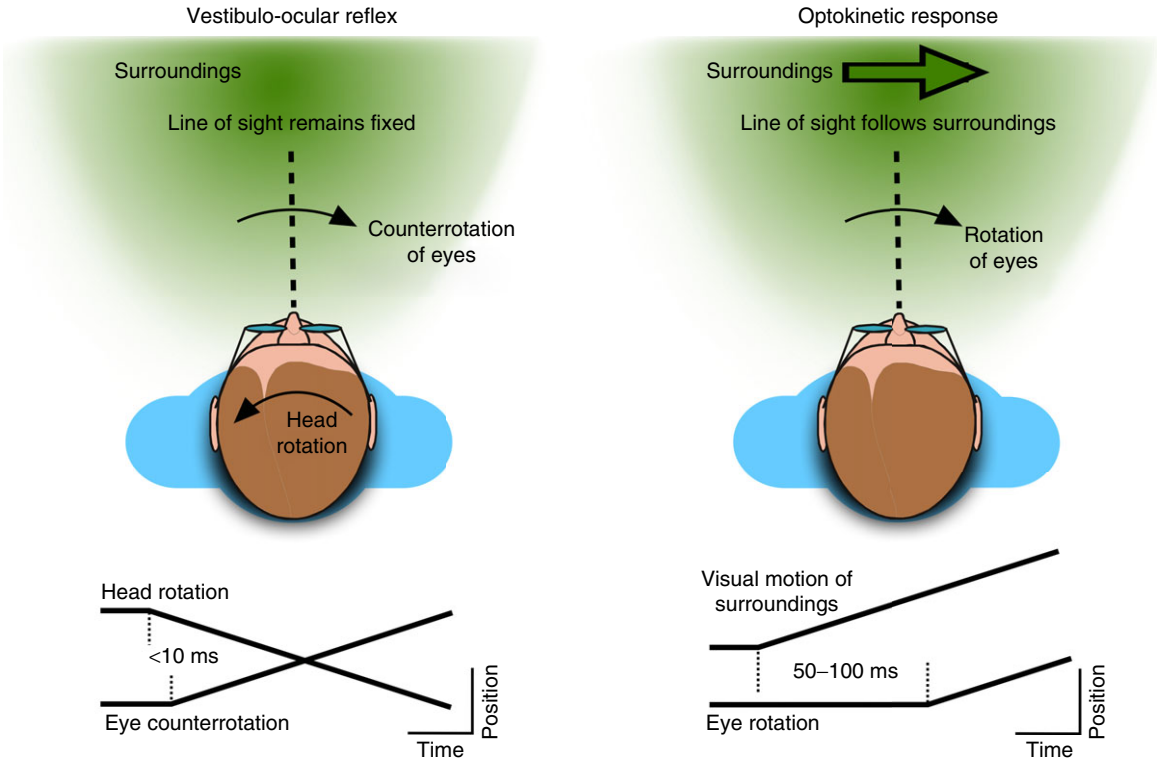

FIGURE 32.1 Eye movements that stabilize gaze. The vestibulo-ocular reflex keeps the line of sight fixed in the world by counterrotating the eyes during movements of the head. Here, the eyes rotate rightward at a short latency after the beginning of the leftward head movement. The optokinetic response stabilizes the line of sight with respect to the moving visual surround, but does so after a longer latency.

periphery, combined with a direct 3-neuron pathway, give the rotational VOR a very short latency (<10 ms). However, because the canals do not accurately transduce constant velocity head rotations, the output of the VOR decays over several seconds. Some vertebrates also possess a *translational VOR*, which is driven by head-movement signals from the otoliths. Unlike the image motion caused by head rotations, which is uniform across the visual field and can be fully compensated for by counterrotating the eyes, the image motion caused by translations are complex and can be only partly eliminated by eye movements. This explains why the translational VOR is found only in animals with central retinal specializations (e.g., foveal vision).

The *optokinetic response* (*OKR*) is driven by visual signals about the en masse movement of images across the retina. Because of the slow transduction of visual signals, the OKR has a longer latency (50–100 ms) than the VOR, but the use of visual motion signals makes it able to compensate for the constant motions and low speeds that the VOR cannot. The properties of the OKR therefore complement those of the VOR in maintaining stable gaze during movements, and the visual signals used by the OKR play a major role in guiding adaptive changes in the VOR. Animals with foveal vision also possess an *ocular following response* that is driven at very short latencies (~50 ms) by shifts in the retinal image, and that serves as the visual complement to the translational VOR (Miles, 1997).

Redirecting Gaze

Animals with foveal vision also possess several mechanisms for redirecting gaze (Fig. 32.2). *Saccadic* eye movements act to quickly move the image of a visual target from an eccentric retinal location to the center of the retina where it can be seen best. Saccades are very fast movements, reaching peak speeds greater than 500 deg/s and lasting only tens of milliseconds. Consequently, although saccades are often triggered by visual stimuli (at typical latencies of 150–250 ms), the trajectory of saccades is not guided by visual feedback, but instead follows a stereotyped profile that is largely determined by the size of the movement. Saccades do not require a visual stimulus, but can be guided by other modalities, and can even be directed toward the location of imagined or remembered targets.

Smooth pursuit eye movements slowly rotate the eyes to compensate for any motion of the visual target and thus act to minimize the blurring of the target's retinal image that would otherwise occur. Smooth pursuit is a relatively slow movement whose trajectory is determined by the moving stimulus. Pursuit is triggered by visual stimuli at latencies similar to, but somewhat shorter than, the latencies

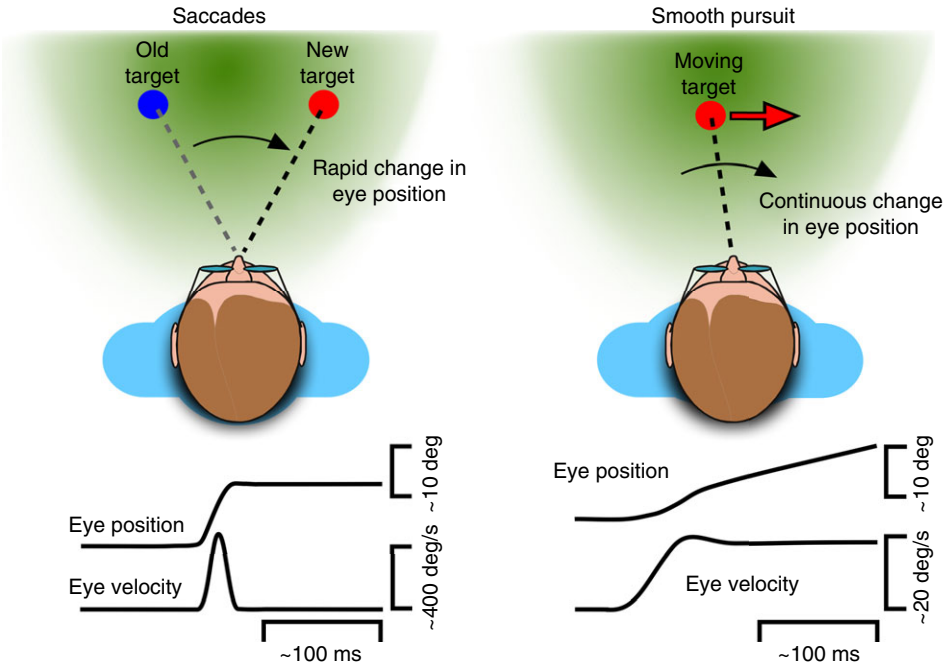

FIGURE 32.2 Eye movements that redirect gaze. Saccades change the line of sight to place the retinal image of visual targets onto the fovea. They are characterized by rapid changes in eye position (upward deflection in eye position trace) involving very high eye velocities (brief pulse in eye velocity trace). Smooth pursuit continuously changes the line of sight to minimize blurring of the target's retinal image. These movements are characterized by smooth and continuous changes in eye position (ramp in eye position trace) involving lower eye velocities (smooth step in eye velocity trace).

of saccades (typically 100–200 ms), and generates eye velocities up to ~50 deg/s, continuously adjusted by visual feedback about the target's retinal image. Unlike saccades, pursuit cannot be generated in the absence of a stimulus, although moving targets that are sensed through modalities other than vision can also guide pursuit.

Saccades and smooth pursuit produce conjugate, or yoked, movements of the two eyes. These are also referred to as *versional* eye movements. In contrast, a third type of mechanism for redirecting gaze, called *vergence* eye movements, produces disconjugate movements; the two eyes move in opposite directions or by different amounts. Vergence eye movements act to change the depth at which the eyes' lines of sight meet. When we look at a near object our eyes *converge* (rotate inward), and when we look at a far object, our eyes *diverge* (rotate outward). Before redirecting our gaze to an object at a different distance, the pair of images produced by that object will be spatially mismatched between the two eyes, causing binocular disparity. Also, because the curvatures of the two eyes' lenses are set to focus the currently viewed object, the image of the new object will also be blurred. These two signals, binocular disparity and blur, drive the combination of vergence eye movements and *accommodation* (which changes the dioptric power of the lenses by contracting or relaxing the ciliary muscle) that bring the new object into focus on the fovea of both eyes. Vergence and accommodation are tightly linked and are often referred to together as the *near response*. When evoked by themselves (e.g., by binocular disparity), vergence movements are very slow, taking up to 1 second to converge or diverge the eyes. However, when they occur in combination with faster versional eye movements such as saccades, vergence movements speed up, and interestingly, so does accommodation.

Fixation and Fixational Eye Movements

In between gaze movements, the eyes are actively held steady by a *fixation* mechanism. By preventing the eyes from redirecting gaze to another visual target, fixation makes it possible to visually inspect a particular object at length. Periods of fixation typically last about 200 ms but vary depending on what the animal is doing. Fixation does not necessarily act to keep the eyes from moving, but to hold the eyes steady with respect to the environment. For example, gaze stabilization mechanisms such as the VOR are active during periods of fixation.

Even during periods of steady fixation of a stationary object, the eyes are not completely still. The eyes typically make tiny movements during fixation in seemingly random directions that cause very slight changes in how images fall on the retinal mosaic but without displacing images from the fovea. *Microsaccades* are very small saccades with amplitudes typically less than 0.1 degree of visual angle, and are interspersed with *slow drifts* (speeds less than ¼ degree per second) of similar amplitude. The function of these movements remains unclear. However, like other larger saccades, they can prevent the adaptation of retinal signals that would occur with perfectly stabilized images, they are influenced by shifts of attention, and they can be strategically targeted or suppressed depending on the task.

BOX 32.1

EYE MOVEMENTS AND READING

During reading, saccadic eye movements bring successive snippets of text images to the center of the retina. The amplitude of the saccades depends on the letter size—a typical reader makes saccades that shift the line of sight by about 8 character spaces. In common situations—for example, viewing 12-point font at a distance of about 18 inches—each saccade is therefore only a couple of degrees in amplitude. The majority of saccades (~85%) form a forward path along the line of text (e.g., left to right for English readers), but a substantial minority of saccades (~15%), referred to as *regressions*, direct the line of sight back to text that has already been foveated.

The periods of fixation between saccades are crucial for reading comprehension, and typically last only about one-fifth of a second (~200 ms). Fixation provides the high-acuity input about individual letters—for example, telling the difference between "o" and "c"—that is necessary to correctly identify words. The number of letters that can be processed during each fixation (the *perceptual span*) is a key factor in determining reading proficiency. In skilled readers, the perceptual span stretches ahead of the currently fixated point, covering about 14 letters forward and only about 4 letters backward. Letters at the center of the perceptual span are processed for meaning and identifying words; letters at the edges of the perceptual span appear to be important for parsing the text and perhaps determining the landing points for upcoming saccades.

The skillful deployment of saccades and fixation for reading requires a great deal of practice, and represents an important developmental milestone for visual-motor control and cognition. In typical individuals, as text becomes harder to read, the amplitudes of saccades decrease, the number of regressions increase, and the duration of fixations increase. In reading disorders, such as dyslexia, these patterns are exaggerated, and accompanied by other unusual scan path features, such as targeting the beginning rather than the middle of words. This situation poses a chicken-or-the-egg problem: are reading disorders caused by a problem with controlling eye movements, or are eye movement problems caused by the reading disorder?

THE MECHANICS OF MOVING THE EYES

Each Eye Is Controlled by Three Pairs of Muscles

Moving the eye involves rotating the globe of the eye in the orbital socket of the skull. Because the eye undergoes minimal translation during movement, it can be viewed as a spherical joint with an orientation defined by three axes of rotation (horizontal, vertical, and torsional). Correspondingly, the orientation and movement of each eye is accomplished by three complementary pairs of extraocular muscles (Fig. 32.3). The lateral and medial rectus muscles form an antagonistic pair that controls the horizontal position of the eye. Contraction of the lateral rectus (and commensurate relaxation of the medial rectus) causes the eye to abduct, or rotate outward. Conversely, contraction of the medial rectus (and relaxation of the lateral rectus) causes the eye to adduct, or rotate inward. The actions of the other two pairs of muscles are more complex. When the eye is centered in the orbit, the primary effect of the superior and inferior recti is to elevate (rotate up) or depress (rotate down) the eye. However, when the eye is deviated horizontally in the orbit, these muscles also contribute to torsion, the rotation of the eye around the line of site that determines the orientation of images on the retina. The primary effect of the superior and inferior obliques is intortion (the top of the eye rotates toward the nose) or extortion (the top of the eye rotates away from the nose), but depending on the horizontal deviation of the eye, these muscles may also help determine the vertical orientation of the eye. Eye movements therefore involve redefining the 3-dimensional orientation of the eye by changing the balance of forces applied to the globe by all three pairs of extraocular muscles.

The mechanics of moving the eye may seem simple, but actually provide a computationally complex challenge for the brain. Because the eye is free to rotate in 3-dimensions, the final orientation of the eye depends on the order in which the rotations are carried out—for example, "turn-then-spin" gives a different outcome than "spin-then-turn." This property is referred to as *noncommutativity*. In fact, when the eye moves, the final 3-dimensional orientation of the eye and the axis of rotation used to get there are not arbitrary, but form an orderly set. *Donder's law* states that the orientation of the eye is always the same when the eye is aimed in a particular direction. *Listing's law* specifies these orientations by stating that the axes used to rotate the eye are confined to a single plane, referred to as Listing's plane. These orderly relationships are achieved, at least in part, by a mechanism that involves the muscles themselves (Klier, Meng, & Angelaki, 2011). The extraocular muscles consist of two distinct layers: *global* fibers, which attach directly to the globe of the eye, and *orbital* fibers,

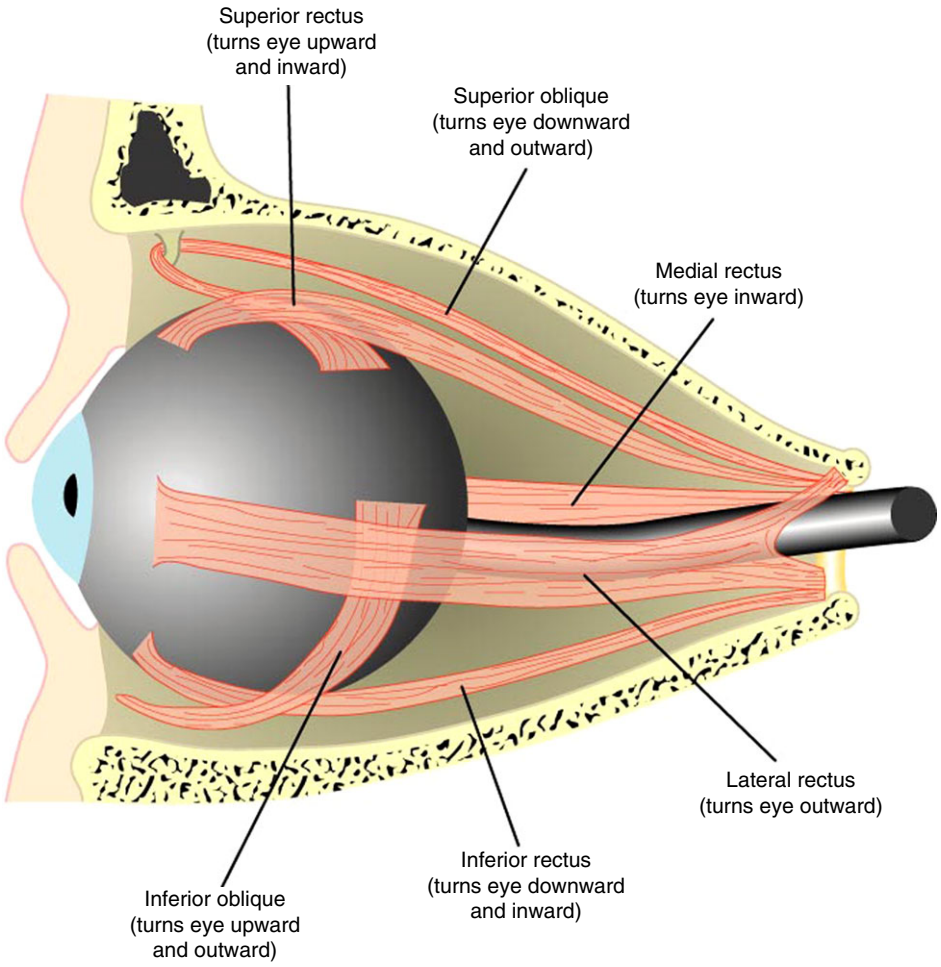

FIGURE 32.3 Muscles of the eye. Eye movements are controlled by six extraocular muscles arranged in three pairs, shown here in a cutaway view of the eye in its socket, or orbit.

which terminate in connective tissue that ensheathes the body of the muscle and acts like a moveable pulley for the global fibers. Because the pulleys themselves move when the muscle is contracted or relaxed, the pulling direction of the extraocular muscles changes with eye position. These gaze-dependent mechanical changes in muscle action largely account for Listing's law (Demer, 2006).

Interestingly, Listing's law is obeyed during saccades and smooth pursuit, but is violated during the VOR and the OKR. This difference presumably stems from the different inputs for these movements. Saccades and smooth pursuit may follow Listing's law because they involve local 2-dimensional retinal inputs that do not uniquely specify the orientation of the eye. In contrast, the VOR is driven by 3-dimensional inputs from the semicircular canals for which the extra degree of freedom is not redundant. Thus, the mechanics of the eye muscles impose kinematic constraints that are helpful during visually guided eye movements, but these constraints can be altered or lifted by neural control signals during gaze stabilization.

Central Control of the Extraocular Muscles

The six extraocular muscles are innervated by three of the bilaterally paired cranial nerves (Fig. 32.4). The oculomotor nerve (cranial nerve III) innervates the medial rectus, the superior and inferior rectus, and the inferior oblique on one side of the head. The cell bodies for these motor neurons thus lie in the third cranial nerve nucleus. The oculomotor nerve also contains the fibers that control accommodation of the lens. The trochlear nerve (cranial nerve IV) innervates the superior oblique muscle, and the abducens nerve (cranial nerve VI) innervates the lateral rectus. These three pairs of nuclei, distributed through the brain stem, contain all of the oculomotor motor neurons and are heavily interconnected by a pathway called the medial longitudinal fasciculus (mlf). This interconnection is crucial for the precise coordination of the extraocular muscles that is necessary for the control of eye movements.

The firing rates of the oculomotor motor neurons determine the forces applied by the extraocular muscles and, consequently, whether the eye moves or is held in place (Fuchs & Luschei, 1970). When the eye is stationary, the

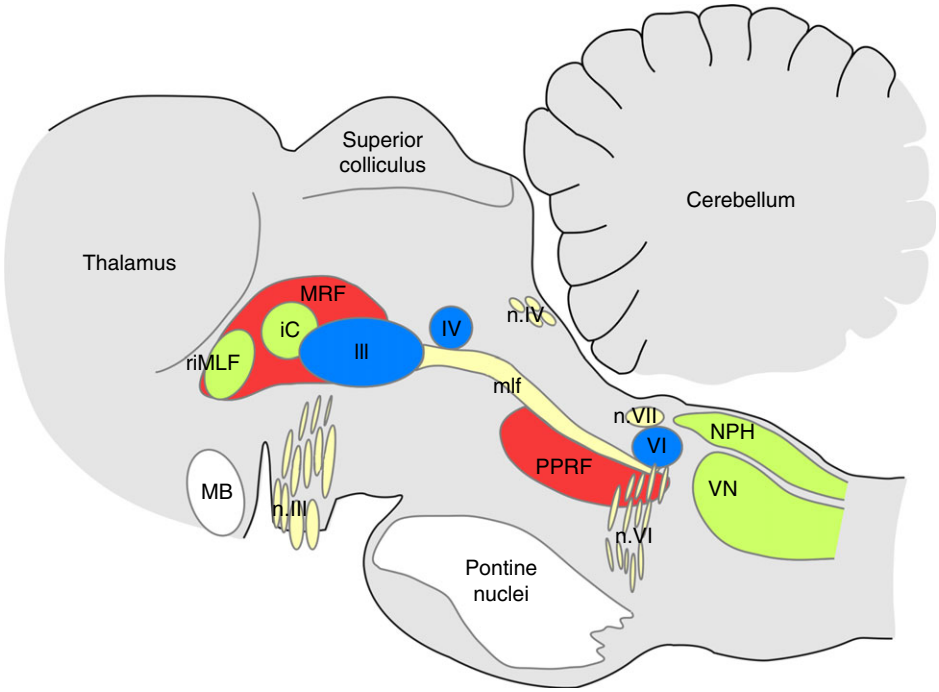

FIGURE 32.4 Oculomotor nuclei in the brainstem. Parasagittal section through the brainstem, cerebellum, and thalamus of a rhesus monkey, showing the location of the major brainstem nuclei involved in the control of eye movements. Motor neurons for the eye muscles are located in the oculomotor nucleus (III), trochlear nucleus (IV), and abducens nucleus (VI), and reach the extraocular muscles via the corresponding nerves (n. III, n. IV, n. VI). Premotor neurons for controlling eye movements are located in the paramedian pontine reticular formation (PPRF), the mesencephalic reticular formation (MRF), rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), the interstitial nucleus of Cajal (IC), the vestibular nuclei (VN), and the nucleus prepositus hypoglossi (NPH). The medial longitudinal fasciculus (mlf) is a major fiber tract containing the axons of these neurons. Other abbreviation: MB, mammillary body of the hypothalamus.

firing rate of oculomotor motor neurons is proportional to eye position, because under static conditions the balance of forces exerted on the globe determines the orientation of the eye (Fig. 32.5). Each motor neuron has a recruitment point (an eye position at which the motor neuron begins to fire) and a characteristic slope (the change in firing rate as the eye rotates in the pulling direction of the relevant muscle). Thus, as in the skeletal system, oculomotor motor neurons have a fixed recruitment order. When the eye moves in the pulling direction of the motor unit, oculomotor motor neurons exhibit a high-frequency pulse of activity that drives the high-velocity phase of the eye movement. The high-frequency pulse is followed by a sustained step-like increase in firing rate appropriate for the new static position of the eye. When the eye moves in the opposite direction, the motor neurons pause their firing during the movement and then resume their activity at a lower sustained level.

The neural commands from these motor neurons therefore take the form of a pulse-step during rapid eye movements such as saccades. The amplitude and duration of the pulse determine the speed and duration of the

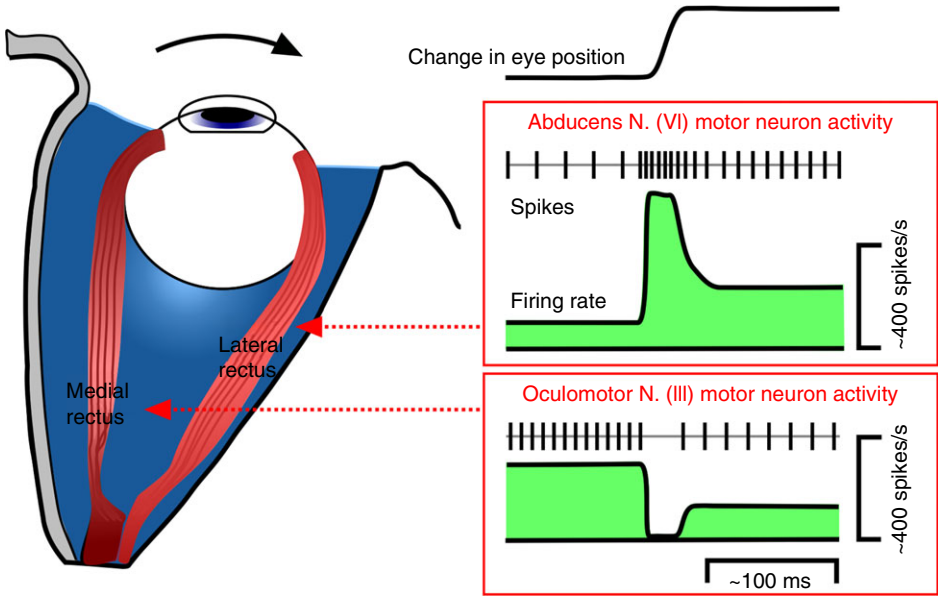

FIGURE 32.5 The firing rate patterns of eye movement motor neurons during horizontal eye movements. The rapid rightward change in eye position, indicated by the upward deflection in the eye position trace, involves contraction of the right lateral rectus and relaxation of the right medial rectus. This is accomplished by a pulse-step increase in activity of the agonist motor neurons in the abducens nucleus, and a pause-step decrease in activity of the antagonist motor neurons in the oculomotor nucleus.

movement, and the amplitude of the step determines the final static eye position. The need for the pulse derives from the sluggish dynamics of the eye and orbital tissues, which is dominated by the viscosity of the extraocular muscles. If the eye were moved by only a step change in force, it would take nearly a second for the eye to settle at its new orientation, which would obviously be incompatible with the goal of supporting vision. Similarly, during slow eye movements such as smooth pursuit, the neural commands from the motor neurons consist of a ramp-like change in activity to drive the smooth changes in eye position, plus an additional increment to overcome the sluggish dynamics of the eye. These patterns of activity are precisely adjusted by central mechanisms involving the brainstem and cerebellum, and illustrate a general problem in motor control—the need to convert desired actions into appropriately formed motor commands. The solution appears to involve the use of internal models that allow central mechanisms to take into account the dynamic properties of the body part or object to be moved.

Oculomotor motor units are also unusual in several ways (Buttner-Ennever, 2007). Unlike skeletal motor units, eye motor neurons participate equally in all types of eye movements, regardless of the speed involved. The extraocular muscles contain muscle spindles, but no Golgi tendon organs, and there are no ocular stretch reflexes. Instead, eye proprioception appears to mainly come from palisade endings on the eye muscle tendons. The function of this input is unclear, but it is distributed via the trigeminal nucleus to many key structures in the oculomotor system (including the vestibular nuclei, cerebellum, superior colliculus, and frontal eye fields) and may play a role in the long-term adaptive control of eye movements.

THE FUNDAMENTAL CIRCUITS FOR STABILIZING GAZE

The Vestibulo-Ocular Reflex (VOR) Stabilizes Gaze during Head Movements

The function of the VOR is to stabilize retinal images during head movements by using head-motion signals from the vestibular organs. A purely rotational VOR can be elicited in complete darkness by rotating the head roughly about its center (e.g., the interaural axis). Head rotations stimulate the semicircular canals of the inner ear (Chapter 29), which provide the sensory signals about head motion that drive this highly conserved mechanism for counterrotating the eyes. During sustained rotations of the head, the eyes cannot continue to counterrotate endlessly in the orbit, but are intermittently and rapidly reset to a central position during the ongoing compensatory eye rotation. The profile of eye position over time during the VOR therefore exhibits a characteristic sawtooth pattern consisting of the slow-phase counterrotations and quick-phase resetting eye movements. This pattern is called *nystagmus*, and is described by the direction of the quick phases (Fig. 32.6 is an example of right-beat nystagmus).

The speed of the slow phases during nystagmus indicates how effectively the VOR is compensating for the head rotation. The degree of compensation is often characterized by the VOR gain, which is defined as the ratio of slow-phase eye speed over the speed of head rotation. Perfect compensation occurs when the eye rotates in the opposite direction at exactly the same speed as the head rotation, which corresponds to a gain of 1. The ability of the VOR to compensate for head motion is limited by the dynamics of the signals from the semicircular canals, which act as "high-pass" sensors of head velocity. Thus, the VOR is very effective (its gain is near 1) for fast back-and-forth head rotations that take a second or less to complete (i.e., frequencies over 1 Hz), but it is much less effective for slow head rotations that continue over many seconds (e.g., 0.1 Hz). Under natural conditions, this limitation of the VOR does not pose a problem for vision, because at these lower speeds visual signals can be used to stabilize gaze very effectively through the optokinetic response.

The fundamental neural mechanism for the VOR consists of brainstem circuits linking the vestibular afferents to the extraocular muscles, including a direct 3-neuron arc pathway (Fig. 32.6). For example, during a rightward head rotation vestibular afferents from the horizontal semicircular canal on the right side increase their firing rates, and this increase is passed on to neurons in the vestibular nucleus (VN) on the same side. These vestibular nucleus neurons, in turn, increase the activity of motor neurons and interneurons in the abducens nucleus (VI) on the opposite (left) side. Motor neurons in the abducens innervate the lateral rectus of the left eye, completing the 3-neuron arc. Interneurons in the abducens provide a crossed projection back to the right oculomotor nucleus, where motor neurons innervate the medial rectus of the right eye. By contracting both the left lateral rectus and the right medial rectus, the two eyes rotate leftward together in response to the rightward head rotation. In addition, because the vestibular afferents on the left side decrease their activity during a rightward rotation, a complementary circuit causes relaxation of the right lateral rectus and the left medial rectus. The VOR is therefore controlled in a push-pull fashion that yokes the movements of the two eyes through the bilateral symmetry of these basic circuits.

These direct pathways are key components of the VOR mechanism, but the VOR also requires indirect pathways to function correctly. As discussed in the previous section, the firing rate of oculomotor motor neurons is primarily related to eye position, but the afferent signals from

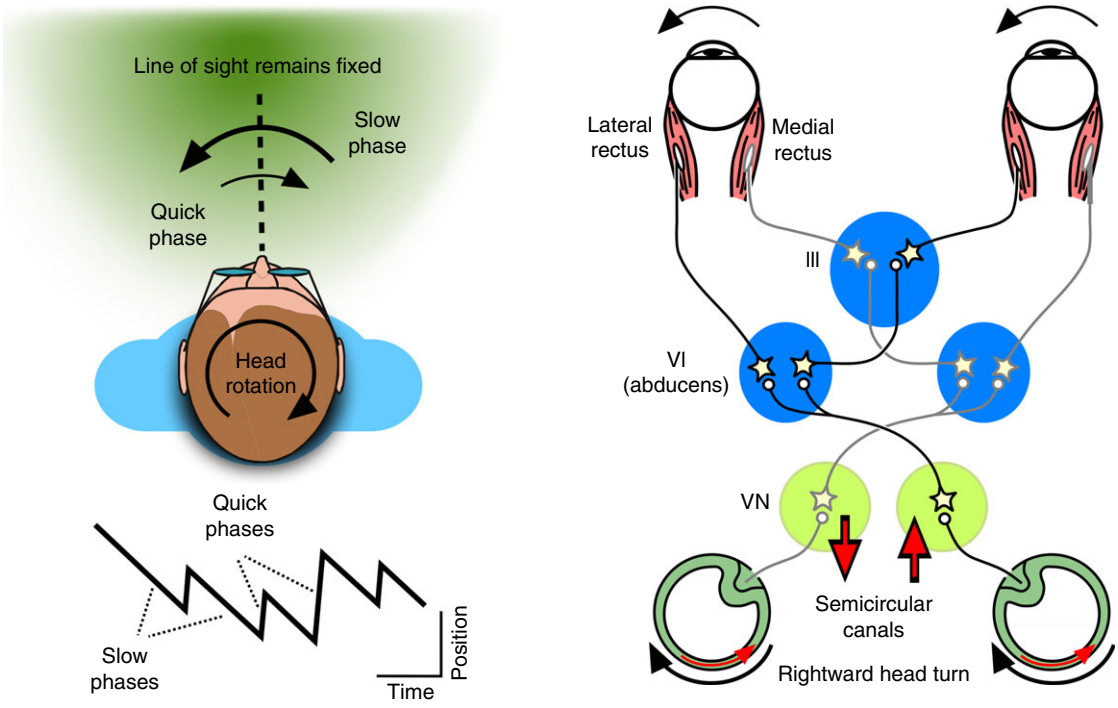

FIGURE 32.6 The eye movements and neural circuits for the VOR. During a sustained rotation of the head (here, rightward), the eyes rotate slowly to the left (downward deflections in eye position trace labeled "slow phases"), and then abruptly shift rightward to reset the eyes toward a central position (upward deflections in eye position trace labeled "quick phases"). This is an example of right-beat nystagmus. The diagram of the basic VOR circuit shows the push-pull organization of the horizontal VOR. When the head rotates rightward, activity increases in the right semicircular canal, right vestibular nucleus (VN), and left abducens nucleus (VI). This leads to increased activation of the left eye lateral rectus and, through a crossed projection to the oculomotor nucleus (III), increased activation of the right eye medial rectus. The complementary set of pathways (colored in gray) show decreases in activity.

the semicircular canals are primarily related to the head velocity. In order to construct the motor commands needed to hold, as well as move, the eyes during the VOR, the brain needs to transform the dynamic signals provided by the vestibular afferents into the combination of dynamic and static commands found on motor neurons. Similar to the operation of mathematical integration in calculus, this process involves the temporal integration of velocity inputs into position signals.

The *neural integrator* for eye movements is accomplished by neurons in the vestibular nuclei and two other brainstem nuclei—the nucleus prepositus hypoglossi (for horizontal components) and the interstitial nucleus of Cajal (for vertical)—and is fine-tuned by connections between these brainstem nuclei and the vestibulocerebellum (Cannon & Robinson, 1987). The output from the neural integrator pathway sums with the signals from the direct pathway to provide the motor neurons with the complete set of velocity and position commands needed to accomplish the VOR. Importantly, all conjugate eye movements also use this same indirect integrator pathway. Thus, although the source of the velocity signals for the VOR, OKR, saccades, and pursuit are quite different, they appear to share a common brainstem mechanism for transforming these signals into the final motor commands.

The Optokinetic Response (OKR) Uses Visual Inputs to Stabilize Gaze

The OKR also functions to stabilize retinal images during head movements, but uses visual inputs to infer the direction and speed of head motion rather than responding directly to head-velocity signals. The optimal stimulus for the OKR is full-field motion of the visual environment that, like head rotations, causes a saw-tooth pattern of eye movements referred to as *optokinetic nystagmus*. Like the VOR, the slow phase movements during nystagmus compensate for the head rotation that presumably caused the full-field motion. However, because the OKR is driven by visual signals, which are processed much more slowly than vestibular signals, the range of motions that are effectively compensated by the OKR is quite different from the VOR. The OKR is very effective (its gain is near 1) for slow rotations that continue over many seconds, but it is much less effective for very fast back-and-forth rotations. These properties of the OKR therefore complement those of the VOR and together, the two types of mechanisms can effectively stabilize gaze over a much wider range of speeds and behavioral conditions than either could achieve alone.

The interlocking nature of the two systems is also evident in the neural pathways for the OKR, despite the

difference in their input signals. In vertebrate species without foveal vision, such as the rabbit, the visual processing for the OKR is accomplished entirely within the brainstem. Direction-selective retinal ganglion cells project directly to a set of visual nuclei in the midbrain called the pretectum and accessory optic nuclei. In species with foveal vision, the visual properties of these nuclei are determined not only by inputs from the retina, but are also shaped by inputs from visual areas of the cerebral cortex. Neurons in the accessory optic nuclei have very large receptive fields and respond selectively to global visual motion that would result from rotating the head about a particular spatial axis. Remarkably, the selectivity of individual neurons is restricted to one of the three axes of rotation that are also detected by the semicircular canals. This common rotational coordinate system makes it easier to combine visual *reafferent* signals about head motion from the accessory optic nuclei with the vestibular *afferent* signals provided by the labyrinths. Accordingly, neurons in the pretectum and accessory optic nuclei project to the vestibular nuclei and nucleus prepositus hypoglossi, where these visual signals join the same final pathways used by the VOR. These nuclei also project to the vestibulocerebellum, where the visual signals contribute to the velocity commands for the OKR and other smooth eye movements, and also act as feedback signals that play a critical role in the long-term adjustment of the VOR.

THE COMMANDS FOR REDIRECTING GAZE ARE FORMED IN THE BRAINSTEM

The commands for redirecting gaze use the same final motor pathways that are used for stabilizing gaze, but the signals and mechanisms giving rise to the movement commands are quite different. For smooth pursuit, they are based on motion signals about the visual target that are first extracted in specialized areas of the cerebral cortex and then used to commandeer the brainstem and cerebellar pathways for the OKR. For saccades, which are not guided by visual feedback, a specialized circuit in the brainstem reticular formation produces the stereotyped velocity command that determines the trajectory of the saccade.

The Motor Commands for Saccades Are Constructed in the Brainstem Reticular Formation

The control signals for saccades descending from higher centers specify the location of the target, which is then transformed by circuits in the brainstem reticular formation into the motor commands for saccades (Fig. 32.7). The horizontal and vertical components of saccades are formed by separate but interconnected circuits—the horizontal commands are formed in the paramedian pontine reticular formation (PPRF), and the vertical commands are formed in a part of the mesencephalic reticular formation called the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF).

Within these brainstem circuits, often referred to as the *saccadic burst generator*, several different classes of neurons work together to construct the saccade motor command (Keller, 1974). *Burst neurons* fire a high-frequency volley of action potentials that begins ~10 ms before the onset of the saccade and ends slightly before the saccade lands on the target. The firing rate during the burst is related to the instantaneous velocity of the saccade, and the number of spikes in the burst is related to the amplitude of the saccade. There are several types of burst neurons. Excitatory burst neurons (EBN), sometimes called "medium-lead burst neurons," provide the velocity signal for the eye muscles that will contract during the saccade, and specify the "pulse" portion of the saccade motor command. The EBNs provide a copy of this velocity signal to the brainstem nuclei of the neural integrator, which then generates the "step" portion of the motor command, just like they do for other eye movements. EBNs also contact inhibitory burst neurons (IBN), which provide a crossed projection that inhibits motor neurons for the antagonist eye muscles that will relax during the saccade. Finally, long-lead burst neurons (LLBN) show changes in their activity well in advance of the saccade, presumably reflecting inputs received from higher centers, and provide an excitatory input to the EBNs.

The other major class of neurons in the saccadic burst generator is the *omnipause neurons* (OPN). These neurons fire at a constant high rate (~100 spikes/s) during fixation, but completely pause their activity just before and during saccades in all directions. Because the OPNs directly inhibit burst neurons, their tonic activity prevents unwanted saccades during fixation, and the pause in their activity unleashes the synchronized bursts of action potentials that initiate and drive the saccade. The onset of the pause in OPN activity appears to be triggered by inhibitory signals originating from higher brain centers, but the duration of the pause does not determine when the saccade ends. Instead, stopping saccades involves another inhibitory influence on burst neurons. One likely candidate is the oculomotor cerebellum (lobules VI and VII of the vermis and the caudal fastigial nucleus). The oculomotor vermis is interconnected with the saccadic burst generator and plays a crucial role in adjusting the metrics of saccades so that the eyes land accurately on the target at the end of the gaze movement.

The Motor Commands for Pursuit Are Formed in the Brainstem and Cerebellum

The control signals for pursuit descending from higher centers continuously specify the motion of the target to be followed with the eyes. Thus, in contrast to saccades,

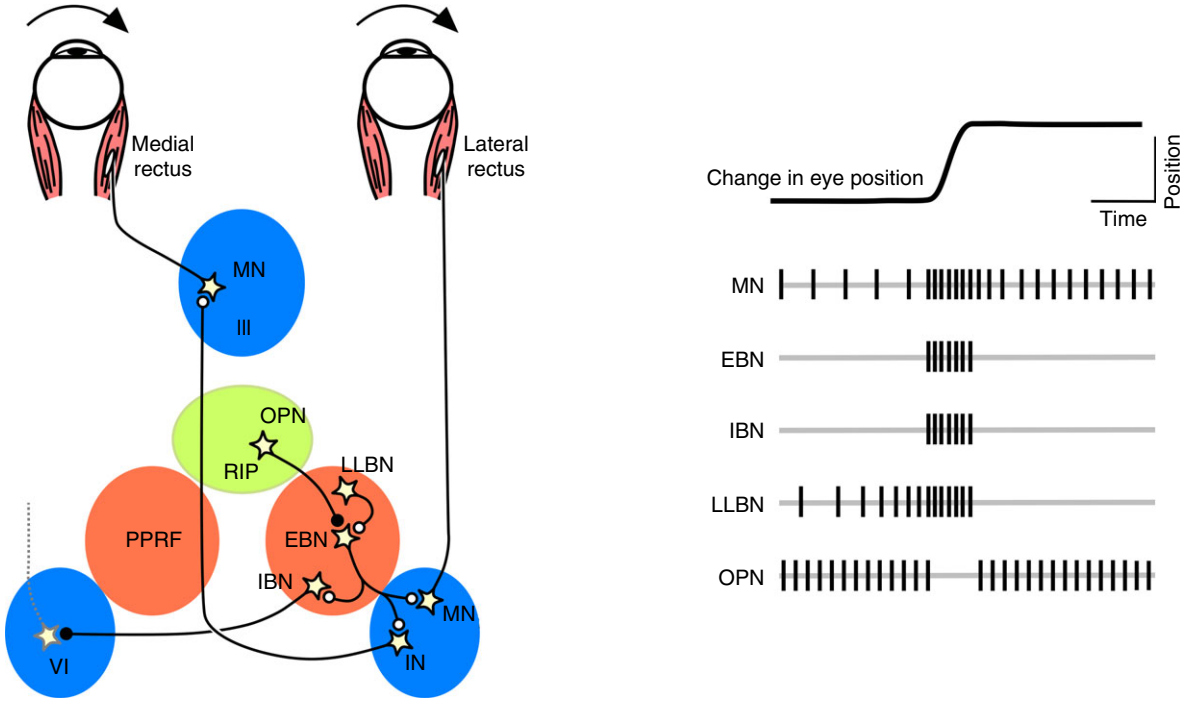

FIGURE 32.7 The brainstem circuits for controlling saccadic eye movements. This diagram of the saccade burst generator outlines the major classes of neurons involved in constructing the motor command for horizontal saccades. Omnipause neurons (OPN) located near the midline in the nucleus raphe interpositus (RIP) tonically inhibit excitatory burst neurons (EBN) located in the paramedian pontine reticular formation (PPRF). When OPNs pause, the EBNs emit a burst of spikes, which activate motor neurons (MN) in the abducens nucleus (VI) innervating the lateral rectus muscle. The burst also activates interneurons (IN) which, in turn, activate motor neurons on the oculomotor nucleus (III) on the opposite side, innervating the medial rectus. Inhibitory burst neurons (IBN) show a pattern of activity similar to EBNs, but provide inhibitory inputs to decrease activation in the complementary circuits and antagonist muscles. Long-lead burst neurons (LLBN) show activity long before movement onset and provide an excitatory input to EBNs.

pursuit does not require motor circuitry to construct the velocity command from scratch. Instead, the pursuit pathways in the brainstem and cerebellum sculpt the descending control signals to form an appropriately shaped velocity command, and provide a copy of this velocity signal to the neural integrator to generate the position component of the motor command.

The velocity commands for pursuit arise in areas of the cerebral cortex and reach the final motor circuits through several routes (Fig. 32.8). One pair of pathways involves projections from the cerebral cortex to the cerebellum via a large set of relay neurons on the floor of the brainstem called the basal pontine nuclei. Areas in extrastriate visual cortex provide signals related to visual motion through the dorsolateral pontine nuclei to a portion of the vestibulocerebellum called the ventral paraflocculus. The frontal cortex provides signals related to target and eye velocity through the dorsomedial pontine nuclei, and the adjacent nucleus reticularis tegmenti pontis, to the oculomotor cerebellum (vermis), the same portion of the cerebellum involved in adjusting the metrics of saccades. Both of these cerebellar regions provide inputs to parts of the brainstem motor pathways that we have already discussed. The output of the ventral paraflocculus is closely related to eye velocity and terminates in the vestibular nuclei, where it contributes to the velocity command for pursuit, and also provides an input to the neural integrator. The output of the oculomotor vermis is less well defined but appears to be related to eye acceleration as well as eye velocity. The outputs of the vermis and the associated deep cerebellar nucleus (the caudal fastigial nucleus) are sent to neurons in the brainstem reticular formation, and may play a role in shaping the velocity command appropriately when the target motion changes.

Another route for conveying motion signals for pursuit involves the pretectum. As described above, the pretectum plays a key role in the OKR, but in primates the pretectum receives inputs from areas of the cerebral cortex that are important for pursuit. Accordingly, some neurons in the primate pretectum have smaller receptive fields and respond well to the small moving stimuli typically used to elicit pursuit. The pretectum provides an input to the cerebellum through the basal pontine nuclei, but also projects directly to the vestibular nuclei and nucleus prepositus hypoglossi, offering a relatively direct route to the final motor pathways.

The brainstem control of pursuit also appears to involve some of the same neurons that are part of the saccadic

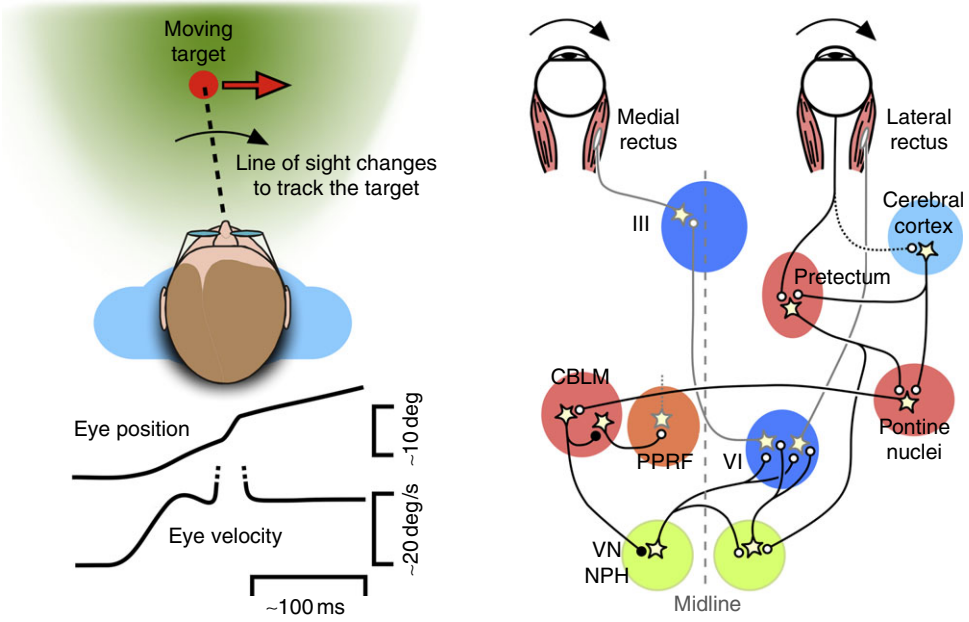

FIGURE 32.8 The brainstem and cerebellar circuits for controlling pursuit eye movements. During pursuit, the line of sight changes smoothly to follow the motion of the target. The smooth changes in eye velocity are often accompanied by small "corrective" saccades, indicated by the upward deflection in the eye velocity trace (dotted lines). The diagram outlines the circuits involved in constructing the motor command for horizontal pursuit. The major pathways involve projections from areas of the cerebral cortex via the pontine nuclei to the cerebellum (CBLM), which then modulates activity in nuclei associated with the VOR—namely, the vestibular nuclei (VN) and nucleus prepositus hypoglossi (NPH)—and also modulates activity in nuclei associated with saccades, such as the paramedian pontine reticular formation (PPRF). A second pathway involves projections from the pretectum to the pontine nuclei, as well as a direct projection to the vestibular nuclei and prepositus hypoglossi.

burst generator. The EBNs and IBNs are not involved in forming the pursuit motor command, but some of the long-lead burst neurons in the brainstem reticular formation increase their tonic firing during pursuit, and show a buildup of activity before the onset of pursuit and saccades. Even more surprisingly, OPNs—the "gatekeepers" for saccades—are also modulated during pursuit. They do not completely pause their activity as they do during saccades, but decrease their activity by about one-third. Moreover, electrical stimulation applied to the OPNs slows down pursuit eye movements, in addition to stopping saccades (Missal & Keller, 2002). The function of this overlap between saccades and pursuit in these premotor circuits is not yet fully understood, but one possibility is that descending information about the target does not directly trigger saccades and pursuit, but instead a motor decision process at the level of the brainstem and cerebellum determines which type or combination of movements is most appropriate under the particular circumstances.

GAZE MOVEMENTS ARE CONTROLLED BY THE MIDBRAIN AND FOREBRAIN

The motor commands for gaze movements formed in the brainstem depend on control signals descending from higher centers, in particular, from the superior colliculus (SC) and several eye-movement related areas of the cerebral cortex (Fig. 32.9). These brain regions make it possible to bring the well-honed motor circuits in the brainstem under the control of higher-order processes such as attention, perception, and cognition.

The Superior Colliculus Contains a Retinotopic Map for Controlling Gaze

The superior colliculus (SC) is a multilayered structure lying on the roof of the midbrain. In nonmammals, the homologous structure is called the optic tectum, which serves as the primary center for processing retinal inputs and for transforming sensory inputs into commands for orienting movements. In mammals, the SC has a similar functional role, and consists of superficial layers that receive direct inputs from the retina and striate cortex, and intermediate and deep layers that receive inputs from extrastriate, parietal and frontal cortex, and the basal ganglia. Neurons in the superficial layers have responses to visual stimuli that are enhanced when the stimulus is the target of a saccade. Neurons in the intermediate and deep layers may also respond to visual stimuli, and also to auditory stimuli from corresponding locations, so that the visual and auditory maps of the animal's surroundings are in register. It is these intermediate and deep layers that also possess the movement-related activity that plays

BOX 32.2

EYE MOVEMENT DISORDERS

Disorders of eye movements arise from damage to widespread regions of the brain, and the symptoms reflect the contributions of the affected structures to eye motor control.

One common disorder of eye motor control is *strabismus*, which occurs when the movements of the two eyes are not properly yoked. This disorder typically occurs in children or infants (about 2% of children are affected), but can also affect adults. Strabismus is caused by deficits in any of the several factors that are necessary to properly align the eyes, including problems with eye muscles or oculomotor nerves, the presence of a large refractive error in one or both eyes, and lesions in central structures. If strabismus occurs during infancy, while connections in the visual system are developing, it can result in *amblyopia*, in which case visual inputs from the affected eye are mostly ignored.

Many eye movement disorders are caused by tumors, stroke, or other damage to the pathways responsible for forming the eye motor commands. Patients with damage to structures in the brainstem or cerebellum often have difficulty maintaining fixation, and exhibit *nystagmus*—a pattern of involuntary drifts in eye position, interspersed with centering saccades. Nystagmus can be caused by peripheral damage to the vestibular labyrinth or the eighth cranial nerve that transmits signals about head motion to the central nervous system. The imbalance in signals received from the left and right vestibular organs causes a slow drift of the eyes, away from the damaged side. If the nystagmus is caused by peripheral damage, then voluntary saccades and smooth pursuit are mostly unaffected. However, nystagmus can also be caused by central damage to brainstem or cerebellar structures. In these cases, voluntary saccades and smooth pursuit are also impaired, because the functions of the neural integrator and final motor pathways are affected.

Because gaze movements are controlled by descending signals from the cerebral cortex and basal ganglia, eye movement disorders also occur in diseases that affect higher-order brain functions, including schizophrenia, Huntington's disease, and Parkinson's disease. These disorders are characterized by problems with voluntary eye movements, most notably a difficulty in suppressing unwanted saccades during fixation or smooth pursuit eye movements. In Huntington's disease, in addition to difficulty with suppressing unwanted saccades during fixation, patients also have difficulty initiating voluntary saccades. This problem can be partly overcome by blinking at the same time, because the circuits for controlling eye blinks and saccades overlap. In schizophrenia, smooth pursuit eye movements do not correctly match the speed of the moving target, and are interrupted by back-and-forth saccades that repeatedly take the eyes off the target. For reasons that are not yet understood, these deficits in smooth pursuit ability also occur in relatives of schizophrenics who are themselves asymptomatic for the disease.

a crucial role in the control of gaze movements (Wurtz & Goldberg, 1972). These movement-related layers provide a major descending projection to the oculomotor nuclei in the brainstem reticular formation, and also a major ascending projection to the frontal cortex through the medial dorsal nucleus of the thalamus.

The most distinctive feature of the superior colliculus is that it contains a retinotopic map of contralateral visual space and this topography applies to the movement-related activity in the deeper layers as well as to the visual activity in the superficial layers (Fig. 32.10). The significance of this retinotopic map becomes evident when neural activity is artificially manipulated by passing small amounts of electrical current through the tip of an electrode placed in the intermediate layers (Robinson, 1972). Such stimulation elicits a saccadic eye movement with an amplitude and direction that depends on the placement of the electrode in the map. If the stimulation is applied as a long train, rather than as a brief pulse, a series of saccades is elicited, forming a "staircase" of eye movements, each with the same characteristic amplitude and direction. Thus, activity in the superior colliculus map is related to changes in eye position and not to absolute eye position, consistent with the organization of the superior colliculus in retinotopic (or oculocentric) coordinates.

During naturally occurring eye movements, activity in the superior colliculus is not restricted to just the few neurons that best match the endpoint of the saccade, but is distributed across a large number of neurons across the retinotopic map. This point was elegantly demonstrated by testing what happens to saccades when the injection of chemical agents into the superior colliculus temporarily inactivates neurons at a particular location in the map (Lee, Rohrer, & Sparks, 1988). Remarkably, it is still possible to make saccades directed to the center of the inactivated region, because the broad distribution of activity across the map leaves a halo of neurons that can still accurately guide the saccade. Moreover, saccades directed to locations slightly beyond the inactivated site become hypermetric (bigger than normal), because the inactivation removes the contribution from neurons that code for more proximal locations and smaller saccades. These

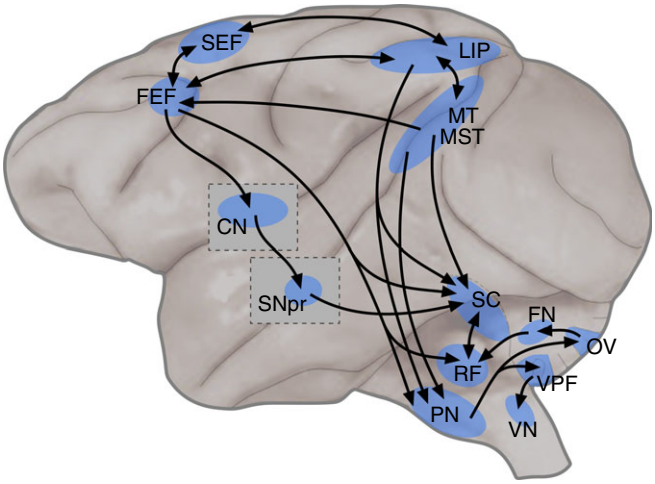

FIGURE 32.9 The descending pathways for controlling gaze movements, depicted schematically on a lateral view of the monkey brain. The superior colliculus (SC), located on the roof of the midbrain, is a major source of descending control signals. In the cerebral cortex, the major areas involved are the frontal eye fields (FEF), supplementary eye fields (SEF), lateral intraparietal area (LIP), middle temporal area (MT), and medial superior temporal area (MST). In the basal ganglia, a cascade through the caudate nucleus (CN) and substantia nigra pars reticulata (SNpr) provides inhibitory control over activity in the superior colliculus. These descending control signals are then converted into motor commands by circuits involving regions such as the reticular formation (RF), pontine nuclei (PN), vestibular nuclei (VN), and parts of the cerebellum such as the ventral paraflocculus (VPF), oculomotor vermis (OV), and fastigial nucleus (FN).

results show that saccades are guided by the vector average of population activity in the superior colliculus, and were the first demonstration of vector averaging in a mammalian motor system.

The intermediate layers of the superior colliculus contain two main classes of neurons related to the control of gaze (Munoz & Wurtz, 1995). Burst neurons in the superior colliculus fire a volley of action potentials that begins ~20 ms before the onset of saccades, somewhat earlier than the burst neurons located downstream in the reticular formation, and often also have a visual response to the onset of visual targets. Unlike the burst neurons in the reticular formation, those in the superior colliculus fire for saccades directed to a portion of the visual field referred to as the neuron's movement field, and the size of the burst depends on where the target falls with respect to the neuron's movement field. Buildup neurons also have visual responses and saccade-related activity, but they are distinguished by the presence of sustained activity when the subject is required to delay their eye movement response after the presentation of a visual stimulus. This sustained activity typically increases over time as the time of the saccade draws near, and is believed to be important for the preparation of saccades, perhaps by facilitating the occurrence of the saccade-related burst. Recent results show that the activity of neurons in these layers of the superior colliculus is not only involved in motor preparation, but is also involved in the antecedent

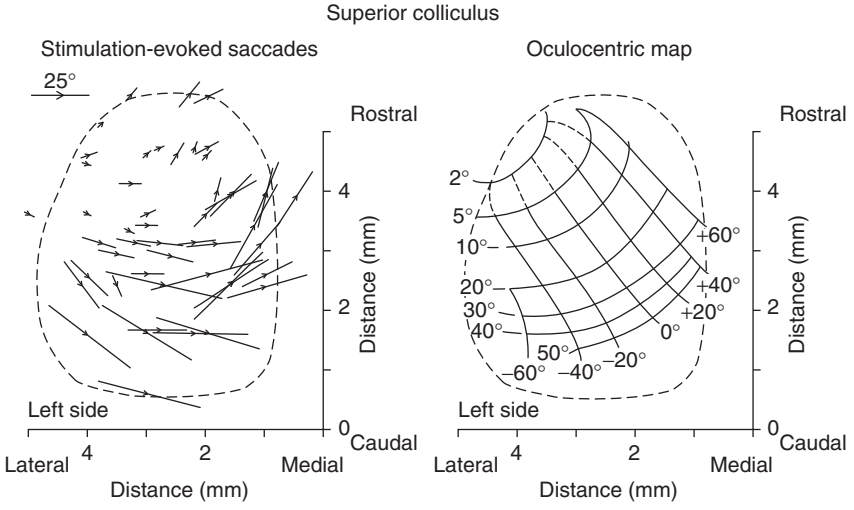

FIGURE 32.10 The superior colliculus and its retinotopic (or oculocentric) map of saccades and target positions. The left plot shows that electrical stimulation in the superior colliculus causes eye movements whose direction and amplitude depend on the location. Each arrow corresponds to a stimulation site in the left superior colliculus, and the length and direction of the arrow indicate the metrics of the evoked saccade. The evoked saccades are all directed rightward, but rostral sites are associated with smaller movements than caudal sites, and medial sites are associated with upward movements whereas lateral sites are associated with downward movements. The right plot summarizes these results in the form of a continuous map of saccades and target positions. As in the visual cortex, the representation of the center of the visual field is amplified. *Adapted from Robinson (1972).*

step of selecting the visual target, and is part of the neural circuits that control visual attention.

The retinotopic map in the superior colliculus includes the central visual field. Like the rest of the map, this part also contains neurons that fire during saccades, although the preferred saccades are smaller, as would be expected from the topography, and even include microsaccades (Hafed, Goffart, & Krauzlis, 2009). However, these same neurons can also show tonic activity during fixation and changes in firing rate for pursuit eye movements. These neurons therefore appear to represent the foveal region of a single "priority" map extending across the superior colliculus that supports multiple eye motor outputs.

The Frontal Eye Field Is the Primary Cortical Area for Controlling Gaze Movements

The frontal eye field (FEF) exerts its control on gaze movements through several descending pathways, including a direct projection to the intermediate layers of the superior colliculus, an indirect projection to the superior colliculus via the basal ganglia, and also projections to the cerebellum and the brainstem reticular formation. The FEF is best known for its role in the generation of saccades, but it also contains zones that are involved in the control of pursuit and vergence eye movements. Like the superior colliculus, electrical stimulation of the FEF causes saccades to a particular location in the contrateral visual hemifield, although the topography in the FEF is less orderly than in the superior colliculus. Electrical stimulation of the pursuit zone of the FEF causes smooth eye movements towards the ipsilateral side, and is the only cortical area where stimulation can directly evoke smooth eye movements. Damage to the FEF produces deficits in saccades, and the impairments are most noticeable when the target stimulus is accompanied by irrelevant distracter stimuli. For pursuit, disruption of the FEF reduces pursuit eye velocity and, in particular, affects the ability of pursuit to follow targets using prediction. The impairments after FEF damage are usually temporary, but combined damage to the FEF and SC results in a permanent deficit in the ability to generate voluntary gaze movements (Schiller, True, & Conway, 1980).

The FEF contains neurons with different combinations of motor and visual activity. Movement-related neurons have movement fields like those found in the superior colliculus; they are active for saccades within a particular range of directions and amplitudes. Movement-related neurons project to the superior colliculus and show changes in activity that are related with when and if voluntary gaze movements will be initiated. In particular, the variability in the timing of saccade initiation is closely correlated with when the firing rates of these neurons reach a fairly constant "threshold" value (Hanes & Schall, 1996). In the pursuit zone of the FEF, neurons exhibit directionally selective responses to moving visual stimuli that are appropriate for determining the velocity command for pursuit eye movements.

Most neurons in the FEF also have visual responses, including a large class of visuo-movement neurons that show activity for both visual stimuli and the eye movements that follow. These visually responsive neurons often show activity related to the selection of the target. Prior to the gaze movement, the activity evoked by the nonselected stimulus is rapidly suppressed, whereas the activity for the selected stimulus remains conspicuous. Some FEF neurons discriminate visual targets even in the complete absence of an eye movement response, indicating that their activity is related to the allocation of visual attention rather than to the preparation of eye movements.

Another region of frontal cortex, the supplementary eye field (SEF), plays a less direct role in the control of saccades but is important for movements that are guided by cognitive factors. Neurons in the SEF are preferentially modulated in tasks that involve more abstract instructions, such as when saccades are directed to a particular side of an object rather than to a spatial location, or when saccades are directed to the location opposite the visual stimulus (the "anti-saccade" task). During pursuit eye movements, SEF neurons are especially active when the target moves along a predictable trajectory.

The Parietal Cortex Contributes to Eye Movements by Controlling Visual Attention

The lateral intraparietal area (LIP) plays a major role in the process of visual selection that precedes the generation of gaze movements. Reversible inactivation of neurons in area LIP does not cause large deficits in the timing or accuracy of gaze movements, but it dramatically reduces the frequency of movements toward the affected portions of the visual field, especially when competing stimuli are present elsewhere (Wardak, Olivier, & Duhamel, 2002). These deficits suggest a visual neglect of stimuli in the affected region, rather than a motor deficit in the generation of eye movements. Damage to the parietal cortex in humans, especially to the right hemisphere, also produces a neglect syndrome with similar deficits in attention.

Neurons in LIP show activity related to visual attention and to the intention to redirect gaze to particular locations in visual space. When an attention-grabbing, but irrelevant, distracter stimulus appears while the animal is preparing a saccade directed elsewhere, the activity of LIP neurons closely tracks the short-lived shift of attention to the distracter and its subsequent return to the intended location of the saccade. Activity in LIP is therefore often described as a salience map that helps to determine the location of spatial attention, as well as the endpoint of gaze movements (Bisley & Goldberg, 2010).

Motion-Processing Areas of Cortex Provide Crucial Signals for Pursuit Eye Movements

The middle temporal area (MT) and the medial superior temporal area (MST) are the primary sources of visual motion information that are used to construct the motor commands for pursuit. This motion information is also used to adjust the size of saccades made to moving visual targets. These cortical areas provide these inputs through several pathways, including projections to other cortical areas involved in controlling gaze movements (in particular, the FEF), descending projections to the vestibulocerebellum via the basal pontine nuclei, and projections to the pretectum, which contains neurons with activity related to the OKR and pursuit.

Neurons in MT and MST have activity related to the velocity of visual stimuli. In MT, neurons have smaller receptive fields and activity that depends on the presence of a visual stimulus. Lesions in MT produce blind spots for seeing motion that affect the motor commands for pursuit and saccades, and the perception of motion as well. In MST, neurons have larger receptive fields and prefer more complex patterns of visual motion. Lesions in MST also produce blind spots for motion, but in addition, cause a directional deficit in pursuit for movements directed to the ipsilateral side (Dürsteler & Wurtz, 1988). Stimulation of MT and MST can affect pursuit eye movements, but only if pursuit is already ongoing, unlike the effects of stimulation in the FEF. Thus, MT and MST are crucial sources of the motion signals needed to drive pursuit eye movements, but other areas appear necessary to determine when and if the movement should be started.

The Basal Ganglia Regulate Saccades by Inhibiting the Superior Colliculus

The caudate nucleus (CN) and the substantia nigra pars reticulata (SNpr) are parts of the basal ganglia that form an important circuit for controlling when gaze movements are initiated. The SNpr applies tonic inhibition to the superior colliculus using GABA-ergic synapses, suppressing the response to the many excitatory inputs to the superior colliculus that might otherwise evoke gaze movements. When SNpr neurons reduce or pause their activity, there is a disinhibition of activity in the superior colliculus, which then permits gaze movements to be initiated. The SNpr itself is under inhibitory control from the CN, which contains neurons that increase their activity with gaze movements. Together, this series of inhibitory connections through the basal ganglia acts to gate the generation of gaze movements by the superior colliculus.

The basal ganglia appear to be especially important for gaze movements involving reward and motivation (Hikosaka, Nakamura, & Nakahara, 2006). For example, the visual responses of CN neurons are larger for stimuli that are associated with larger rewards. This modulation in excitability may be caused by dopaminergic inputs from neurons in the substantia nigra pars compacta (SNpc), the same neurons whose degeneration is implicated in Parkinson's disease.

The Thalamus Provides Feedback about the Control of Gaze Movements

In addition to these descending pathways, there are also ascending pathways to eye movement-related areas of cortex from nuclei in the central thalamus. These nuclei receive inputs from a wide range of oculomotor structures, including the superior colliculus, substantia nigra pars reticulata, cerebellum, the nucleus prepositus hypoglossi, and the brainstem reticular formation. Feedback through the thalamus appears to convey *corollary discharge* signals about the gaze movements that are executed by downstream motor structures, and is used to update the control signals formed in the cortex. Thus, when the central thalamus is inactivated by chemical agents, single saccades can still be made accurately, even in the dark, but subsequent saccades are spatially inaccurate, as though the intervening movement had not been taken into account (Sommer & Wurtz, 2002).

THE CONTROL OF GAZE MOVEMENTS INVOLVES HIGHER-ORDER PROCESSES

Saccades and Pursuit Are Coordinated during Redirecting of Gaze

The functions of saccades and pursuit are distinct, and yet during normal gaze movements the two types of movements are tightly coordinated and almost always select the same visual target. For example, when subjects are presented with two moving stimuli simultaneously, they almost always begin smooth pursuit in a direction that is a weighted average of the two motions. After a brief period of this "vector average" pursuit, subjects make a saccade toward one stimulus or the other and then pursue that one selectively. However, pursuit can selectively follow one stimulus in the presence of distracters without a targeting saccade, showing that saccades are not strictly necessary for pursuit target selection. Pursuit and saccades also exhibit nearly the same tradeoff between speed and accuracy, with saccades tending to be delayed and somewhat more accurate. This suggests that target selection for the two movements is guided by the same decision signals, but saccades use a somewhat more stringent decision criterion (Krauzlis, 2004).

Voluntary Gaze Movements Are Tightly Linked to Shifts of Visual Attention

A crucial aspect of voluntary gaze movements is that they are selectively guided by objects of interest to the

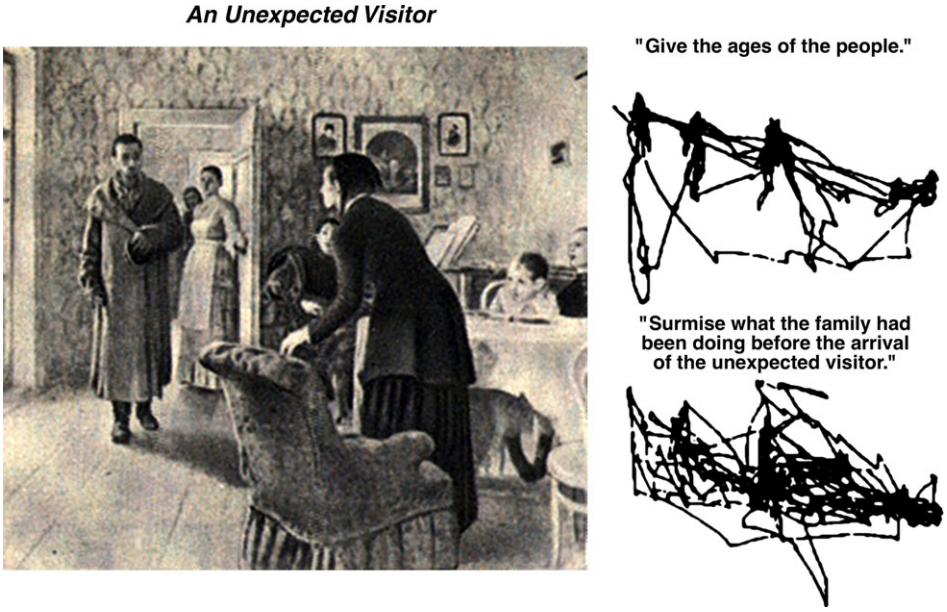
observer, despite the fact that our surroundings usually contain many other distracting signals. This selectivity is achieved by a tight functional link between the control of gaze movements and the mechanisms of visual attention. When gaze is redirected, the movement of the eyes is always preceded by a shift of visual attention to the new location. For example, when subjects are asked to detect visual targets that appear just before a saccade is made, performance is much better when the target and saccade locations coincide than when they do not (Deubel & Schneider, 1996). Similarly during pursuit, subjects make more accurate perceptual judgments about the stimulus they are smoothly tracking with their eyes than about other, nontracked stimuli in the visual display. However, judgments about nontracked stimuli are still better than chance, showing that the selection of targets for gaze movements can occur in parallel with the perceptual processing of other visual stimuli. Also, although redirecting gaze typically requires visual attention, the converse is not true: visual attention can shift to new locations in the absence of gaze movements, and these are referred to as *covert* shifts of attention.

The tight linkage between visual attention and the planning of eye movements was a major rationale for the premotor theory of attention, which posited that the mechanisms for spatial attention and eye motor programming are essentially the same. Although it is generally recognized that the neural mechanisms for attention and eye movements are not identical, there is overlap in their control. Specifically, stimulation within the FEF with currents too weak to directly cause eye movements can nonetheless enhance the visual responses of neurons located in other visual areas of cortex, and can improve the behavioral performance on visual discrimination tasks (Moore & Fallah, 2004). Also, reversible inactivation of the SC causes profound deficits in the performance of spatial attention tasks, even in the absence of targeting eye movements (Lovejoy & Krauzlis, 2010).

Visual Perception and Cognition Contribute to the Control of Gaze Movements

Much of what we know about the neural control of gaze movements was learned using very simple visual, often small bright spots in an otherwise dark room. These studies made it possible to test and identify the basic feedback mechanisms and motor circuits that control gaze. However, under more natural conditions eye movements show properties that are more complex and flexible. One striking set of examples is provided by the work of Yarbus (1967), who showed that the pattern of saccades made while looking at visual scenes depends heavily on the instructions given to the observer (Fig. 32.11). These results illustrate that gaze movements are normally not just reactions to retinal events, but instead are guided by longer-term goals and serve to collect relevant visual information from the environment.

Gaze movements also reveal properties of the visual processing steps required to segment and interpret the visual scene. In one demonstration, a few lights are attached to the rim of a wagon wheel, which is then rolled along in an otherwise dark display. Although the retinal stimulus consists of several spots each undergoing cycloidal motion, subjects perceive the horizontal motion of the wheel and are able to easily track this motion with their eyes (Steinbach, 1976). More recent studies have examined how these processes evolve over time. For many moving objects, the true trajectory of the object cannot be calculated



An Unexpected Visitor
"Give the ages of the people."
"Surmise what the family had been doing before the arrival of the unexpected visitor."

FIGURE 32.11 The scan path depends on the goals of the observer. Among other experiments, Yarbus (1967) monitored the eye movements of subjects as they viewed Repin's painting *The Unexpected Visitor* and found that the pattern of eye movements depended on the task. When subjects were instructed to give the ages of the people, the scan path mostly settled on the faces, whereas when subjects were instructed to surmise what the family had been doing, the scan path included many more objects in the room.

locally in the retinal image, but requires integrating information over regions of visual space. This integration evidently takes some time (for example, ~100 ms), and the transition from local-motion signals to object-motion signals can be found in both the eye motor output and perceptual judgments.

Visual perception is also changed during eye movements. In particular, the world is not perceived as moving during saccadic eye movements, despite the rapid motion of the retinal image. You can demonstrate this to yourself by watching yourself make saccades in a mirror: you can see that your eyes change position, but you cannot see them actually move. This perception of a stable world is achieved through a combination of mechanisms, including the use of a *corollary discharge* of the outgoing eye motor command, *saccadic suppression* of visual signals during the eye movement, and *visual masking* by the advent of new visual signals on the retina (Wurtz, 2008). Together, these mechanisms help the visual system reduce its sensitivity to the unreliable visual signals that occur during gaze movements.

CONCLUSIONS

Eye movements serve two different functions. First, eye movements stabilize gaze when animals move about in their environment. Unpredictable high-speed rotations of the head, which are produced whenever an animal moves, change the line of gaze and, by smearing the optical image, reduce the resolution of the visual system. These high-velocity movements are compensated for by counter-rotations of the eyes generated by the VOR. Working in tandem with the VOR is the optokinetic system. The optokinetic system compensates for the slower movements of the head, which happen so gradually that the vestibular system cannot accurately detect them. Second, in animals with retinas that have a small region of high resolution, eye movements redirect gaze to aim the line of sight at objects or features in the visual scene that are of particular interest. Saccades are fast, discrete movements that quickly move the image of a visual target to the center of the retina where acuity is best. Pursuit is a slow, continuous movement that compensates for the motion of the visual target, minimizing the blurring that would otherwise limit acuity. Although the properties of saccades and pursuit are distinct, the two types of movements are closely coordinated during visual search of the environment and both are tightly linked to visual attention. Together, the different types of eye movements make it possible to efficiently gather the visual information that is important for achieving other, longer-term behavioral goals.

Eye movements are controlled by circuits that span the brain. The eyes themselves are a relatively simple motor apparatus, and they are controlled by a final motor pathway in the brainstem that is shared by all classes of eye movements. The construction of the motor commands involves generating an eye velocity command to move the eyes, and an integrated version of this command to hold the eyes at their new position. These motor commands are constructed by circuits in the brainstem reticular formation, and fine-tuned by additional circuits involving several parts of the cerebellum. The descending control signals that drive these motor commands are provided by multiple brain regions, but the superior colliculus in the midbrain and the frontal eye fields in the cortex are especially important. These brain regions help integrate sensory inputs with a variety of higher-order influences so that eye movements are directed to the appropriate visual stimuli. Overall, eye movements provide a window into the brain mechanisms that accomplish motor control, and they also involve sensory-motor interactions and higher-order processes like attention and perception.

CHAPTER

33

The Hypothalamus: An Overview of Regulatory Systems

The hypothalamus is an integrative center essential for survival of an organism and reproduction of its species. Regulatory systems emerged as each organism adapted to its environment and have evolved to control the complex interactions of physiology and behavior.

The diversity in regulatory function of the hypothalamus is reflected in its structure, neurochemistry, and connections. Almost every major subdivision of the central nervous system (CNS) communicates with the hypothalamus and is subject to its influence. In addition, the hypothalamus communicates with peripheral organ systems by converting synaptic information to blood-borne hormonal signals. In turn, the hypothalamus responds to feedback from the peripheral systems that it regulates. The chapters in this section discuss the processes by which the hypothalamus influences physiology and behavior, and the purpose of this chapter is to provide an introductory context for those presentations. We begin by providing a historical perspective on research that has defined the hypothalamus as an important regulatory center, continue with an overview of its structural and functional organization, and conclude with a discussion of how this region of the diencephalon functions within brain circuitry devoted to the control of motivated behaviors.

HISTORICAL PERSPECTIVE

Research on the hypothalamus has a rich and storied history. Although depicted in early brain atlases, the hypothalamus was not recognized as a distinct division of the diencephalon until the work of Wilhelm His (1893). Our understanding of the structure and function of the hypothalamus developed as basic and clinical neurosciences were integrated. Harvey Cushing, a neurosurgeon who studied endocrine disorders from a neuroscience perspective, provided important and influential early insights into hypothalamic function. He described diabetes insipidus, a neuroendocrine dysfunction of uncontrolled urinary water excretion and thirst, and identified the importance of injury to the pituitary stalk in the condition. Cushing also described the syndrome that bears his name, Cushing's syndrome, a disorder characterized by excessive secretion of adrenal corticoids, and he was among the first to recognize that the hypothalamus and pituitary form a functional unit. He was a pioneer in the development of pituitary surgery and is viewed as a founder of the fields of neurosurgery and endocrinology. In 1929, summing up his work in this area shortly before his retirement, Cushing wrote of the hypothalamus, "*Here in this well-concealed spot, almost to be covered with a thumb nail, lies the very mainspring of primitive existenceve getative, emotional, reproductiveon which, with more or less success, man has come to superimpose a cortex of inhibitions.*"

Gurdijian (1927), Kreig (1932), and Le Gros Clark, Beattie, Riddoch, and Dott (1938) build upon the clinical observations of Cushing and others, using histological procedures to describe the cytoarchitecture of hypothalamic nuclei. Their observations proved to be remarkably predictive of functional specializations revealed by the work of Ranson, Hess, and others during the same period. These investigators demonstrated that lesions and localized stimulation of the hypothalamus could selectively affect appetite, weight control, water balance, autonomic control, reproductive function, and emotional behavior. This work progressed so well that in 1940 it could be summarized only in a large volume of the annual series of the "Association for Research in Nervous and Mental Disease." In that volume, Scharrer and Scharrer (1940) presented evidence for "neurosecretory neurons," providing

the foundation for a fundamental tenet of hypothalamic function. That is, there are neurons—in the brain—that secrete hormones directly into the bloodstream. In 1949, Wolfgang Bargmann demonstrated neurosecretory neurons with cell bodies in the hypothalamus and axons projecting to the posterior lobe of the pituitary gland. Bargmann's work provided a framework for our current understanding of neuroendocrine regulation, that is, release of peptides into the peripheral circulation allows the hypothalamus to exert a profound influence on the physiology of peripheral organs.

In the 1950s, Harris and Green defined the means through which the hypothalamus regulates the anterior lobe of the pituitary. Their identification of a neurovascular link, the portal plexus, through which the hypothalamus regulates the anterior pituitary, fundamentally altered concepts of hypothalamic function and neuroendocrine regulation. The neurochemical basis of anterior pituitary regulation was revealed in the 1970s when Guillemin and Schally independently isolated and characterized peptide hormones that acted on the anterior pituitary. In subsequent years the field of neuroendocrinology built enormously on these observations, and the resulting literature documents a diverse family of hypothalamic peptides that are transported through the portal plexus to stimulate or inhibit the release of other hormones from the anterior lobe of the pituitary gland.

Contemporary research has exploited a revolution in technology development to bring further transparency to the organization and function of the hypothalamus. Data derived from a variety of new technical approaches has dramatically improved our understanding of the hypothalamic "connectome," including the phenotype of constituent neurons, and the underlying mechanisms that allow integrated, adaptive regulation of physiology and behavior. Similarly, advances in molecular technology have allowed targeted functional dissection of the diverse regulatory systems resident in the hypothalamus. While much remains to be learned, our knowledge of hypothalamic regulatory systems has advanced considerably in a relatively short period of time.

We have made great progress in improving understanding of Cushing's "mainspring of primitive existence." Fundamental insights into CNS function have emerged from the analysis of hypothalamic structure and function, underscoring the importance of this small, complex subdivision of diencephalon in the regulation of homeostasis and behavior essential to survival.

HYPOTHALAMIC CYTOARCHITECTURE

Early studies of hypothalamic organization defined subdivisions that were largely based upon landmarks visible on the ventral surface of the brain. Three major subdivisions were defined based upon their associations with the optic chiasm (chiasmatic), the protuberance containing the pituitary stalk (tuberal), and the mammillary bodies (mammillary) (Fig. 33.1). Contemporary research indicates

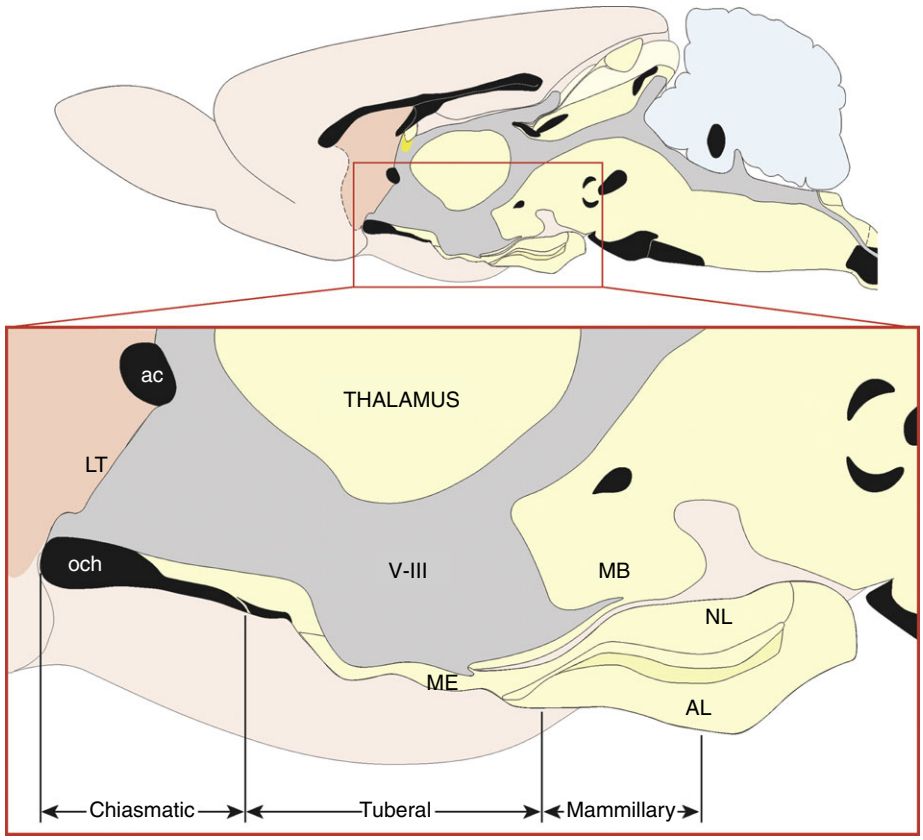

FIGURE 33.1 Boundaries of the rat hypothalamus viewed in midsagittal section. The ventricular system is shaded gray. The boxed area shows the approximate location of the hypothalamus in the ventral quadrant of the diencephalon, below the thalamus. The floor of the third ventricle (V–III), formed by the optic chiasm (och), median eminence (ME), and rostral portion of the mammillary body (MB), defines a large portion of the rostrocaudal extent of the hypothalamus. These landmarks also define the major subdivisions (chiasmatic, tuberal, and mammillary) classically used to subdivide the hypothalamus. The tuberal hypothalamus is distinguished by the infundibular stalk, which connects the ventral diencephalon to the pituitary. The rostral limit of the hypothalamus is the lamina terminalis (LT), a thin strip of tissue extending between the optic chasm and anterior commissure (ac) that also forms the rostral wall of the third ventricle. NL, neural lobe of posterior pituitary; AL, anterior lobe of pituitary.

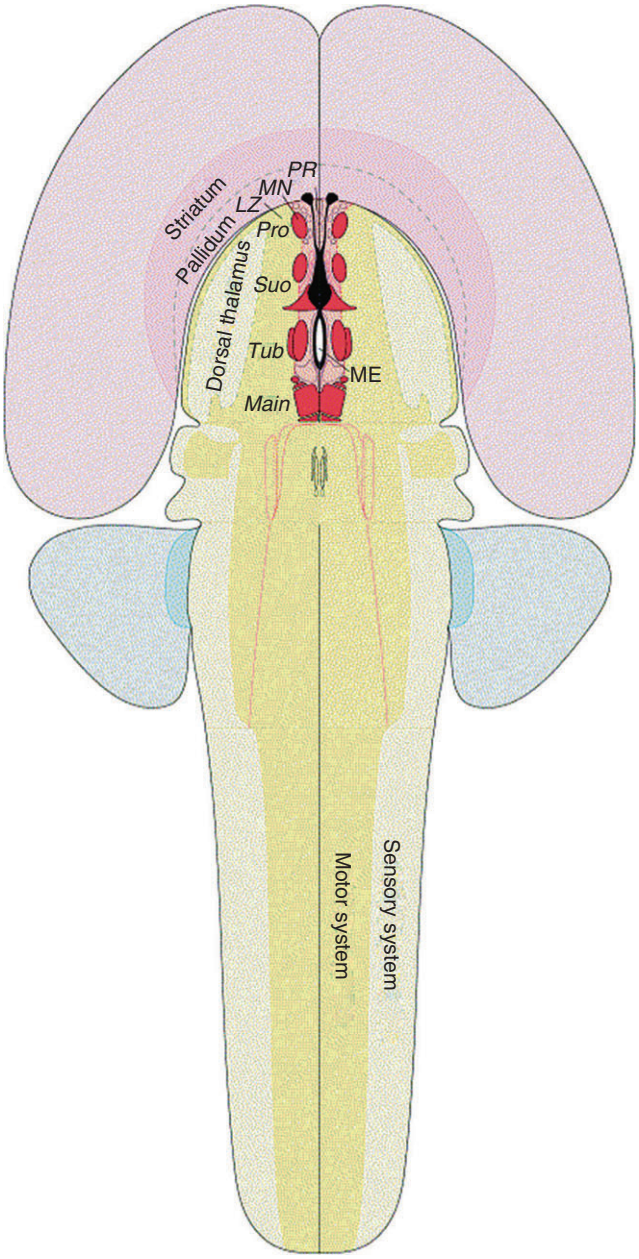

FIGURE 33.2 The columnar organization of hypothalamic cell groups is illustrated on a flat map of the rat central nervous system. Three longitudinal zones form columns that extend through the rostrocaudal extent of the hypothalamus. The periventricular region (PR; light red) lies immediately adjacent to the third ventricle and contains cell groups responsible for neuroendocrine control of the pituitary gland (black). The medial nuclei consist of cytoarchitecturally distinct cell groups (dark red) between the periventricular and lateral zones. The diffusely organized but phenotypically distinct neurons of the lateral zone (LZ) are shown in yellow. Contemporary research also recognizes four transverse subdivisions of hypothalamus (pro, preoptic; supraoptic or anterior, SUO; tuberal, tub; mammillary, mam). *Source: Reprinted with permission from Swanson (2000).*

that the hypothalamus is organized into longitudinal columns on either side of the third ventricle (Fig. 33.2). These columns are largely consistent with the initial descriptions of Gurdjian (1927) and Krieg (1932) and consist of *periventricular*, *medial*, and *lateral* zones that extend through the entire rostrocaudal extent of the hypothalamus. The periventricular zone, as the name implies, lies adjacent to the ependymal lining of the third ventricle. Its constituent neurons are densely packed within a narrow zone adjacent to the ependyma and occasionally expand into cytoarchitecturally distinct nuclear groups such as the suprachiasmatic and arcuate nuclei. The medial zone lies adjacent to the periventricular zone and contains cell groups that vary in size and cell morphology, but are organized into cytoarchitecturally distinct nuclei. This contrasts with the diffusely distributed neurons of the lateral zone, which is the least distinct of the three columns. Neurons in all three regions have been further subdivided on the basis of cellular phenotype, connectivity, and cellular markers of neural activation, allowing investigators to impose functional definitions.

FUNCTIONAL ORGANIZATION OF THE HYPOTHALAMUS

To effectively integrate diverse physiological processes and behaviors, the hypothalamus must communicate with systems in both the brain and periphery. Projections from all major subdivisions of the nervous system terminate within the hypothalamus. In some instances, such as vision, monosynaptic projections bring first-order sensory information from the periphery directly to hypothalamic nuclei. In other cases, such as limbic projections, multisynaptic processed information is relayed to the hypothalamus. More than any other region of the nervous system, the hypothalamus depends on conversion of synaptic information to hormonal signals. In addition, the hypothalamus is subject to feedback regulation by the physiological processes that it controls. These diverse systems are best understood by looking at functions that they modulate.

Olfaction

Multisynaptic pathways allow the olfactory system to influence neurons in many parts of the hypothalamus. Olfactory information passes directly to the olfactory tubercle, piriform cortex, and amygdala, which in turn relay it to the hypothalamus through the medial forebrain bundle (corticohypothalamic projections), stria terminalis, ventral amygdalofugal pathway, and fornix. In many vertebrates, olfaction is integral to behaviors involved in reproduction, defense, and feeding, and this is reflected in the large amount of forebrain dedicated to the processing of olfactory stimuli. Insight into the complexity of these circuits is apparent in recent rodent studies employing transneuronal tracing technology to define polysynaptic olfactory circuits innervating hypothalamic neurons involved in the regulation of reproduction and fertility (Boehm, Zou, & Buck, 2005; Yoon, Enquist, & Dulac, 2005). Thus, olfaction is an important sensory modality integral to hypothalamic functions essential to reproduction and survival.

Visual Projections

A principal function of the hypothalamus is to impose temporal organization on hormone secretion and behavior through the timekeeping properties of the biological clock in the rostral hypothalamus. The neurons that constitute this clock are found within the suprachiasmatic nuclei (SCN). The genetically determined circadian rhythmicity of SCN neurons provides a timekeeping capacity that is essential to successful adaptation to the environment and, in many instances, reproduction of organisms. Importantly, the rhythmic activity of the biological clock is responsive to environmental cues, which is accomplished through central visual projections of the retina. A unique population of ganglion cells that contain light sensitive melanopsin transduces light in the retina. The central projections of these ganglion cells through the retinohypothalamic projection synchronize the circadian activity of SCN neurons with the daily cycle of light and dark. Polysynaptic connections from the clock influence melatonin secretion from the pineal gland as part of a feedback mechanism for measuring day length, an ability important for the timing of reproduction in photoperiodic species. The responsiveness of this regulatory system to variations in photoperiod is also responsible for the "jet lag" that humans suffer when traveling across time zones.

Visceral Sensation

Sensory information reaches the hypothalamus through ascending projections arising from neurons in the nucleus of the solitary tract (NTS) of the caudal brain stem. The NTS is the principal visceral sensory nucleus that receives topographically organized input from the major organ systems of the body by way of cranial nerves X and IX, the vagus and glossopharyngeal nerves. As such, it is the first region in the CNS to process information about visceral, cardiovascular, and respiratory functions, as well as taste. The NTS coordinates reflex modulation of peripheral organ function and sends processed sensory information to forebrain nuclei, where it is integrated to control more complex physiological processes and behaviors.

Neurons in the paraventricular hypothalamic nucleus (PVH) and the lateral hypothalamic area (LHA) are prominent among a subset of hypothalamic nuclei that receive direct projections from the caudal brainstem through the medial forebrain bundle. In addition, the NTS and parabrachial nuclei relay splanchnic visceral and nociceptive sensory information from the spinal cord. This "interoceptive" sensory feedback has an important influence upon autonomic and endocrine outputs of the hypothalamus essential for regulation of homeostasis, and also influences mood through interactions with higher brain regions. Evidence for the latter is particularly prevalent in literature examining sensory integration related to stress induced activation of the endocrine and autonomic axes.

Integration of Physiology and Behavior

In the 1930s, James Papez (1937) postulated that the mammillary nuclei in caudal hypothalamus were components of a multisynaptic pathway, classically known as Papez's circuit, responsible for the expression of emotion. Although this function has not been confirmed, contemporary studies have demonstrated that projections, direct and polysynaptic, to hypothalamus from higher brain centers, play an integral role in coordinating adaptive changes in physiology with affect. Advances in defining the identity and organization of projection systems influential in this regulation have substantially advanced our understanding of how this is achieved. It is now well established that the prefrontal cortex, hippocampus, and amygdala contribute to this regulation through extensive topographically organized projections to the hypothalamus.

Prominent among the observations that have forged this vision are studies demonstrating that the hippocampal formation influences the hypothalamus through both direct and indirect projections through the fornix. The direct path, or postcommissural fornix, is a prominent component of Papez's original circuit in that it is composed of axons that arise from neurons in the hippocampal formation and terminate in the mammillary bodies. The indirect path, or "precommissural," fornix, influences the hypothalamus through a synaptic relay in the septum (Risold & Swanson, 1996). The topography of this projection is apparent at its origin in the hippocampus and is preserved in the lateral septal nuclei and in the hypothalamus, where second order septal projections innervate three longitudinally organized hypothalamic columns, although not equally (Fig. 33.3). Thus, this projection system is in a position to regulate neuroendocrine and autonomic function and ingestive behavior (periventricular zone), modulate motivated reproductive and agonistic behaviors (rostral medial zone), and also provide polysynaptic feedback projections to the hippocampus via the mammillary complex. The demonstration of "place" and "head-direction" cells in the hippocampal formation suggests that this projection is also the source of adaptive multimodal sensory information relevant to a variety of hypothalamic functions (e.g., foraging).

Projections from the amygdala to the hypothalamus and cortex coordinate endocrine and autonomic responses with the behavioral expression of fear. Projections from the amygdala reach the hypothalamus through two prominent projection pathways. The stria terminalis arises from neurons in the amygdala and follows a looping trajectory similar to the course of the fornix. Axons coursing through this pathway ramify within the bed nuclei of stria terminalis (BST) and continue into the hypothalamus. Amygdala neurons also innervate the hypothalamus via the ventral amygdalofugal bundle, which passes directly over the optic tract into the hypothalamus.

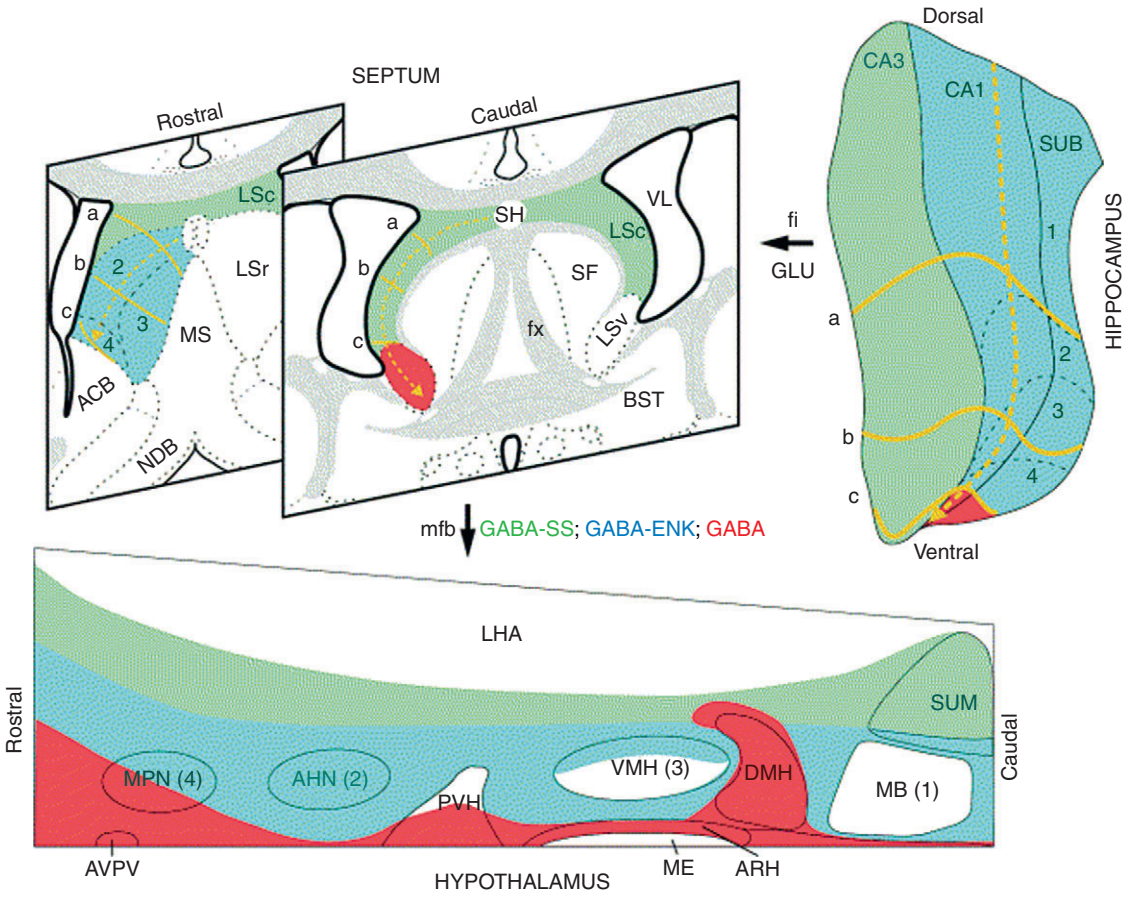

FIGURE 33.3 The organization of pathways that bring hippocampal input to hypothalamic columns is illustrated. The hippocampal formation projects topographically upon the lateral subdivision of the septum which, in turn, projects topographically upon the periventricular (red), medial (blue), and lateral (green) zones of the hypothalamus. Subfields of the hippocampal formation (CA1, CA3, subiculum) are represented on the flat map of the unfolded hippocampus in the upper right. The topography of the projection systems is coded in the colors, numbers (1, 2, 3, 4), and small letters (a, b, c) included in the maps of hippocampus, septum, and hypothalamus. ACB, nucleus accumbens; AHN, anterior hypothalamic nucleus; ARH, arcuate nucleus; AVPV, anteroventral periventricular nucleus; BST, bed nucleus of stria terminalis; DMH, dorsomedial nucleus; ENK, enkephalin; fi, fimbria of fornix; fx, fornix; GLU, glutamate; LS, lateral septum (small letters designate rostral, caudal, and ventral subdivisions); MB, mammillary body; ME, median eminence; mfb, medial forebrain bundle; MPN, medial preoptic nucleus; MS, medial septum; NDB, nucleus of the diagonal band; PVH, paraventricular nucleus; SH, septohippocampal nucleus; SS, somatostatin; SUM, supramammillary nucleus; VL, lateral ventricle; VMH, ventromedial nucleus. *Source: Reprinted with permission from Risold and Swanson (1996).*

A large literature has established the BST, hippocampal formation, and medial prefrontal cortex, and paraventricular nucleus of thalamus (PVT) as essential components of the neural circuitry through which the brain responds to stressful stimuli (Hsu & Price, 2009; Ulrich-Lai & Herman, 2009). The BST and PVT are integral to this regulation in that it integrates information from a variety of systems in response to psychogenic and physical stressors and exerts control over the endocrine (hypothalamic-pituitary-adrenal axis) and autonomic regulatory centers in hypothalamus. The paraventricular nucleus of hypothalamus (PVH) is a particularly important nodal point in this control in that it houses neurons at the apex of the HPA axis and also influences autonomic function through descending projections.

Circumventricular Organs

Not all sensory information reaching the hypothalamus is of synaptic origin. Some regions of the CNS are chemosensitive to blood-borne molecules. Such information about body fluid composition has important implications for the maintenance of homeostasis. Circumventricular organs (CVOs) are integral to this regulation. Seven CVOs surround the ventricular system in the diencephalon, midbrain, and hindbrain (Fig. 33.4). These include the subfornical organ (SFO), the vascular organ of the lamina terminalis (OVLT), the median eminence (ME), the pituitary gland (PG), the pineal gland (P), the subcommissural organ (SCO), and the area postrema (AP) (Fig. 33.3). Three of these regions, the OVLT, ME, and PG, are components

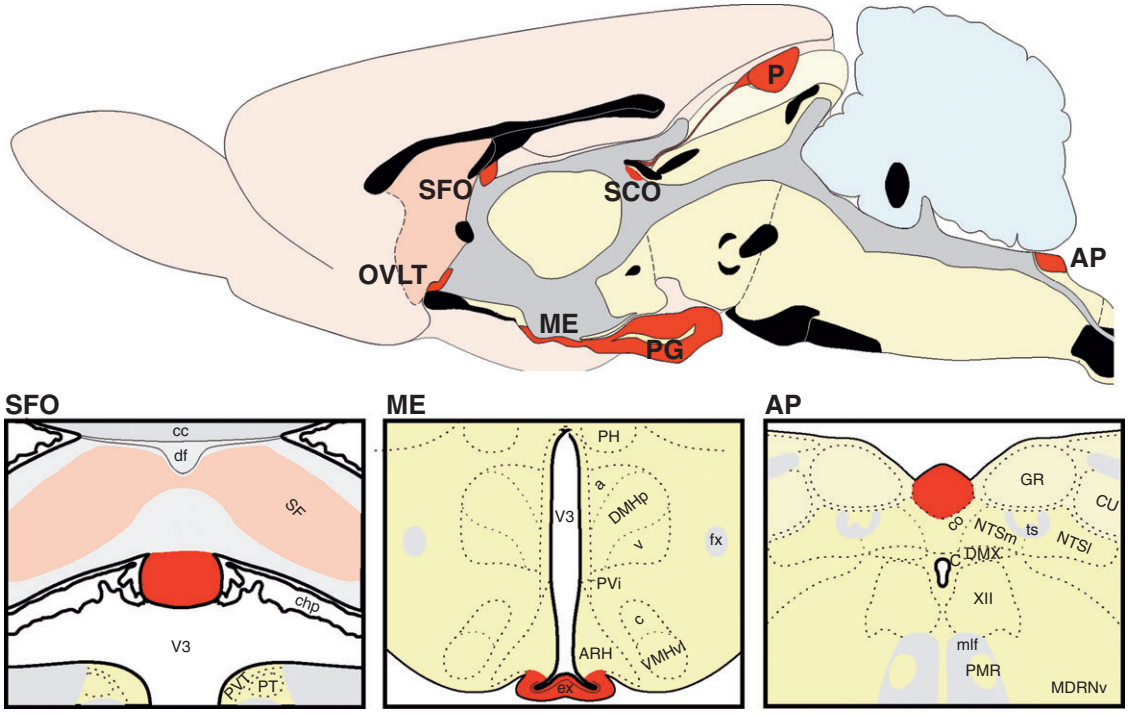

FIGURE 33.4 The location of the seven circumventricular organs (shown in red) in the rat brain (midsaggital section) are illustrated. Three CVOs that have an intimate functional association with the hypothalamus are illustrated in transverse sections in the lower figures. AP, area postrema; ARH, arcuate nucleus; cc, corpus callosum; CU, cuneate nucleus; df, dorsal fornix; DMHa, anterior portion of the dorsomedial nucleus; DMHp, posterior portion of dorsomedial nucleus; DMHv, ventral portion of dorsomedial nucleus; DMX, dorsal motor vagal nucleus; GR, gracile nucleus; ME, median eminence; mlf, medial longitudinal fasiculus; co, commissural portion of the nucleus of the solitary tract; NTSl, lateral portion of the nucleus of the solitary tract; NTSm, medial portion of the nucleus of the solitary tract; OVLT, vascular organ of the lamina terminalis; PH, posterior hypothalamus; P, pineal gland; PMR, paramedian reticular nucleus; PVi, intermediate part of periventricular nucleus; SCO, subcommissural organ; SF, septofimbrial nucleus; SFO, subfornical organ; ts, tractus solitarius; V–III, third ventricle; VMHc, central part of ventromedial nucleus; VMHvl, ventrolateral part of ventromedial nucleus; XII, hypoglossal nucleus.

of the hypothalamus. Two others, the SFO and AP, have extensive connections with hypothalamic nuclei involved in neuroendocrine and homeostatic function. Paul Ehrlich identified these regions in the late 1800s when he noted that they selectively accumulated vital dyes injected into the peripheral vasculature. Later studies demonstrated that the dye accumulated due to fenestrations in the capillaries in these regions that permitted relatively large molecules to leave the vascular lumen and enter the extracellular milieu. As a result, CVO neurons are accessible to blood-borne molecules that cannot enter other regions of the brain. The absence of a blood–brain barrier also allows CVOs to influence peripheral function through the release of bioactive molecules. Thus, CVOs represent important "windows" through which the brain controls peripheral function and, importantly, that render CNS neurons responsive to feedback regulation by the secretory products of the target organs that they modulate. This type of architecture is fundamental to the way in which the hypothalamus achieves tightly regulated control over the pituitary and, by extension, its peripheral targets.

EFFECTOR SYSTEMS OF THE HYPOTHALAMUS ARE HORMONAL AND SYNAPTIC

The extensive influence of the hypothalamus on behavior and physiology is reflected in its effector systems. The hypothalamus has conventional synaptic connections with essentially every major subdivision of the CNS and plays a major role in the control of behavioral state. As noted earlier, it also has regulatory control over the pituitary gland and thereby exerts a profound influence over peripheral physiology. Thus, the output of hypothalamic systems is integral to the integrated expression of physiology and behavior.

Behavioral State Control

Regulation of the sleep–wake cycle is a distributed process that involves the integrated action of the reticular activating system and the diencephalon. Early studies employing lesions and knife cuts conducted by Moruzzi,

Magoun, and Bremer demonstrated the importance of the brain stem reticular activating system in the generation of consciousness. Subsequently, Nauta (1946) postulated the existence of sleep centers in the hypothalamus based upon the consequences of lesions to the rostral or caudal hypothalamus. In those rodent studies, he demonstrated that lesions of the preoptic region produced insomnia and that somnolence resulted from lesions of the caudal hypothalamus.

Until recently, little was known regarding the specific hypothalamic cell groups involved in sleep regulation. However, identification of the circadian pacemaker in the early 1970s by Moore and colleagues marked the beginning of an era in which the hypothalamic contributions to behavioral state regulation have become increasingly clear. This literature has confirmed the early hypotheses of Nauta and identified cell groups in the rostral and caudal hypothalamus whose activity correlates with sleep or arousal.

The rostral hypothalamus is resident to two cell groups that are influential in the regulation of the sleep–wake cycle. Of these, the suprachiasmatic nuclei, or "Mind's Clock," are well known for their genetically determined oscillatory activity. A large literature has established that SCN activity opposes the homeostatic drive for sleep and is essential for the temporal organization of rest and activity (Chapter 40). In contrast, Saper, Scammell, and Lu (2005) identified hypothalamic neurons that become active at the onset of sleep in rats. These cells, located in the ventrolateral preoptic region, contain the inhibitory neurotransmitter GABA and project to the caudal hypothalamic cell groups that produce arousal when activated. These observations reveal a circuitry whose function coincides with the opposing effects of the rostral and caudal hypothalamus in sleep regulation documented by Nauta.

Two distinct populations in caudal hypothalamus generate arousal when activated. These neurons are similar in that they project diffusely to the cortical mantle but differ in phenotype. One group uses histamine as a neurotransmitter and is resident in the tuberomammillary nuclei. Another group is present in the posterior and lateral hypothalamus and contains the neuropeptide known as hypocretin (or orexin). Studies of the causal mechanisms underlying the sleep disorder known as narcolepsy implicate this population of neurons in the regulation of behavioral state. Narcolepsy is a disorder characterized by excessive daytime sleepiness and sudden inappropriate intrusion of sleep during waking. A defect in one of the hypocretin receptors has been demonstrated in a canine model widely employed to study the disease, and transgenic mice lacking the hypocretin gene display sleep–wake disturbances similar to narcolepsy. Additionally, cerebrospinal fluid (CSF) levels of hypocretin are reduced in humans suffering from this disorder, and postmortem analysis of the hypothalamus of narcoleptics has demonstrated substantial reductions in the number of hypocretin neurons.

Collectively, these findings are consistent with an important role for the hypothalamus in the regulation of behavioral state. Nevertheless, it is important to emphasize that the hypothalamus functions within a larger ensemble of neurons devoted to behavioral state regulation. Particularly important in this regard are monoaminergic and cholinergic brain stem neurons, as well as thalamic and basal forebrain cell groups (Chapter 40). Understanding how this distributed system functions in an integrated fashion to control behavioral state remains an important goal.

Neuroendocrine Regulation through the Pituitary Gland

The median eminence is the gateway through which the hypothalamus exerts regulatory control over peripheral organ systems. This CVO is continuous with the pituitary gland through a thin tissue bridge known as the pituitary stalk. Parvicellular hypothalamic neurons exercise this regulatory control over the anterior lobe of the pituitary via the release of peptides and small molecule neurotransmitters into fenestrated portal vessels that connect the median eminence with another fenestrated plexus in the anterior pituitary. These molecules act upon cells in the anterior pituitary to control release of hormones into the peripheral circulation. The posterior lobe of the pituitary gland also contains a fenestrated vascular plexus that is contacted by axons of magnocellular neurons that project through the median eminence and pituitary stalk to release their peptides—oxytocin or vasopressin—into the vasculature. These peptides are well known for their influences on fluid homeostasis (vasopressin) and milk letdown in lactating females (oxytocin).

The parvicellular hypothalamic neurons acting in the anterior lobe of the pituitary exert a profound and diverse influence over peripheral physiology and metabolism. A variety of parvicellular neuroendocrine neurons distinguished by peptide phenotype contribute to this regulation either by stimulating or by inhibiting the release of hormones from the anterior lobe of the pituitary. The PVH and arcuate nuclei contain a large proportion of these neurons. As noted previously, the PVH is the apex of the HPA axis, the neuroendocrine arm through which the brain responds to stressful stimuli. Parvicellular neurons that secrete corticotropin-releasing hormone provide the essential neuroendocrine output of the hypothalamus that activates this axis. PVH parvicellular neurons that synthesize and secrete thyrotropin-releasing hormone are similarly influential in the regulation of peripheral metabolism. Considered collectively, the parvicellular neurons in the PVH, arcuate nucleus, and other regions of the

hypothalamus provide the means through which the brain regulates peripheral systems essential to the life of the organism and the survival of species. The integrative capacity of the hypothalamus therefore is essential to the regulation of the many systems that operate through this neuroendocrine "final common pathway."

Reproductive Function

The ability of mammals to reproduce depends on the function of the hypothalamus and its ability to communicate with the pituitary gland. This is especially true for the production of gametes, whose maturation and release in both males and females require a functionally intact hypothalamic–pituitary axis. The hypothalamus also plays an essential role in the organization and expression of the complex behaviors necessary for copulation (see Chapter 38).

Experimental studies in rodents have demonstrated that the rostral medial zone of the hypothalamus plays an important role in orchestrating reproductive behaviors. The medial preoptic region participates in the control of masculine sexual behavior, such as erection, mounting, and ejaculation, whereas ventral regions of the hypothalamus play a major role in the control of feminine sexual behaviors, such as lordosis.

A number of hypothalamic cell groups implicated in reproductive function are sexually dimorphic (Simerly, 2002). For example, ultrastructural studies of a preoptic region in male and female rats have demonstrated differences in synaptology that develop in response to perinatal exposure to androgens. Also, differences in the size and serotonergic innervation of the medial preoptic nuclei of male and female rats have been demonstrated. The possibility that similar dimorphisms are present in the human hypothalamus is supported by the identification of a region of the human preoptic region that is approximately twice as large in males as in females. Although the functional significance of sexual dimorphism in the structure and connectivity of the hypothalamus remains to be established, the gender of the brain is clearly determined by the hormonal milieu present during a critical period of development.

Much is known about the hypothalamic cell groups that influence the production of gametes. The production of ova and sperm is controlled by the release of gonadotropins from the anterior pituitary gland, which in turn is regulated by the hypothalamus in a gender-specific manner. For example, spermatogenesis occurs in response to constant release of gonadotropins in males, whereas ovulation is a cyclic event initiated by a rhythmic surge in gonadotropin release in females. In both cases, hypothalamic neurons produce gonadotropin-releasing hormone (GnRH) to stimulate the release of gonadotropin from the anterior lobe of the pituitary. The gender-specific patterns of gonadotropin release imply that there are sexual differences in the functional organization of circuitry that controls the activity of GnRH neurons. One postulated sexually dimorphic difference is a central pattern generator, thought to be responsible for the cyclic release of GnRH in females. The identity, organization, and regulation of the cell groups that contribute to this pattern generator remain an active and important focus of investigation.

Central Integration of Autonomic Function

The hypothalamus is a prominent component of the central network of neurons that regulates autonomic function. Descending projections from the hypothalamus to autonomic cell groups in the brain stem and spinal cord exert a strong influence upon the sympathetic (thoracic) and parasympathetic (cranial-lumbosacral) divisions of the autonomic nervous system (ANS). Several hypothalamic cell groups also indirectly influence the ANS through relays that integrate processed sensory information and project to the preganglionic neurons of the spinal cord that are the final common pathway for autonomic outflow. Brain stem neurons involved in cardiovascular regulation are among the best-characterized examples of such relays. For example, brain stem neurons in the rostroventrolateral medulla (RVLM) exert control over mean arterial pressure through direct projections to sympathetic preganglionic neurons in the intermediolateral cell column of thoracic spinal cord (Guyenet, 2006). The activity of these neurons is controlled in a reflex manner through a caudal brain stem circuit that integrates baroreceptor sensory input terminating in the NTS (Chapter 34). However, descending projections from the hypothalamus (e.g., paraventricular nucleus) and other CNS cell groups important for coordinating autonomic function and behavioral responses to environmental challenges also influence the activity of RVLM neurons. This is one of many relays through which the central network devoted to autonomic control provides a dynamic regulatory capacity ideally suited for maintaining homeostasis and ensuring adaptive changes in physiology to environmental challenges.

Immune Function and Thermoregulation

A major function of the hypothalamus is to integrate sensory information and elicit adaptive changes in physiology and behavior to achieve homeostasis. As noted above, this is accomplished through both synaptic interactions with other regions of the neuraxis and neuroendocrine regulation of peripheral systems. Immune activation is a major challenge to homeostasis so it should not be surprising that there is communication between the immune system and the hypothalamus. Clear documentation that such interactions

exist has largely emerged from contemporary literature that has benefited from the identification and characterization of pro- and anti-inflammatory cytokines and analyzed their effect upon neural systems. The seminal contributions of Hugo Besedovksy have been particularly influential in establishing that immune activation alters the turnover of classical neurotransmitters (e.g., noradrenaline) and activates the HPA axis. Numerous investigators have built upon these observations and a large literature has established that interactions between the immune and nervous systems are bidirectional; for example, immune activation can alter neuronal function and the brain also has the capacity to elicit changes in the immune response.

Fever is one consequence of an activated immune system. Thus, the neural circuits that control temperature regulation provide important insights into neural-immune interactions. In this regard, it is well known that the hypothalamus contains populations of neurons that either stimulate or inhibit heat production. These include heat sensitive neurons in the medial preoptic area that act to reduce core body temperature by inhibiting hypothalamic and brainstem cell groups that generate heat production. Nakamura and Morrison (2008) recently brought further insight into the way in which this circuitry functions to defend body temperature. These investigators demonstrated that sensory information activated by skin cooling is relayed to a "thermoregulatory command center" in the preoptic hypothalamus through the parabrachial nucleus to induce compensatory thermogenic, metabolic, and cardiovascular responses. This sensory transduction occurs in parallel with somatosensory pathways that mediate temperature perception and discrimination through thalamocortical projections. In rodents and other small mammals, nonshivering thermogenesis is achieved through the activation of sympathetic outflow to brown adipose tissue (BAT). The mitochondria of BAT adipocytes contain an uncoupling protein that converts energy from fatty acid metabolism to heat, a process that is increased by sympathetic activity. Interestingly, there is considerable overlap of cell groups that regulate energy balance, stress, and fever. Although there is much to be learned regarding the neural systems involved in temperature regulation, it is clear that the hypothalamus is at the center of the sensory integration necessary to respond to interoceptive challenges (e.g., inflammatory responses to infection) as well as those encountered in the environment.

Fluid Homeostasis and Thirst

Insight into the regions of the brain involved in fluid homeostasis has come from observing the response of neurons to dehydration and other experimental changes in the internal milieu. The hypothalamus is a prominent component of a set of CNS nuclei in which neurons respond to dehydration (an increase in fluid osmolarity) and changes in blood volume by increasing their metabolic activity. Activated neurons have been demonstrated in the subfornical organ, the paraventricular and supraoptic nuclei, and an area of the rostral hypothalamus known as the AV3V region, which includes the median preoptic nucleus and the OVLT. These regions interact with neurons in the area postrema, the nucleus of the solitary tract, the noradrenergic cell groups of the brain stem, and the parabrachial nucleus to integrate peripheral stimuli and elicit adaptive changes in the fluid environment of the organism. CVOs subserve prominent regulatory functions within this circuitry (Fig. 33.5).

The SFO has dense projections to the supraoptic and paraventricular nuclei, to the region adjacent to the OVLT, and to the perifornical region of the lateral hypothalamic area. Such projections are consistent with postulated roles of the SFO in autonomic and homeostatic functions. The peptide hormone angiotensin II (AII) is integral to the way in which the SFO transduces peripheral signals and then produces compensatory neural responses. When blood pressure falls, the kidneys release renin into the bloodstream. Renin triggers a biochemical cascade that produces AII. Because of the absence of a blood–brain barrier in the SFO, circulating AII can enter the SFO and bind AII receptors on SFO neurons. Interestingly, SFO neurons appear to use AII as a neurotransmitter in projections to hypothalamic cells that are involved in the control of fluid dynamics. In this example, activation of hypothalamic

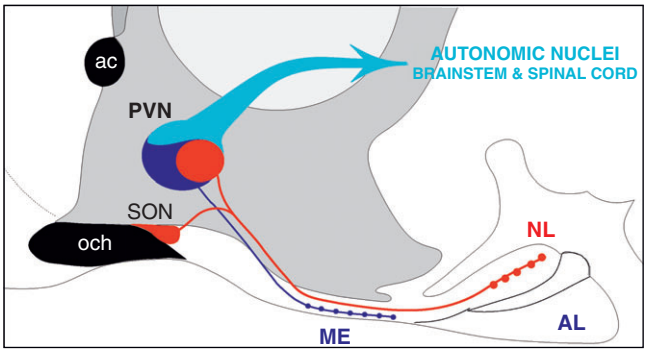

FIGURE 33.5 Functional associations of the paraventricular nucleus (PVH) with endocrine and autonomic systems are illustrated. Axons of magnocellular neurons in the PVH and supraoptic nuclei (SON) (shown in red) traverse the internal layer of the median eminence (ME) and the infundibular stalk to terminate on a vascular plexus in the neural (posterior) lobe of the pituitary gland (NL). Parvicellular PVH neurons influence the functional activity of the anterior lobe of the pituitary gland (AL) through projections (shown in blue) that terminate on a fenestrated capillary plexus, the portal plexus, in the external zone of the median eminence. The terminals of these axons release peptides and neurotransmitters into the portal vasculature, which carries them to the anterior lobe of the pituitary. Parvicellular PVH neurons also give rise to descending projections (shown in turquoise) to autonomic nuclei in the brain stem and spinal cord. ac, anterior commissure; och, optic chiasm.

systems that elicit drinking and reduce fluid excretion at the kidneys would produce the adaptive compensatory homeostatic increase in blood pressure. Further details on the components of the regulatory system are provided in Chapter 37.

Different populations of hypothalamic neurons elicit adaptive responses to changes in fluid osmolarity. Osmosensitive neurons are located primarily in the AV3V region, which includes the OVLT. The response of these neurons to alterations in fluid osmolarity elicits an adaptive compensatory thirst. The neural circuitry that modulates this response is not fully understood but is known to involve input from the OVLT, SFO, and NTS. Further, it takes advantage of the same output regulatory pathway, hypothalamic magnocellular neurons, utilized by the SFO. Chapter 37 considers the hypothalamic role in fluid homeostasis in greater detail.

Food Intake

The consumption of food is another complex behavior that involves several regions of the brain. The hypothalamus plays an essential role in this circuitry as an integrative center for a variety of sensory stimuli, both synaptic and hormonal. It also serves to modulate autonomic outflow to the viscera. This modern view of neural regulation of food intake is a substantial modification of the simple concept of opposing centers for hunger and satiety that was popular in the older literature. Chapter 36 contains a detailed discussion of literature that has contributed to the modern view of the neural control of food intake. The following description summarizes the functional organization of hypothalamic nuclei that regulate food intake.

When food is consumed, hormones are released from the viscera, and sensory pathways innervating the alimentary tract are stimulated. These sensory pathways regulate neurons in the area postrema and NTS that are connected bidirectionally with hypothalamic nuclei. Hypothalamic nuclei are also subject to feedback regulation from hormonal signals arising in the gut. At least four hypothalamic nuclei are involved in the control of feeding, and a prominent part of their influence is exerted via descending projections to autonomic nuclei in the brain stem and spinal cord. Paraventricular nuclei provide a prominent descending hypothalamic influence. In particular, parvicellular oxytocinergic neurons in the PVH provide an important descending projection to the dorsal vagal complex (including the NTS) and the sympathetic preganglionic neurons of the thoracic spinal cord. At least some of this descending influence appears to be under the control of neuropeptide Y (NPY)-containing neurons that project from the arcuate nucleus to the PVH. In experiments, infusion of NPY into the PVH stimulates food intake and NPY-containing neurons in the arcuate nucleus are inhibited by insulin released into the peripheral circulation after a meal and by leptin, a peptide released from adipose tissue. Thus, hypothalamic nuclei regulate food intake through the autonomic nervous system, and a subset of these neurons is influenced by peripheral signals from the periphery (see Chapter 36).

Summary

It is clear that the hypothalamus plays a pivotal regulatory role central to the survival and propagation of vertebrate species. This regulation is achieved by output pathways that utilize both synaptic and hormonal mechanisms and is subject to feedback regulation by sensory information derived from the systems that they regulate. The integrative capacities of the hypothalamus are fundamental to its ability to orchestrate the complex and diverse adaptive behaviors that underlie homeostasis, reproduction of the species, and motivated behaviors. Within this context it is important to view the hypothalamus as an integral component of ensembles of neurons devoted to specific functions rather than an individual unit. Swanson has advanced a conceptual framework consistent with this philosophy. In this formulation, the hypothalamus is part of a "behavioral control column" that functions as a topographically organized integrative center subject to the control of cerebral hemispheres. The functional organization of this column is consistent with the distributed localization of functions classically associated with the hypothalamus. For example, the rostral portion of the column is devoted to the control of ingestive (eating and drinking) and social (defensive and reproductive) behaviors, whereas the caudal portion, which is continuous with the substantia nigra, functions in support of exploration and foraging. Modulation of these functions is under the control of the cerebral hemispheres through three descending projections involving the cortex, striatum, and pallidum. The role of the hypothalamus in imparting temporal organization on the behavioral state and physiology is an important component of this organizational framework. The explosion of organizational and functional data that has accumulated over recent decades has expanded our understanding of hypothalamic function and established this small but complex subdivision of the diencephalon as an important integrative unit for the expression of behavior and maintenance of homeostasis.

CHAPTER

34

Central Control of Autonomic Functions: Organization of the Autonomic Nervous System

The autonomic nervous system (ANS) consists of the neural circuitry that controls the body's physiology. This network is a morphologically, embryologically, functionally, and pharmacologically distinct division of the nervous system. Working in concert with neuroendocrine mechanisms, the ANS is responsible for homeostasis, or what Walter B. Cannon (1939) referred to as the "wisdom of the body."

Unlike the skeletal motor system, which innervates striated muscles, the autonomic nervous system innervates the body's smooth muscle organs and tissues. The ANS projects to, and forms plexuses within, the hollow organs, or viscera, such as the heart and lungs in the thorax and the gastrointestinal, genital, and urinary tracts in the abdomen. It also projects to the blood vessels, glands, and other target tissues found within trunk muscles, limb muscles, and skin.

The ANS also coordinates the body's physiology to support behavior. In tandem with endocrine controls, the ANS orchestrates the continuous adjustments in blood chemistry, respiration, circulation, digestion, reproductive status, thermoregulation, and immune responses that protect the integrity of the internal milieu, while enabling the functioning and coordination of skeletal muscles and exteroceptive senses into what we know as behavior. Autonomic adjustments are often phasic responses that occur with latencies typical of neural reflexes; in contrast, endocrine responses usually occur more slowly, taking anywhere from minutes to hours to seasons for full expression.

Autonomic impairments lead to the loss of ability to mobilize physiological responses to counter challenges to homeostasis. For example, Cannon (1939), in his landmark experiments, found that destruction of different autonomic pathways devastated the ability of an animal to regulate body temperature, to respond to perturbations of fluid and electrolyte balance, to control blood sugar homeostasis, or to mobilize in response to threats.

A familiar experience illustrates autonomic operations: occasionally, when you have been lying down resting and then jump up suddenly, you may feel dizzy, your vision may become blurred, and you may momentarily have trouble maintaining your balance—let alone doing something active and coordinated. This phenomenon is postural, or orthostatic, hypotension and is caused by insufficient oxygenated blood reaching your brain under the altered hemodynamic conditions produced by the rapid change in posture. Most people experience postural hypotension only occasionally, though for some it is a chronic medical problem. Indeed, it is a debilitating condition in people with various forms of dysautonomia (Bannister, 1989).

A principle underscored by postural hypotension is that behaviors, indeed even simple movements such as a change in posture, require near-instantaneous redistributions of blood flow throughout the body to protect the privileged supply of blood, and thus oxygen and glucose, to the brain. The demands of postural adjustments require unceasing monitoring and rebalancing of circulatory loads. The fact that these adjustments happen continuously and automatically is testimony to the efficiency of the ANS in producing homeostatic adjustments. This example also illustrates two other characteristics of many autonomic responses: often the responses either are initiated in anticipation of the perturbation or

© 2013 Elsevier Inc. All rights reserved.

implemented so rapidly that the individual does not experience a deficit, and the activity of the ANS is coordinated with activity of the somatic nervous system.

The scope of autonomic functions is hard to overemphasize. Though many early experiments concentrated on autonomic emergency responses, ANS operations are by no means limited to cardiovascular and metabolic adjustments, to "fight-or-flight" situations, or to short-term responses. The ANS has equally essential roles, for example, in all reproductive behavior and physiology, including the choreographies of copulation, gestation, parturition, and lactation. Autonomic reflexes control, on a continuous basis, all bodily interfaces with the environment (e.g., the dermal, respiratory, and digestive epithelia). By its rapid and unceasing adjustments of pupillary diameter and lens accommodation, the ANS facilitates optimal vision. And the ANS plays critical roles in immune system responses; it also coordinates the elimination of metabolic waste products.

The autonomous nature of ANS function is another characteristic of autonomic control. We are rarely aware of ongoing reflex adjustments made to maintain cardiovascular and regulatory dynamics, fluid and electrolyte homeostasis, energy balance, immune system operations, or reproductive functions. Like the batch files of a computer, which execute without normally intruding on the screen or requiring management, autonomic reflex adjustments run unceasingly in the "background." This makes it practical for other sensory events and functional decisions to occupy the "foreground." In one of his delightful and trenchant essays, Lewis Thomas (1974) speculates on how disastrous and overwhelmingly confusing it would be if he were put in charge of his liver—if he had to consider all visceral inputs and make a conscious decision for all adjustments in liver function. The ANS takes care of such hepatic, as well as all other visceral, decisions automatically, allowing the individual to focus on the behavioral and cognitive functions that typically require awareness.

The hub of the autonomic nervous system is the visceral motor outflow, which is divided into *sympathetic* (SNS) and *parasympathetic* (PSNS) divisions. Each division is organized hierarchically into pre- and postganglionic levels (Fig. 34.1). The cell bodies of the preganglionic neurons lie within the central nervous system, specifically in the brainstem and spinal cord. Descending projections from more rostral levels of the neuroaxis converge on these ANS preganglionic motor neurons in a pattern similar to that of the centrifugal projections to somatic motor neurons of the brainstem and spinal cord. However, unlike the outflow pattern of the skeletal motor system, in which neurons of the ventral horn or the cranial nerve nuclei project directly to the effector or muscle target, autonomic preganglionic neurons project to peripheral ganglia located between the last CNS station and the target tissues. These ganglia of the ANS contain

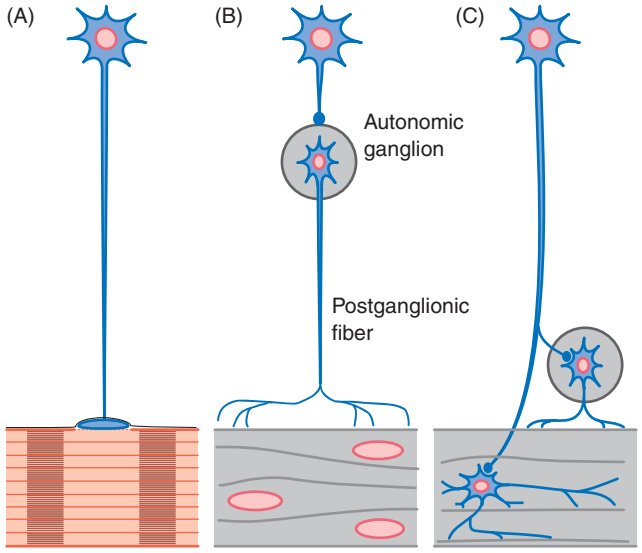

FIGURE 34.1 Somatic and autonomic styles of motor innervation are different. In the somatic motor pattern (A), motor neurons of the spinal cord and cranial nerve nuclei project directly to striated muscles to form neuromuscular junctions. In the autonomic or visceral pattern (B and C), in contrast, motor neurons in the central nervous system project to peripheral postganglionic neurons that in turn innervate smooth muscles. (B) The SNS has preganglionic neurons in the thoracic and lumbar spinal cord (intermediolateral cell column) that project to postganglionic motor neurons in para- and prevertebral autonomic ganglia. (C) The PSNS consists of preganglionic neurons in brainstem cranial nerve nuclei and in the sacral spinal cord (intermediomedial cell column) that project to postganglionic motor neurons in ganglia located near or inside the viscera. *From Nauta and Feirtag (1986).*

the postganglionic motor neurons that project to the effector tissues. The extra synapse interrupting the autonomic outflows at peripheral ganglia allows for more divergence, and it also provides opportunities for more local integrative circuitry to impinge on the outflow. Different locations both of the preganglionic motor neurons in the CNS and of the ganglia containing the somata of the postganglionic motor neurons in the periphery are distinguishing features of the two principal divisions of the autonomic nervous system (Langley, 1921; Table 34.1).

SYMPATHETIC DIVISION: ORGANIZED TO MOBILIZE THE BODY FOR ACTIVITY

Sympathetic Responses Coordinate Energy Expenditure, Catabolic Functions, and Adjustments for Intense Activity

"Fight or flight," Cannon's prototypical example, epitomizes the operation of the sympathetic division of the ANS. Say you are walking alone at night in an unfamiliar part of town. Although the area is somewhat unsafe and it is too dark to see much of your surroundings, the night is quiet, and you manage to relax. After you walk for several

TABLE 34.1 Classical Comparisons of Sympathetic and Parasympathetic Divisions of the ANS[a]

Characteristic	SNS	PNS
Location of Preganglionic Somata	Thoracolumbar Cord	Brainstem; Sacral Cord
Location of Ganglia (and thus Postganglionic Somata)	Distant from Target Tissues	Near or in Target Tissues
Postganglionic Transmitter	Norepinepherine	Acetylcholine
Length of Preganglionic Axon	Relatively Short	Relatively Long
Length of Postganglionic Axon	Relatively Long	Relatively Short
Divergence of Preganglionic Projections	One-to-Many	One-to-Few
Functions	Catabolic	Anabolic
Innervates Trunk and Limbs, in addition to Viscera	Yes	No

[a]*Langley (1921), in splitting the ANS motor outflow into the now-accepted divisions, stressed the contrasting and distinguishing traits of the sympathetic (SNS) and parasympathetic (PSNS) divisions of the ANS. Since his time, most discussions have identified several contrasting features. Most of these distinctions apply generally, but not universally. Although many of these distinctions have blurred (e.g., transmitter) or may be completely unfounded (e.g., divergence), they are often discussed.*

minutes, however, there is a sudden, loud, and unfamiliar noise close by and behind you. In literally the time of a heartbeat or two, your physiology moves into high gear. Your heart races; your blood pressure rises. Blood vessels in your skeletal muscles dilate, increasing the flow of oxygen and energy. At the same time, blood vessels in your gastrointestinal tract and skin constrict, making more blood available to be shunted to skeletal muscle. Digestion is inhibited; release of glucose from the liver is facilitated. Your pupils dilate, improving vision. You begin to sweat, a response serving several functions, including promoting additional dissipation of heat so muscles can work efficiently. Multiple other smooth and cardiac muscle adjustments occur automatically, and almost all of them are affected by the sympathetic division of the ANS.

This fight-or-flight example illustrates important features of the ANS generally and its SNS division more particularly. First, the situation points out the utility of the housekeeping functions of the ANS. If the alarming noise turns out to be a threat and it is necessary to fight or flee, skeletal muscles must be optimally tuned and provisioned. Extra quantities of oxygen and energy are essential. Second, the synergy of adjustments indicates a coordinated and adaptive program of responses, which in this case happen immediately, almost before cognitive evaluation. Third, the short latency of the response is characteristic. Some of the physiological adjustments could be accomplished by hormonal mechanisms, but such adjustments would be too slow to be of much immediate help.

Though the flight-or-fight scenario highlights short-latency responses, not all sympathetic (or parasympathetic) responses happen on such short time scales. ANS operations also involve continuous, ongoing adjustments. Textbook accounts of the emergency functions of the ANS and of single, isolated reflex adjustments sometimes leave the incorrect impression that the ANS is quiescent in the absence of a threat or specific stimulus. Instead, the autonomic nervous system, like the somatic nervous system, always maintains an operating tone. Even during rest, the system maintains appropriate homeostatic balances and autonomic programs.

Preganglionic Neurons of the Sympathetic Nervous System Are Located in the Thoracic and Lumbar Spinal Cord

Sympathetic preganglionic neurons occupy the *intermediolateral nucleus*, a columnar grouping of cells running longitudinally, in the lateral horn of the spinal gray (Strack, Sawyer, Marubio, & Loewy, 1988). In humans, these cells are found between the first thoracic spinal segment (T1) and the third lumbar segment (L3) (Fig. 34.2A). The location of these preganglionic neurons and their axonal outflow gives the SNS another of its names: the *thoracolumbar division*. Cells within the intermediolateral column are aggregated segmentally. There is a rostral-to-caudal viscerotopic organization to the distribution (Fig. 34.2A). The column is distributed bilaterally, and preganglionics on one side send their axons out the ipsilateral ventral root. The axon of a preganglionic neuron typically exits from the segment in which its soma is located. Many of the preganglionic axons are lightly myelinated, and, as they separate from the ventral root to project to the appropriate peripheral ganglion, they form a *white ramus*, a connective that takes its descriptive name from myelinated fibers.

Sympathetic postganglionic neurons are found in two distinct types of peripheral ganglia: paravertebral and prevertebral. *Paravertebral ganglia*, as the name implies, are adjacent to the spinal cord bilaterally, in a position slightly ventral and lateral to the vertebral column (Figs. 34.3 and 34.4). Each ganglion receives a white ramus from the appropriate ventral root. These ganglia also are interconnected longitudinally into a sympathetic paravertebral chain linked by axons from the preganglionic neurons that run rostrally or caudally to neighboring ganglia of the chain. Axons of the postganglionic neurons of the paravertebral ganglia course centrifugally out of the ganglion to join the peripheral nerves that will carry the individual fibers to their targets. Because most postganglionic axons in the sympathetic nervous system are unmyelinated, these connectives joining the ventral roots are called *grey rami*.

Paravertebral ganglia of the sympathetic chain supply the postganglionic innervation of the head, thorax, trunk,

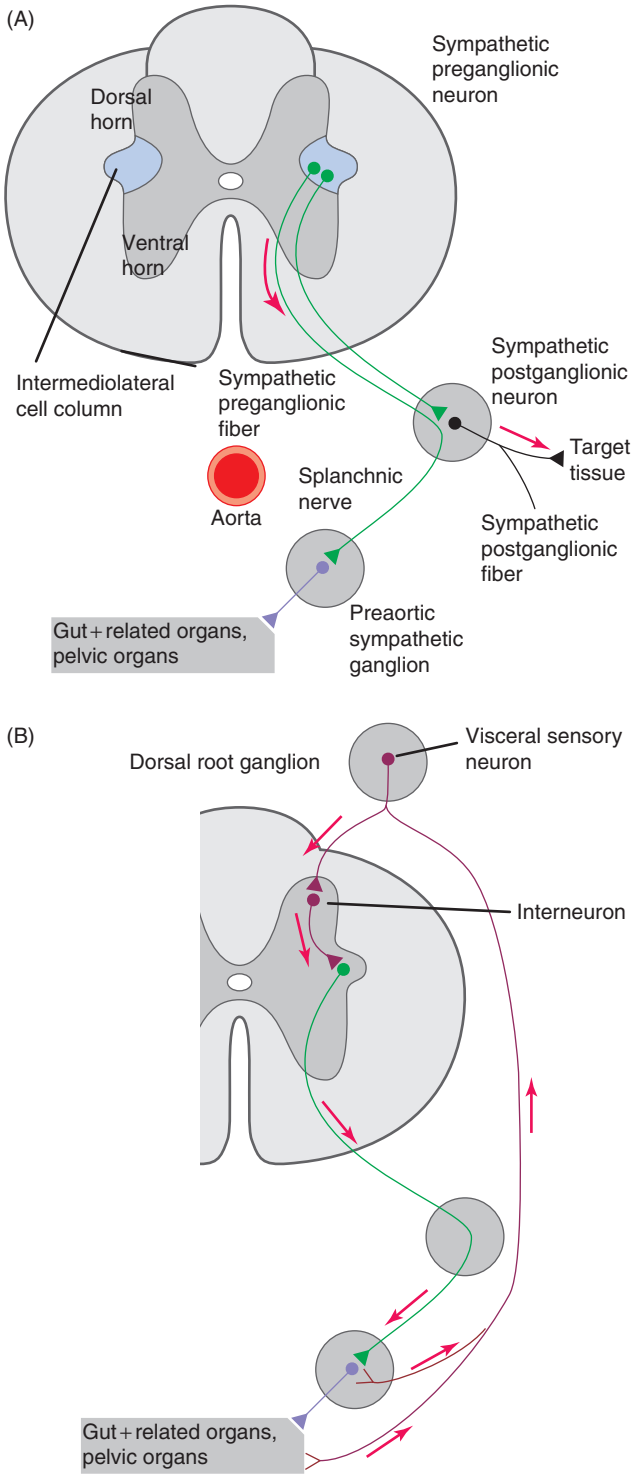

FIGURE 34.2 Details of the organization of the SNS and its sensory inputs. In thoracic and lumbar levels of the spinal cord, preganglionic neuronal somata located in the intermediolateral cell column project through ventral roots to either paravertebral chain ganglia or prevertebral ganglia, as illustrated for the splanchnic nerve (A). Visceral sensory neurons located in the dorsal root ganglia transmit information from innervated visceral organs to interneurons in the spinal cord to complete autonomic reflex arcs at the spinal level (B). *From Loewy and Spyer (1990).*

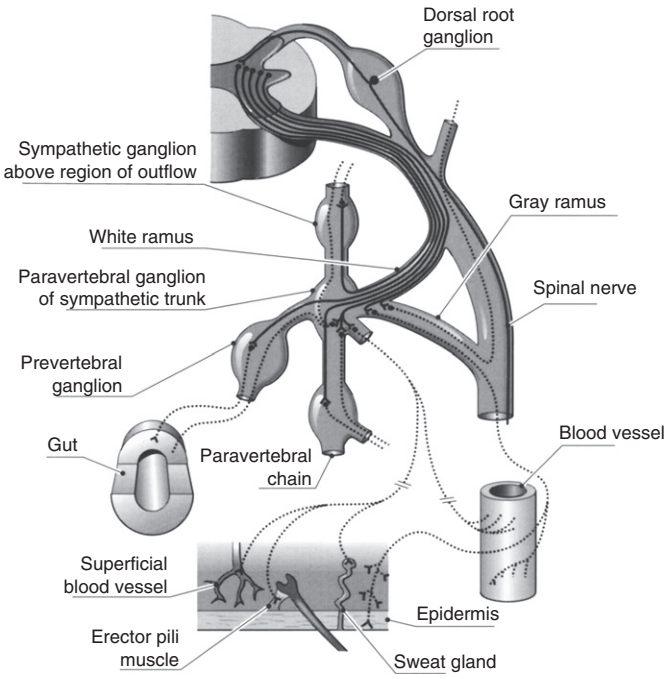

FIGURE 34.3 The SNS is organized segmentally. As illustrated here for one segment of the thoracic spinal cord, preganglionic axons exit through the ventral root of the segment in which the preganglionic cell body is located. These preganglionic axons can be myelinated or unmyelinated and can project to the paravertebral ganglion associated with the segment, to neighboring ganglia of the paravertebral chain, to postganglionic neurons located distally in the prevertebral ganglia, or through one of the autonomic nerves. *From Brading (1999).*

and limbs. For the trunk and limbs, postganglionic axons course both alongside and within the somatic peripheral nerve innervating the region. These autonomic fibers innervate the blood vessels in the muscles (vasoconstrictor fibers), as well as different targets within the skin, including the sweat glands (sudomotor fibers) and erector pili muscles of erectile hairs (pilomotor fibers).

At the rostral end of the sympathetic chain, individual segmental ganglia are fused into aggregate ganglionic groupings. The sympathetic chain, in a modification of the paravertebral chain pattern (Figs. 34.4 and 34.6), innervates the head and the thoracic viscera. The most rostral group, the *superior cervical ganglion* (supplied from the first and second thoracic segments), supplies the head and neck. The targets of its projections are extensive, including the eyes, salivary glands, lacrimal glands, blood vessels of the cranial muscles, and even the blood vessels of the brain. The paravertebral ganglia just caudal to the superior cervical ganglion form the *middle cervical ganglion* and, moving caudally, the *stellate ganglion*. These latter ganglia supply the postganglionic sympathetic outflows that innervate the heart, lungs, and bronchi.

Unlike the trunk, limbs, head, heart, and lungs, organs of the abdominal cavity are innervated by postganglionic

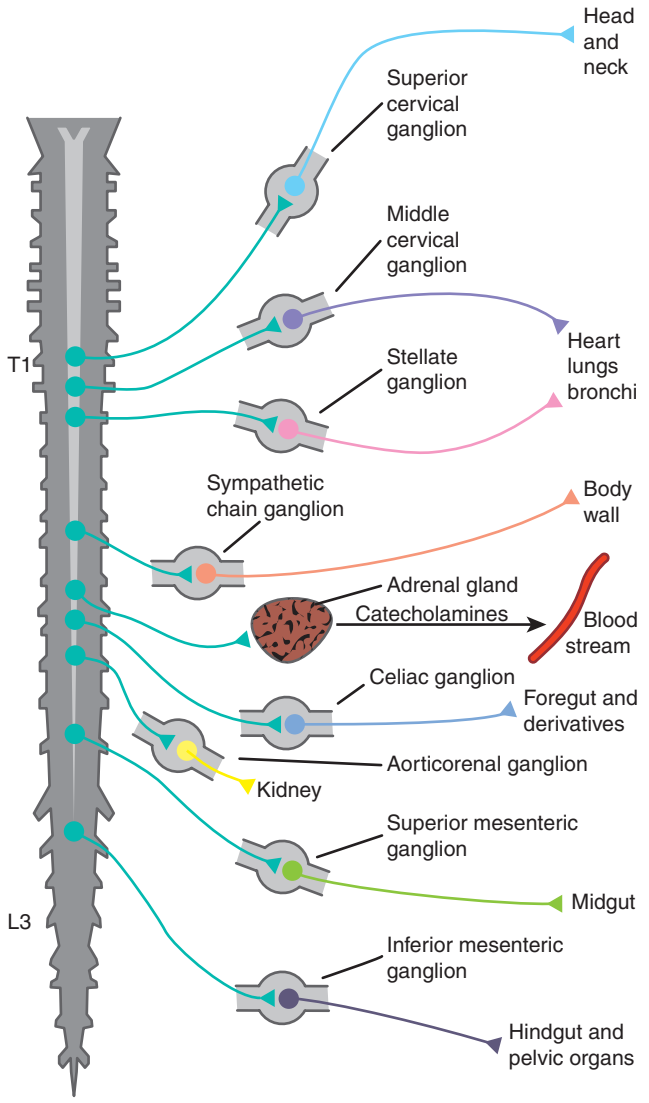

FIGURE 34.4 Summary of the major SNS ganglia and their target organs or tissues. Spinal cord is illustrated on the left. *From Loewy and Spyer (1990).*

neurons in ganglia situated distal to both the spinal cord and the paravertebral sympathetic chain in locations closer to the target tissue. These sites give the ganglia their distinguishing name: *prevertebral ganglia*. The preganglionic neurons innervating these sets of postganglionic neurons are located in the intermediolateral column of the spinal cord, like those innervating the paravertebral chain, but their axons pass through the white rami, the chain ganglia, and the gray rami without synapsing. They then make contact with the peripherally situated prevertebral ganglion cells (Fig. 34.3).

There are four major prevertebral postganglionic stations. The more rostral three are located at points where major abdominal arteries separate from the descending aorta, and the ganglia take their names from their associated arteries (Fig. 34.5). Moving from more rostral to caudal, the *celiac*, *superior mesenteric*, and *inferior mesenteric ganglia* innervate the gastrointestinal tract. The celiac ganglion (also commonly called the solar plexus because its connectives radiate from it) projects predominantly to the stomach and rostral-most parts of the foregut and its embryological derivatives, such as the liver and pancreas. Consistent with their progressively more caudal locations, the middle and inferior mesenteric ganglia innervate the mid- and hindgut tissues, respectively. The inferior mesenteric ganglion also supplies the postganglionic innervation to the pelvic organs. The fourth, and most caudal, prevertebral ganglion is the *pelvic–hypogastric plexus*, which innervates urinary and genital tissues. Perhaps because these prevertebral ganglia are located farther from the spinal cord and closer to the target organs (than the paravertebral ganglia) and because they coordinate responses of visceral organs containing separate nerve networks (the enteric nervous system is described later), these prevertebral ganglia may have more complex neural organization than the paravertebral chain ganglia.

The adrenal medulla is a unique variant of the sympathetic postganglionic pattern. By several criteria, the adrenal medulla is a sympathetic prevertebral ganglion containing postganglionics. However, neurons of this medullary ganglion, rather than issuing axons to innervate target organs, function as a neuroendocrine organ. The adrenal medulla secretes the classical postganglionic sympathetic transmitter norepinephrine, as well as epinephrine, directly into the bloodstream. These catecholamines then circulate as hormones. Release of catecholamines from the adrenals during sympathetic activation provides powerful reinforcement and modulation of the more focal release of catecholamines at traditional—and local—effector sites.

Summary

Overall, the two major motor outflows, or divisions, of the ANS are responsible for the maintenance of homeostasis and support of behavioral responses, but the sympathetic nervous system is the branch specialized for the mobilization of energy. The SNS provides the vascular, glandular, metabolic, and other physiological adjustments that optimize behavioral responses, particularly in emergency situations and conditions requiring activity. The SNS efferent outflow consists of preganglionic neurons, which are located in the intermediolateral column of the thoracic and lumbar spinal cord. SNS efferent axons course to paravertebral and prevertebral ganglia containing the postganglionic neurons, the axons of these postganglionic neurons project to the target tissues.

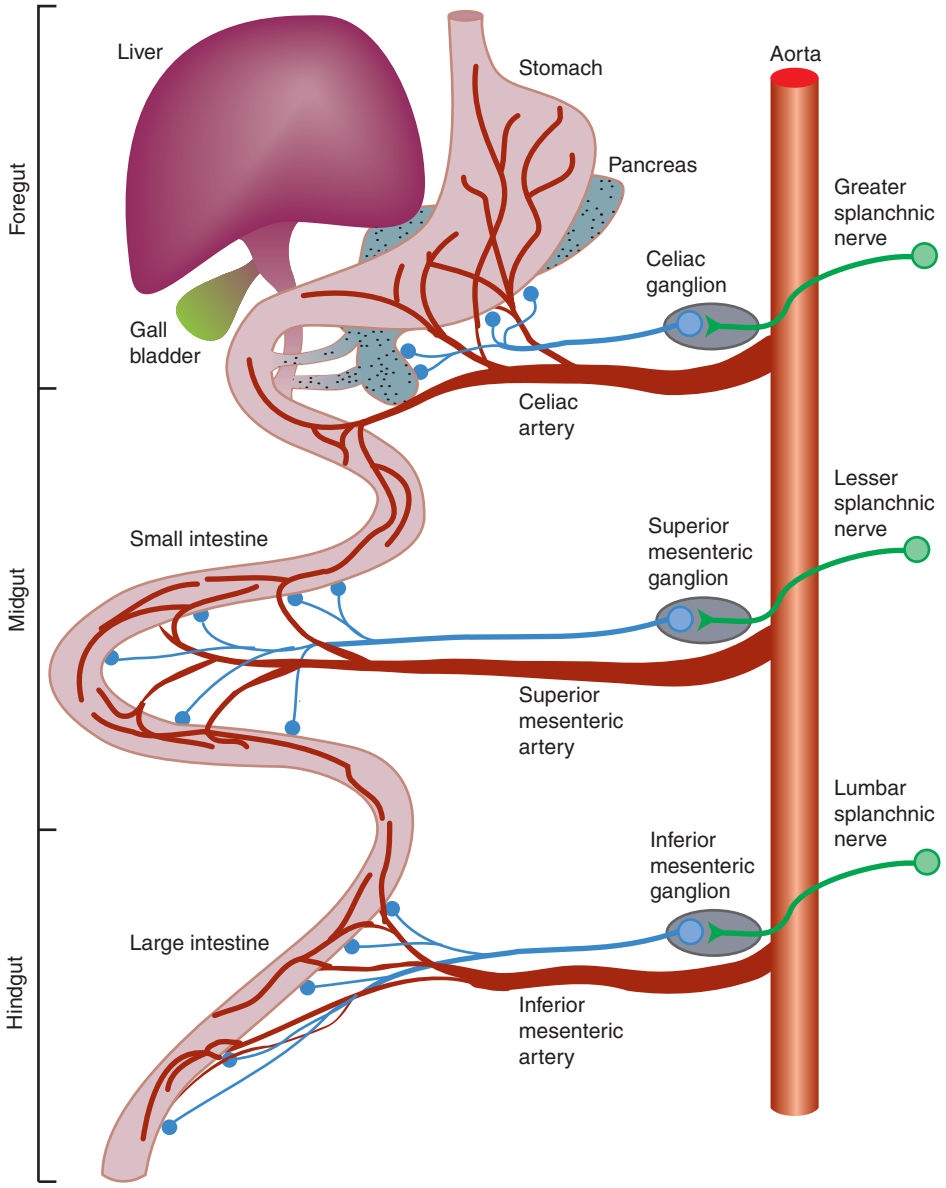

FIGURE 34.5 SNS innervation of the gastrointestinal tract. This more detailed schematic (compared to Fig. 35.4) illustrates how separate segmental levels of the spinal cord and the associated prevertebral ganglia innervate targets in a topographic, specifically viscerotopic, pattern. The association of autonomic pathways and vasculature is also shown. *From Loewy and Spyer (1990).*

PARASYMPATHETIC DIVISION: ORGANIZED FOR ENERGY CONSERVATION

Parasympathetic Nervous System Functions Reduce Energy Expenditure and Increase Energy Stores

Functionally, the parasympathetic nervous system mobilizes homeostatic adjustments that are often opposite and reciprocal to those activated by the SNS (see Table 34.1). In particular, PSNS adjustments usually are considered "rest and digest" responses, in contrast to the "fight-or-flight" sympathetic activation. The PSNS promotes anabolic processing, whereas the sympathetic nervous system augments catabolic activity. The PSNS promotes the gastrointestinal processes required to digest and absorb nutrients effectively. This branch of the ANS also augments the efficient use of energy and the storage of extra calories as fat and glycogen. The PSNS, particularly the vagus nerve, plays a central role in controlling the flow of body reserves or energy between storage depots and the tissues that use the energy. The body's energy reserves are fat in adipose tissue and glycogen in liver and muscle. After a meal, the gastrointestinal tract serves as an additional reservoir of potential energy for the body. By mobilizing triglycerides from adipose tissue or glycogen from liver and muscle, the ANS can make reserves available for metabolism; similarly, by moving nutrient stores (e.g., from the stomach) and promoting their digestion and absorption from the intestines into the bloodstream,

the ANS supplies energy to fuel metabolism or to restock triglyceride and glycogen stores, as needed.

Preganglionic Neurons of the Parasympathetic Nervous System Are Located in the Brainstem and the Sacral Spinal Cord

One of the features distinguishing the PSNS from the SNS is the location of their respective preganglionic neurons. PSNS preganglionic neurons are located in two longitudinal columns of neurons: one in the brainstem and the other in the sacral spinal cord. These locations of PSNS preganglionic neurons are responsible for the alternative name of this division of the ANS: the *craniosacral* (or *bulbosacral*) *division*. The longitudinal column of motor neurons in the brainstem is the general visceral cell column, which condenses into a number of nuclei ventrolateral to the cerebral aqueduct system within the brain. These nuclei then project through cranial nerves to targets in the head (cranial nerves III, VII, and IX) or thorax and abdomen (cranial nerve X) (Fig. 34.6). Cranial nerve III, the oculomotor nerve, carries the axons of the accessory, or autonomic, nucleus of the Edinger–Westphal complex, which participate in the control of the pupillary sphincter and ciliary muscles. Cranial nerve VII, the facial nerve, carries preganglionic axons of the superior salivatory nucleus and controls the submaxillary and sublingual salivary glands, as well as the lacrimal glands. Cranial nerve IX, the glossopharyngeal nerve, carries axons of the inferior salivatory nucleus, which control the parotid salivary glands and mucus secretion.

Preganglionic motor neurons of the Xth cranial nerve, the vagus nerve, control smooth muscles and glands throughout the digestive tract, from the pharynx to the distal colon, including viscera such as the liver and pancreas. These Xth nerve neurons occupy the dorsal motor nucleus of the vagus, a long fusiform nucleus in the medulla oblongata (Fig. 34.7). They control numerous motor and secretomotor responses that participate in the ingestion and digestion of food, as well as in the assimilation of the nutrients. The vagus nerve also carries motor fibers of a special visceral nucleus, the nucleus ambiguus or ventral vagal nucleus, which controls the striated muscles of the pharynx, larynx, and esophagus and the cardiac muscle of the heart. Much like the case described for sympathetic neurons, motor neurons of

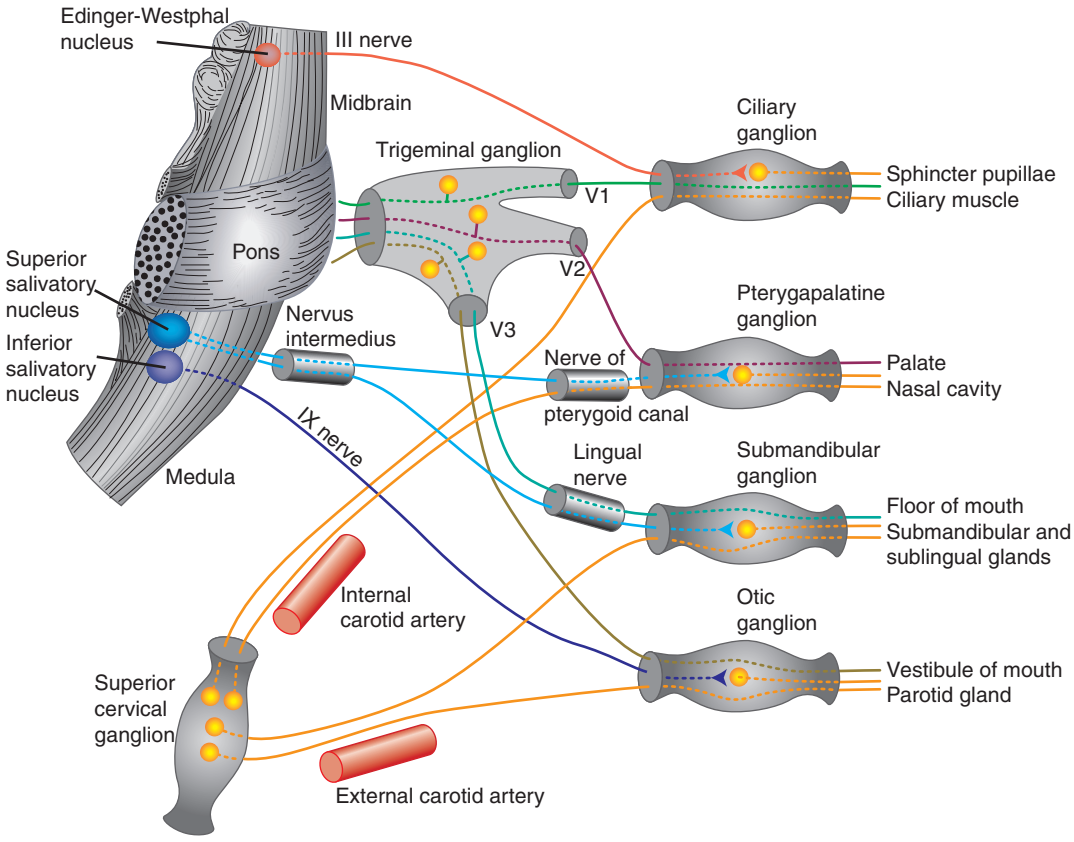

FIGURE 34.6 Autonomic innervation of the head by both sympathetic (superior cervical ganglion) and parasympathetic (cranial nerve nuclei in the medulla and midbrain projecting to the several prevertebral ganglia) pathways. Visceral afferents associated with the autonomic nervous system are found in the trigeminal nerve (cranial nerve V) ganglion. *From Loewy and Spyer (1990).*

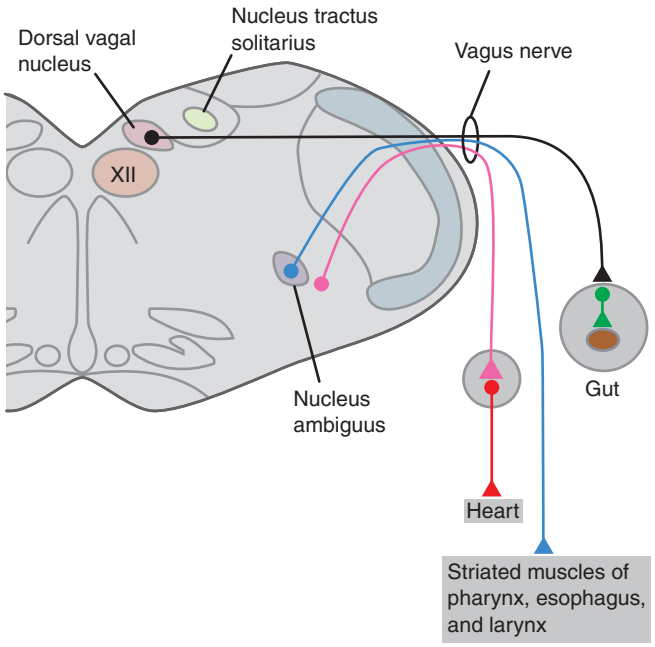

FIGURE 34.7 Parasympathetic projections of the vagal motor pathways, the most extensive of the PSNS circuits, to the viscera of the thorax and abdomen. *From Loewy and Spyer (1990).*

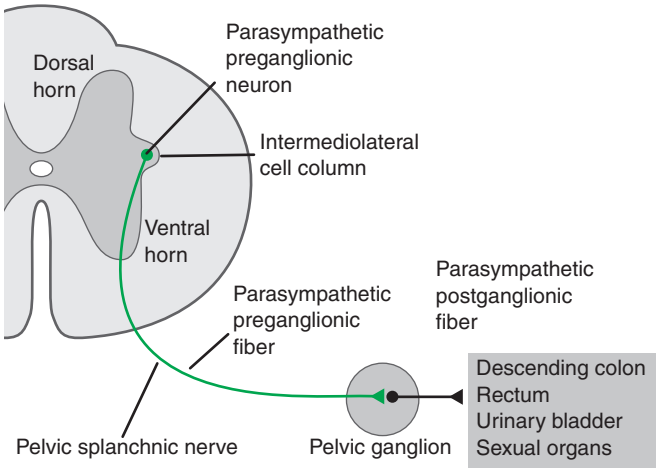

FIGURE 34.8 Spinal cord organization of the sacral division of the craniosacral, or parasympathetic, nervous system. *From Loewy and Spyer (1990).*

the dorsal motor nucleus of the vagus and the nucleus ambiguus are organized into viscerotopic subnuclei (e.g., Bieger & Hopkins, 1987; Fox & Powley, 1992).

The central representation of the more caudal part of the PSNS is found in the sacral spinal cord, in humans the second (S2) through fourth (S4) sacral segments (Fig. 34.8). The parasympathetic preganglionic somata occupy two longitudinal groupings: one column immediately dorsolateral to the central canal and the other in the same transverse location as that of the intermediolateral column of cells, which sympathetic preganglionics occupy in the thoracic and lumbar cord. Axons of the sacral preganglionics exit the cord in the ventral roots, run in a sacral plexus, and project to the target organs. The sacral preganglionic cell columns control parasympathetic motor, vasomotor, and secretomotor functions of the kidneys, bladder, transverse and distal colon, and reproductive organs.

The locations of their respective postganglionic neurons constitute another feature that distinguishes the PSNS from the SNS. Ganglia containing the PSNS postganglionic neurons are juxtaposed to, on the surface of, or even in, the target organ, in contrast to the para- and prevertebral locations of the SNS (Fig. 34.1c). These juxta- and intramural stations often are called *plexuses*, rather than ganglia. Like SNS prevertebral ganglia, the PSNS postganglionic plexuses are complex integrative sites that typically receive inputs not only from preganglionic neurons, but also from afferents within the plexuses or target tissues. Because the PSNS postganglionic neurons are situated so near their targets, the parasympathetic division of the ANS has, perforce, longer preganglionic axons and shorter postganglionic fibers than the sympathetic division. The relative lengths of the postganglionic fibers in the two divisions have been taken as an indication that individual axons of the SNS may diverge more extensively and innervate larger projection fields, whereas the PSNS may exhibit less divergence and more localized projections. (For counterarguments, see Wang, Holst, & Powley, 1995).

Summary

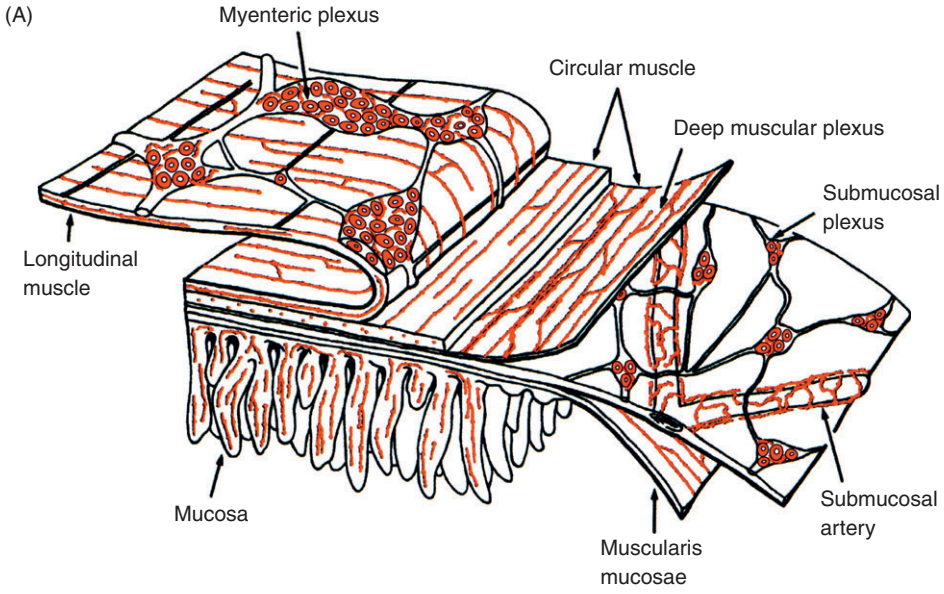
The parasympathetic nervous system or craniosacral division (i.e., the second major outflow of the ANS) is organized to digest, assimilate, and conserve energy, as well as promote rest. Its anabolic functions include not only those associated with the metabolism of nutrients, but also numerous protective reflexes, such as those that limit heat loss, reduce energy expenditure, and slow the heart. The PSNS outflow consists of preganglionic neurons located in brainstem cranial nerve nuclei or the autonomic columns of the sacral spinal cord. Their axons project to the postganglionic neurons located in ganglia situated near or in the target organs. Postganglionic neurons, in turn, project to the smooth muscle of the target viscera.

THE ENTERIC DIVISION OF THE ANS: THE NERVE NET FOUND IN THE WALLS OF VISCERAL ORGANS

Discussions of the ANS sometimes focus on the SNS and PSNS, but there is a third division as well. When Langley articulated the classic definition of the ANS, he

identified the *enteric nervous system* (ENS) as the third division. The alimentary canal, or "entrum," and the tissues derived from it, such as those in the pancreas and liver, contain extensive and well-formed neural networks. In particular, the gastrointestinal tract contains two major plexuses that contain as many neurons as the entire spinal cord (Fig. 34.9). Each plexus consists of an extensive sheet of small nodes of cells linked by connectives. One plexus, the myenteric plexus, is situated between outer longitudinal and inner circular muscle layers of the viscus. The other plexus, the submucosal or submucous plexus, is located between the circular muscle layer and the lumenal mucosal layer of the viscera. As illustrated in Figure 34.9, there are additional, less extensive, enteric networks as well.

The number of neurons in the enteric plexuses, their extensive interconnections, and their capacity to support motility have led to proposals that the enteric nervous system serves as a more or less independent "brain" in the gut (Wood, 1987). Early descriptions emphasized



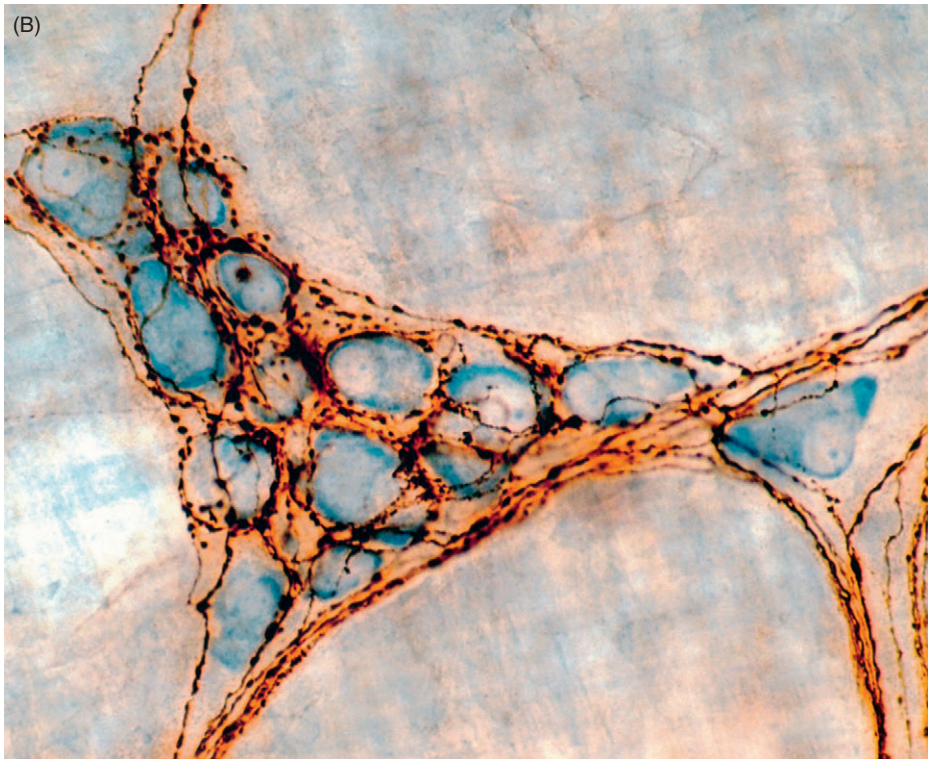


FIGURE 34.9 (A) The enteric nervous system plexuses in the wall of the intestine. Enteric neurons form two conspicuous and extensive networks, or plexuses, of ganglia and connectives located between the longitudinal and circular muscle layers of the wall (the myenteric plexus) and the circular muscle layer and the inner mucosal layer (the submucosal plexus). The deep muscular plexus, periglandular plexus, and villous plexus are additional networks of enteric neurons and their processes. *From Furness (2006).* (B) Autonomic preganglionic terminals innervating postganglionic neurons. This example of vagal preganglionic projections (brown, labeled with the tracer *Phaseolus vulgaris*) innervating myenteric ganglion neurons (blue, stained with Cuprolinic blue) in the stomach wall illustrates that autonomic preganglionic axons can form extensive networks controlling postganglionics. *From Holst, Kelly, and Powley (1997).*

the autonomy of the ENS by observing that the gastrointestinal tract could exhibit movement, peristalsis, even after all extrinsic connections to it were cut. However, fully integrated or coordinated responses of the gastrointestinal tract, including motor responses other than peristalsis, as well as absorptive and secretory responses, involve extrinsic projections from the central nervous system to the enteric nervous system.

Because the preganglionic neurons of the vagus nerve project to the enteric ganglia rather than to independent postganglionic stations, the ENS serves as an extensive postganglionic relay station for the vagus (Fig. 34.9B).

Summary

The ENS or enteric nervous system, the third division of the ANS, consists of ganglia and plexuses of intrinsic neurons in the walls of the viscera such as the gastrointestinal tract. These nerve networks contain intrinsic afferents, interneurons, and efferents that control local functions; they also receive extrinsic inputs from autonomic preganglionic efferents, particularly those PSNS projections coursing in the vagus nerve.

ANS PHARMACOLOGY: TRANSMITTER AND RECEPTOR CODING

Early in the twentieth century, pharmacological studies performed with naturally occurring agonists and antagonists provided the basis for the original differentiation of two major ANS divisions: the SNS and PSNS. Prior to the pharmacological analyses, the two often had been lumped together. Dale (the contributor of "Dale's law" of neurotransmitters), Langley, and a number of other early investigators applied natural extracts such as muscarine, nicotine, *d*-tubocurarine, and others to autonomic ganglia while measuring responses in order to infer the chemical taxonomy of the ANS. Subsequent experiments have replicated the basic distinctions made by these investigators, but this newer research, with access to a pharmacopoeia of synthetic agonists and antagonists, as well as to immunocytochemistry for the characterization of transmitter substances, has described a much richer and more complicated multiplicity of neurotransmitters, neuromodulators, and receptor subtypes in autonomic nerves (Lundberg, 1996).

Preganglionic Neurons Use Acetylcholine as a Transmitter

Most preganglionic neurons of both the SNS and PSNS have a cholinergic transmitter phenotype. Only relatively small subpopulations of preganglionic neurons express other (e.g., dopaminergic or adrenergic) phenotypes. In the peripheral ganglia of these two divisions of the ANS, most postganglionic neurons, which receive inputs from the preganglionics, express a predominance of a nicotinic form of the cholinergic receptor on their somata. As discovered by the early autonomic pharmacologists, nicotine can serve as a general "ganglionic blocker" to thwart transmission at these synapses. Additional specificity and response selectivity, or coding, at the ganglionic level normally are maintained by the segregation of sympathetic and parasympathetic postganglionic neurons in separate ganglia, by point-to-point axonal projections, by distinguishing neuropeptides colocalized with the transmitter, and by the spatial separation of synapses within ganglia.

SNS and PSNS Postganglionic Neurons Use Different Transmitters

The respective transmitter phenotypes of the postganglionic neurons constitute one of the cardinal defining differences between the sympathetic and parasympathetic nervous system. The majority of SNS postganglionic neurons release the transmitter norepinephrine, whereas PSNS postganglionic neurons release primarily acetylcholine. Such a two-transmitter chemical code produces push–pull or positive bidirectional control of individual targets.

The biomechanics of smooth muscle are quite different from the biomechanics of striated muscle. In contrast to skeletal muscle, smooth muscle is not always organized into antagonistic pairs, with each member of the pair being innervated by a different motor neuron. Also, the smooth (and cardiac) muscles forming the walls of the viscera are not differentially attached to a hard frame to provide mechanical leverage through opposal activity. Reciprocal motor programs of the viscera, for the most part, involve active, phased contraction and relaxation of the same muscle to achieve coordination. To produce these patterns of excitation and inhibition, the target organs and tissues express both adrenergic and cholinergic receptors and have different, often antagonistic or complementary, responses to selective activation of the different receptors.

Response patterns of smooth muscle are further differentiated by specializations of the receptors. Adrenergic receptors, influenced by the catecholaminergic transmitter released by sympathetic fibers, are differentiated into at least four different metabotropic subtypes linked to different intracellular pathways. Similarly, the muscarinic acetylcholine receptor, influenced by the cholinergic transmitter released by parasympathetic postganglionic neurons, is differentiated into at least three ionotropic subtypes with differential influences on intracellular transduction. These heterogeneities of transmitter species and receptor types make it practical to mobilize multiple, different, and

BOX 34.1

AUTONOMIC POSTGANGLIONIC NEURONS CAN CHANGE THEIR TRANSMITTER PHENOTYPES

Transmitter phenotypes of autonomic neurons generally seem fixed, dictated by both intrinsic and extrinsic developmental cues. At least some ANS neurons, however, can alter their phenotypes under appropriate environmental conditions. This conclusion first was reached when populations of postmitotic adrenergic and cholinergic neurons were cocultured *in vitro* in different media or in the presence of different tissues. Without changes in overall cell number, the percentages of adrenergic and cholinergic neurons in a given culture changed over time. Even more definitively, when single postganglionic cells were grown in microculture wells, the presence of a medium conditioned by heart cells caused some of these mature neurons to change from an adrenergic to a cholinergic phenotype (Potter, Landis, & Furshpan, 1980).

This phenotypic switching does not appear to be an artifact of cell culture situations; the change appears to occur normally *in vivo* in development to generate the specialized minority of sympathetic postganglionic neurons that are cholinergic (e.g., for innervation of sweat glands). Landis and Keefe (1983) have verified this hypothesis by using rat foot pad sweat gland innervation *in vivo* and characterizing the transmitter phenotype of the autonomic projections at different stages of development. The developing sympathetic postganglionic innervation of the sweat glands initially expresses a typical adrenergic phenotype as the axon grows toward its target. Once the sweat gland target is innervated, however, the tissue induces the change in neurotransmitter phenotype to a cholinergic one.

Such changes in transmitter are not unique to these examples. Perhaps reflecting pluripotential patterns seen earlier in phylogeny, at least some cholinergic neurons (e.g., avian ciliary ganglion cells) appear to remodel into an adrenergic phenotype, whereas other cells (e.g., maturing neural crest cells in the developing gut wall) exhibit a transient catecholaminergic stage that is lost during the ingrowth of extramural innervation.

Finally, in addition to such switching, autonomic postganglionic neurons also have been shown to exhibit plasticity in altering their levels of transmitters and cotransmitters as a function of the activity of their preganglionic inputs. For example, after preganglionic inputs are blocked or transected pharmacologically, postganglionic neurons of the superior cervical ganglion decrease their levels of tyrosine hydroxylase while increasing their level of substance P.

Terry L. Powley

potentially highly differentiated responses from one effector tissue (Box 34.1).

Response selection may also be facilitated by neuropeptides that the postganglionic neurons synthesize and corelease during activity. Somatostatin, neuropeptide Y, or both are found in many sympathetic neurons; vasoactive intestinal polypeptide and calcitonin gene-related peptide are often coexpressed in parasympathetic neurons. These peptides may serve as neuromodulators that vary postsynaptic responses to the conventional autonomic neurotransmitters (e.g., Costa, Furness, & Llewellyn-Smith, 1987). The release of different neuropeptides and cotransmitters can vary with different rates or patterns of firing and is not invariantly proportional to transmitter release. Thus, a heterogeneity of different cotransmitter and transmitter release patterns can be produced by a single fiber or fiber type, depending on firing pattern and other local factors at the synapse (e.g., Lundberg, 1996).

Although dual innervation in an oppositional or push–pull pattern is presumed to yield faster, more responsive adjustments and to provide a mechanism that can adjust response gain, some tissues are innervated by only one arm of the ANS. The SNS has a wider distribution than the PSNS. In particular, white and brown adipose tissue, peripheral blood vessels, and sweat glands are innervated by the SNS without reciprocal PSNS projections. One possible explanation for this arrangement is that the functions of these particular effectors do not require the speed associated with push–pull projection patterns, particularly in terminating responses once activated. Furthermore, in the evolution of the autonomic nervous system, the SNS is thought to be the older, and correspondingly more extensive, network, whereas the PSNS occurred more recently in phylogeny and therefore has less widespread projections.

Finally, the enteric nervous system also has an extensively varied set of transmitters, cotransmitters, and neuromodulators, providing highly differentiated chemical coding of local functions (Furness, 2006; Lundberg, 1996).

Summary

Both the SNS and the PSNS use acetylcholine as a preganglionic transmitter, but they are distinguished by different postganglionic phenotypes: most SNS postganglionic neurons are catecholaminergic; most PSNS postganglionics

are cholinergic. The different neurotransmitter and cotransmitter elements expressed in the postganglionic neurons, as well as numerous postsynaptic receptor subtypes, provide the chemical coding for responses of the PSNS and SNS. This functional organization ensures a varied, powerful, and dynamic push–pull operation of homeostatic systems.

AUTONOMIC COORDINATION OF HOMEOSTASIS

The "self-governing" or autonomic characteristic that gives its name to the ANS is based largely on reflexes that involve more than peripheral efferent pathways. Though the early history of autonomic neuroscience emphasized this motor outflow, homeostasis is maintained through the cross-coupling and coordination of multiple reflex arcs. These reflexes involve afferent inputs as well as efferent outputs.

Two major inflows of visceral, or autonomic, afferents (Box 34.2) establish the input arms of the basic reflex arcs. These visceral afferents also provide critical cross-linked feedback between the sympathetic and the parasympathetic outflows, keeping them in balance. For example, sympathetic activity can increase heart rate (tachycardia) and produce constriction of strategic vascular beds, thus leading to an increase in blood pressure. This increase in blood pressure, in turn, is detected by vagus nerve baroreceptors in the aortic arch and other sites. Visceral afferents in the vagus can then reflexively stimulate vagal parasympathetic efferents that slow heart rate (bradycardia). The visceral afferents monitoring the effects of autonomic activity produce positive, reciprocal, and dynamic regulation of physiological responses. When a more sustained adjustment in blood pressure is required (e.g., in the general arousal of the fight-or-flight response), these outflows are adjusted centrally in a process akin to the α–γ linkage so that sympathetic activation is not nullified by parasympathetic responses damping the needed activation.

Visceral Afferents Link Target Tissues and the CNS

In the case of the sympathetic nervous system, motor neurons receive direct afferent input from most of the autonomic targets. The cell bodies of these primary afferents are located in the dorsal root ganglia of the spinal cord segment(s) in which the corresponding preganglionic neurons are located (Figs. 34.2B and 34.10). Afferent somata are similar to other dorsal root ganglion cells, although they frequently are distinguishable as relatively small, dark neurons or B afferents. From endings in the innervated viscera or tissue, the centripetally directed

BOX 34.2

AUTONOMIC REFLEXES: ACTIVATED BY VISCERAL AFFERENTS, AUTONOMIC AFFERENTS, OR JUST AFFERENTS?

A long-standing dispute about terminology still influences discussions of autonomic reflexes. Some authors (and textbooks) adhere to the original autonomic classification of Langley, who considered the ANS a motor system without a corresponding sensory inflow. This classic view acknowledges that autonomic effectors are influenced by afferents but considers visceral afferents, as well as somatic afferents, as independent of the ANS. Conversely, other scientists (and textbooks) consider afferents arising in and associated with the viscera as the necessary counterpart to autonomic efferents and label them autonomic afferents.

The controversy goes back to Langley's concentration on a pharmacological definition of the ANS. In his initial studies, Langley speculated about the existence of autonomic afferents, but was unable to find a neurochemical marker to distinguish visceral from somatic afferents. He sidelined the issue pending more information (his seminal book is subtitled Part I), focused his studies on efferents, and never returned to the search for an afferent marker (Part II never appeared). Adherents to his original motor-only classification stress that somatic and visceral afferents can elicit autonomic responses and that both classes of afferents elicit somatic responses, as well.

However, advocates for including visceral afferents within the autonomic schema argue that these afferents innervate the target tissues of the ANS efferents, share similar embryological histories with autonomic efferents, course in the same peripheral nerves as the autonomic efferents (e.g., the vagus), and form mono- and oligosynaptic reflex arcs influencing autonomic preganglionic neurons. These proponents for revision of the autonomic terminology also point out that more recent analyses have identified neuropeptide markers shared by visceral afferents (but not somatic afferents) and autonomic motor neurons. This more inclusive view of the autonomic nervous system seems to be gaining ground. It works more naturally for the discussion of reflexes, and we have adopted it in this text.

Terry L. Powley

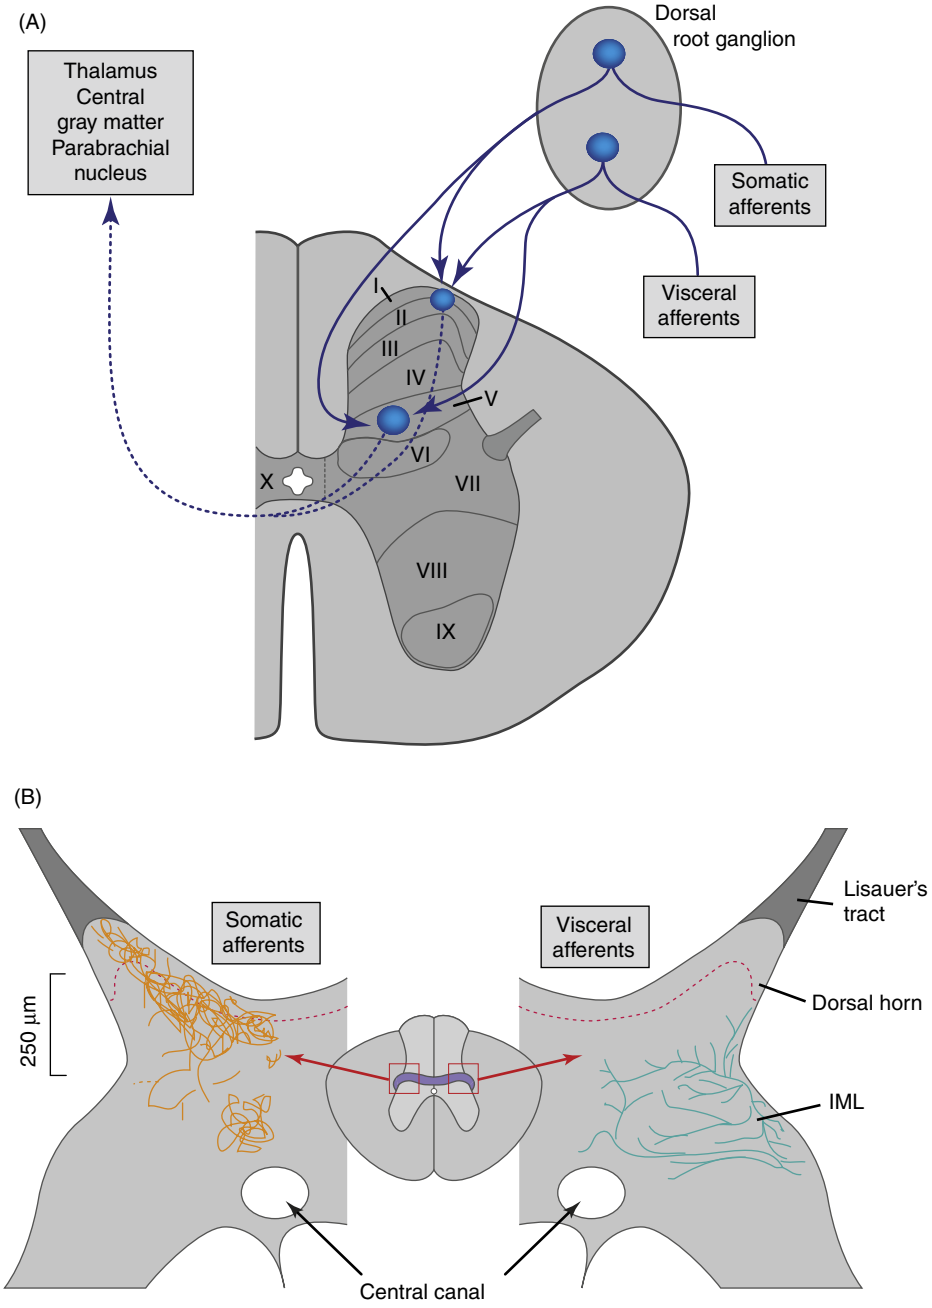

FIGURE 34.10 Visceral and somatic afferents follow parallel but distinct paths in the central nervous system. Visceral and somatic afferents consist of different populations of dorsal root ganglion neurons that project to laminae I and V of the dorsal horn of the spinal cord. These relay sites provide local spinal reflexes and also project to higher autonomic and somatic sites, respectively, in the brain (A). Although visceral and somatic afferents follow similar trajectories, more detailed analyses indicate the two types of afferents end in distinctly different distributions and densities within the spinal cord (B). IML, intermediolateral cell column. *From Cervero and Foreman (1990).*

peripheral processes of the afferents typically course in mixed nerves that also contain the motor outflow. These processes then reach the dorsal roots through the major peripheral nerves. The central processes of these visceral afferents enter the spinal cord in association with Lissauer's tract, ending in laminae I and V of the dorsal horn (Cervero & Foreman, 1990). For many of these visceral afferents, their endings in the periphery and in the spinal cord contain substance P (SP) and other neuropeptides of the tachykinin family, such as neurokinin A (NKA) and neurokinin B (NKB) (see Lundberg, 1996).

Visceral afferent nerves relay sensory information about visceral volume, pressure, contents, or nocioceptive stimuli to spinal centers, where automatic responses are interpreted and reflex responses are generated.

In the parasympathetic limb of the ANS, there are two major afferent inflows with different organization. In the cranial division, visceral afferents most often are found in the same cranial nerve as their corresponding motor counterparts. These mixed cranial nerves have sensory ganglia located outside the cranium, and the cell bodies of the afferents are found in these ganglia. Like other visceral afferents, these neurons are typically pseudounipolar neurons with a peripheral neurite extending to the target tissue and a central process projecting to the CNS. The central terminals of these afferents end in a cranial nerve sensory

nucleus. Visceral afferents associated with the outflow of cranial nerve III are complex and enter through different channels (e.g., cranial nerve V, the trigeminal nerve). Most of the visceral afferents associated with cranial nerve autonomic reflexes terminate in the extensive nucleus of the solitary tract, which is located immediately dorsal to the general visceral column of the brainstem. Specifically, afferents of VII, IX, and X all end in the nucleus of the solitary tract. These inputs form a viscerotopy in the nucleus, with facial gustatory information projecting most rostrally and medially, the glossopharyngeal information somewhat more caudally, and the afferents of the different branches of the vagus nerve terminating most caudally in different subnuclei of the nucleus of the solitary tract. As the largest and most complex of the visceral afferent relays in the brain, the nucleus of the solitary tract also receives afferent inputs from the spinal division of the trigeminal nerve and second-order inputs from the dorsal column nuclei.

Like visceral afferents associated with the SNS, visceral afferents associated with the PSNS contain SP and other tachykinins. In addition, several neuropeptides found in the gut are also found in some of these afferents. For example, the gut hormone and neuropeptide cholecystokinin (CCK) is found in vagal afferents relaying information from the gastrointestinal tract to the brain. CCK is also found in higher-order ascending relays of vagal projections in the neuraxis, leading some to argue that CCK provides chemical coding for visceral afferents associated with the gastrointestinal tract.

The second major inflow of afferents to the parasympathetic limb of the ANS is associated with the sacral division. Visceral afferents in this division are organized much like the spinal afferents associated with the thoracolumbar or sympathetic division of the ANS (e.g., Morgan, Nadelhaft, & de Groat, 1981).

At the central relays of autonomic reflex arcs, the thoracolumbar spinal circuitry of sympathetic reflexes and the craniosacral circuitry of parasympathetic responses have similar morphological elements. The SNS motor neurons preferentially distribute their dendrites within the long longitudinally oriented column that constitutes the intermediolateral nucleus of the spinal cord. The neurons also distribute a subset of their dendrites dorsolaterally in an arch that brings the dendrites into contact with the incoming visceral afferents (e.g., Dembowsky, Czachurski, & Seller, 1985). Parasympathetic preganglionics exhibit similar dendroarchitecture (e.g., Fox & Powley, 1992). This characteristic dendroarchitecture is consistent with the ideas that local mono- or oligosynaptic reflexes are organized segmentally and at the preganglionic outflows.

Visceral Afferents Also Organize Axon Reflexes and Signal Visceral Pain

In addition to forming conventional reflex circuits throughout the ANS, at least some visceral afferents support effector responses known as *axon reflexes*. Unlike a conventional reflex, which typically involves an afferent neuron, at least one central nervous system synapse, and an efferent neuron, axon reflexes involve only the afferent neuron and they occur in the target tissue—without a CNS relay. The phenomenon can be seen clearly in the type of experiment that was instrumental in establishing the existence of axon reflexes. If all motor axons projecting to a target tissue are eliminated by surgery or other appropriate means while the afferent innervation of the site is spared, the afferent axons can be stimulated selectively. When the afferent axons are stimulated such that their peripheral processes innervating the target are invaded antidromically, one can measure an effector response or assay the release of a neuropeptide from the peripheral afferent neurite. Such experiments performed on a variety of different visceral and cutaneous afferent systems have demonstrated that axon reflexes produce a number of inflammatory and vascular effector responses (Lundberg, 1996).

When a peripheral ending of a visceral afferent transduces a stimulus, the resulting action potential can release the neuropeptide contained in vesicles in that ending (Fig. 34.11). The released compound then acts as

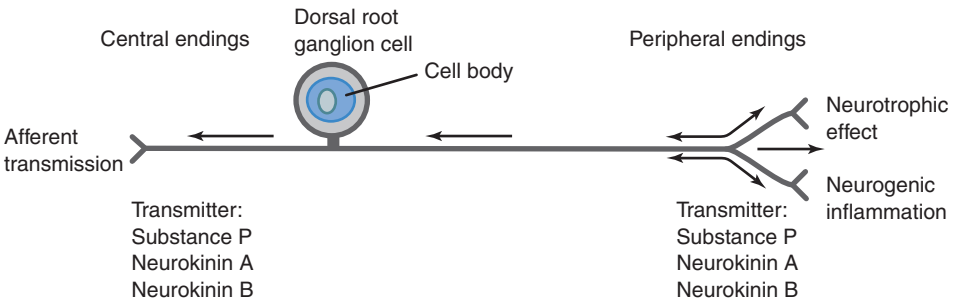

FIGURE 34.11 The architecture of visceral afferents that produce axon reflexes. Visceral and cutaneous afferents release transmitters from the tachykinin family. When action potentials (indicated by arrows) are generated peripherally, they are propagated centrally. Peripherally generated action potentials also produce a local release of tachykinins in the affected terminals and in terminals of the peripheral collaterals. *From Cervero and Foreman (1990).*

a neuromodulator or neurotransmitter to produce local changes on smooth muscle—a local, or peripheral, axon reflex. The response is also relayed to neighboring tissues. When an action potential is transmitted centrally in an afferent axon, it can also be transmitted centrifugally by collaterals of the same fiber, and release of the neuromodulator from these collateral endings can propagate the reflex in the immediate area. The inflammatory responses and extravasation associated with the classic "wheal and flare" reaction to skin damage were the first axon reflexes analyzed and are a classic illustration of the phenomenon. Such local responses have been widely documented not only in the skin, but also in viscera such as the lungs.

Finally, visceral afferents, particularly those associated with SNS pathways, are responsible for visceral pain (Craig, 2002; Jänig, 1996).

Summary

Visceral afferents innervate the target tissues of the ANS, and their axons frequently course in the same peripheral nerves as autonomic efferents. Also commonly called autonomic afferents, these sensory elements associated with the ANS constitute the afferent limbs of autonomic reflexes and carry the inputs recognized as visceral pain. Visceral afferents also mediate axon reflexes and are cross-linked with somatic, as well as autonomic, nervous system activity.

HIERARCHICALLY ORGANIZED ANS CIRCUITS IN THE CNS

Homeostasis no more occurs through isolated autonomic reflexes than posture is maintained, or movement is executed, through isolated somatic reflexes. Nevertheless, methodological and historical considerations have yielded a tendency to focus on individual autonomic reflexes. Methodologically, the need for experimental control typically dictates that experiments isolate a reflex (or small set of reflexes) for examination. In addition, historically, the ANS was conceptualized primarily as a motor branch of the peripheral nervous system.

Though the separate-reflex perspective has in some ways shaped a view of ANS functions as a collection of individual motor responses, autonomic activity typically involves finely coordinated, fully integrated adjustments of multiple outflows. Just as somatic posture and movement are coordinated by supraspinal CNS controls, autonomic integration is achieved by supraspinal controls. The preganglionic motor pools of the craniosacral and thoracolumbar outflows are final common paths for descending projections from the CNS. Similarly, the first- and second-order visceral afferent relays (e.g., the nucleus of the solitary tract and the spinal lamina V), which form short, mono-, or oligosynaptic reflex arcs with these preganglionic motor pools, are targets of rostral CNS stations that coordinate and modulate the autonomic outflows.

The CNS coordination of autonomic activity achieves a number of integrative functions:

- Much like the suprasegmental organization of skeletal motor responses, central ANS stations provide coordination and sequencing of different local autonomic reflexes. These stations provide, for example, the efferent choreography necessary to coordinate the sequential autonomic responses in the mouth, stomach, intestines, and pancreas during and after a meal. Such programs coordinate brainstem and spinal cord efferents, as well as reflexes within the SNS and PSNS divisions of the autonomic outflow.
- Central ANS circuitry also cross-links autonomic activity and somatic motor activity. The example used earlier of cardiovascular adjustments occurring in concert with postural adjustments illustrates such linkage between autonomic and somatic nervous system outflows.
- The CNS stations of the autonomic nervous system also provide the information, as well as the organization and planning, that enables an organism to mobilize autonomic adjustments or responses in anticipation of environmental contingencies and developing needs. For example, both fluid and energy homeostasis involve physiological adjustments in anticipation of major imbalances or deficits, responses that cannot be explained solely by reactive reflexes.

The importance and the nature of central autonomic controls are underscored by clinical disorders that result from interruptions in the connections between the central autonomic circuitry and the preganglionic motor neurons (Box 34.3). Quadriplegia and paraplegia, which result from injuries that divide the separate thoracic and lumbar sympathetic loops and sacral parasympathetic pathways from higher central regions, illustrate how essential these longitudinal connections are. Interruption of the longitudinal connections causes loss of voluntary bladder and bowel control. Disruption of the spinal cord also causes men to become impotent because penile tumescence is a predominantly parasympathetic response and ejaculation is a sympathetic response. Although erections can occasionally be elicited as local reflexes caused by direct mechanical stimulation, ejaculations, which normally require suprasegmental coordination, almost universally disappear. In addition, numerous vascular and glandular reflexes are also disordered by the interruption of long autonomic pathways connecting the brain and spinal cord (Bannister, 1989).

BOX 34.3

DISEASES AND AGING IMPAIR THE AUTONOMIC WISDOM OF THE BODY

The importance of the autonomic nervous system to health often goes unnoticed. When ANS functions operate normally, they typically occur automatically, without the individual being aware of any adjustments. Nevertheless, loss of an autonomic response can be disruptive, and autonomic disorders can be debilitating (Bannister, 1989). In a classic example of ANS degeneration known as multiple system atrophy and autonomic failure, or the Shy–Drager syndrome, individuals exhibit postural hypotension, urinary and fecal incontinence, sexual impotence, loss of sweating, cranial nerve palsies, and a movement disorder similar to Parkinson's disease. Disconnection of the suprasegmental autonomic stations from the spinal cord can occur in neurological disorders, such as multiple sclerosis, and traumatic spinal cord injury. As a result, bowel and bladder control are lost, and impotence is caused by a loss of autonomic genital reflexes.

Some autonomic disorders are less conspicuous. In part, the apparently more subtle deficits may be ones that are less important in the carefully controlled environments found in modern societies. For example, impaired thermoregulatory responses may be tolerated well by a person living in a climate-controlled environment. Also, metabolic emergencies are unlikely to occur and need autonomic compensation if a person regularly eats enough food. Nevertheless, autonomic disorders occasion a number of serious, even life-threatening, health problems.

Autonomic imbalances can take many different forms. Excess activation of the ANS is implicated in various stress-related disorders, including ulcers, colitis, high blood pressure, and heart attacks. As discussed earlier, chronic failure of autonomic cardiovascular homeostasis can cause debilitating postural hypotension. Developmental autonomic disorders, such as immature or anomalous medullary respiratory circuitry, are thought to contribute to sudden infant death syndrome. Some sleep disorders, such as sleep apnea, are also thought to have autonomic elements. Furthermore, widespread autonomic dysfunction resulting from autonomic neuropathies of diabetes, alcoholism, and Parkinson's disease complicates the primary diseases. Autonomic disturbances can also underlie metabolic disorders, such as stress-induced diabetes and reactive hypoglycemia. Autonomic disturbances have also been hypothesized to be a cause of obesity.

Autonomic function is not only impaired by diseases, it is also compromised by aging processes—even those of healthy aging (Amenta, 1993). With aging, both cell losses and neuropathies of surviving neurons occur in ANS circuits. Such age-related changes in the ANS reduce an individual's ability to optimize and sustain homeostatic responses. These consequences of aging produce both primary autonomic disorders and secondary complications and vulnerabilities when the individual is challenged by disease or injury.

Terry L. Powley

Early Stimulation and Lesion Experiments Identified a Central Component of the ANS

Like the concept of the ANS itself, the corollary that the ANS includes a hierarchy of central mechanisms was first demonstrated by physiological experiments. Nineteenth- and early twentieth-century experiments manipulating the brain caused autonomic disturbances. In one classical experiment, for example, Claude Bernard demonstrated that localized mechanical lesions, or stab wounds, in the floor of the fourth ventricle near the dorsal vagal complex produced a "piqure glycosurique," a disturbance of blood glucose homeostasis characterized by a diabetes-like condition in which glucose spills into the urine. Subsequent lesion and stimulation studies identified a number of "centers" for micturition, respiration, and other autonomic functions in the medulla oblongata and pons.

Other experiments implicated the hypothalamus in even more extensively coordinated and cross-linked autonomic patterns. This work led to the concept of the hypothalamus as the "head ganglion" of the autonomic nervous system. Following an earlier application of electrical stimulation to the hypothalamus by Karplus and Kreidl, Walter Hess found that focal electrical stimulation of regions of the hypothalamus elicited coordinated patterns of sympathetic and parasympathetic adjustments (e.g., changes in pupil size, piloerection, and respiration) and affective responses that were appropriate to behavioral responses elicited from the same loci. In fact, central manipulations that affect autonomic function seem practically invariably to produce adjustments of both SNS and PSNS outputs, an observation that underscores the integrative role the brain plays in ANS function.

Brain lesions in virtually all limbic system regions, and notably in the septal area, amygdala, hippocampus, frontal cortex, cingulate cortex, and insular cortex, have been shown to exaggerate, dissociate, blunt, or in other ways distort autonomic responses to environmental situations.

Anatomical Mapping Experiments Have Identified Multiple Hierarchically Organized, Reciprocally Interconnected Stations of the Visceral Neuroaxis That Control Autonomic Activity

As neuroscience tracing tools have become more powerful, they have revealed an extensive CNS autonomic control hierarchy coupling visceral afferent inputs with autonomic efferent outflows, linking the SNS and PSNS divisions of the ANS, and interconnecting the central autonomic stations with somatic and endocrine pathways in the brain (Box 34.4). This central autonomic circuitry has been considered a "central visceromotor system" (Nauta, 1972) or a "central autonomic network" (Loewy, 1981). These studies revealed a network of multisynaptic relays descending from the hypothalamus and midbrain to preganglionic neurons in the brainstem and spinal cord. Similar projections, both direct and relayed through the hypothalamus, were also found for a number of limbic system nuclei, including most prominently the amygdala (Nauta, 1972). Neural tracers, immunocytochemical techniques, and electron microscopy subsequently have increased the resolution of the maps of this circuitry and its transmitters (e.g., Loewy, 1981).

The paraventricular nucleus of the hypothalamus is a prototype of the extensive and profound central autonomic coordination. Parvocellular neurons in the paraventricular nucleus project monosynaptically to preganglionic neurons in the dorsal motor nucleus of the vagus and preganglionics in the intermediolateral column of the spinal cord. The paraventricular nucleus also projects to the visceral afferent relay nuclei associated with each of these efferent outflows (the nucleus of the solitary tract and spinal lamina V, respectively). These descending projections influence several cardiovascular and gastrointestinal responses. Illustrating the extent of the central integration of responses, additional neurons of the paraventricular nucleus control corticotropin-releasing factor and oxytocin neuron responses,

BOX 34.4

CENTRAL ANS CIRCUITS INTEGRATE AUTONOMIC REFLEXES WITH AFFECTIVE OR EMOTIONAL RESPONSES

The autonomic nervous system participates in emotion and motivation. Consider Cannon's prototypical fight-or-flight example: The somatic and autonomic adjustments in this emergency situation contain elements we associate with anger or fear. The central relays, including the limbic circuitry just discussed, organize the autonomic components of these responses to external environmental stimuli and coordinate them with the appropriate somatic responses. Thus, the central ANS circuitry is involved in the *expression* of emotional reactions. This central circuitry has been called the "emotional motor system."

Some have hypothesized that in addition to being involved in the expression of emotions, the ANS is also the substrate for the *experience* of emotions. The classic theory of this type was suggested over a century ago independently by James and Lange, who speculated that afferent experience resulting from autonomic adjustments might be the basis of emotional experiences. For the fight-or-flight example, the James–Lange idea could be considered the proposition that "you do not run because you are afraid; you are afraid because you run (and mobilize the requisite autonomic adjustments registered by your visceral afferents)." Cannon, in the early twentieth century, offered an influential refutation of the James–Lange theory and delayed acceptance of these ideas, but most of his argument was based on now-outmoded ideas about the ANS and on a lack of distinction between expression and experience.

In an experiment designed to examine the James–Lange idea, Hohmann (1962) surveyed army veterans who had sustained spinal cord injuries at different levels. Consistent with a prediction of the theory, Hohmann found that, for the veterans' self-reported experiences of both fear and anger, the higher their spinal cord lesions (and thus the more of their visceral afferent inflow that was disconnected from the brain), the greater the reduction in their affective experiences.

In recent years, observations with fMRI and other scanning techniques, with modern electrophysiological techniques combined with tracing and with neuropsychological analyses of patients with brain damage or spinal injury, have converged to suggest that emotions or "feelings" are central representations of visceral afferent inputs. In particular, experiments that elicit visceral afferent activity and others that generate experiences judged to be emotions are associated with comparable activation patterns in limbic structures and forebrain sites. Recently, in views compatible with the James-Lange account of emotion, Damasio (1999), Craig (2002), and others as well have suggested that emotional experience is to the autonomic adjustments of the body what proprioception and somatosensation are to skeletal nervous system operations.

Terry L. Powley

which often are activated or modulated in association with autonomic functions.

Most mesencephalic, diencephalic, and telencephalic nuclei considered part of the limbic system affect visceral motor outflows and are now included in the concept of the central visceromotor system. In addition to the central gray and paramedian regions of the mesencephalon and the entire hypothalamus, including the preoptic hypothalamus, these limbic sites include the amygdala, bed nucleus of the stria terminalis, septal region, hippocampus, cingulate cortex, orbital frontal cortex, and insular and rhinal cortexes.

Summary

Multiple subcortical and diencephalic structures impose special controls over the SNS and PSNS. This network of hierarchically organized central stations, many of them part of the limbic system, forms a central visceral neuroaxis that receives inputs from visceral afferents and issues descending projections to the ANS preganglionic neurons in the brainstem and spinal cord. This central autonomic circuitry organizes and sequences sets of separate autonomic reflexes, coordinates SNS and PSNS responses so that they are synergistic, cross-links autonomic and skeletal responses, and integrates autonomic activity with ongoing and anticipated behavior of the individual.

PERSPECTIVE: FUTURE OF THE AUTONOMIC NERVOUS SYSTEM

Our understanding of the autonomic nervous system is incomplete and evolving, driven by the technological advances in neuroscience. Molecular biology, immunocytochemistry, electron microscopy, fMRI and similar imaging protocols, and other modern techniques are changing the autonomic nervous system definition that was derived with the techniques available to Langley and his contemporaries at the beginning of the twentieth century. The distinction that sympathetic postganglionic neurons are noradrenergic whereas parasympathetic postganglionics are cholinergic has been blurred by the recognition of nonadrenergic noncholinergic (NANC) neurons, nitric oxide synthetase (NOS)-containing neurons, purinergic synapses, a large number of colocalized and coreleased neuropeptides, postganglionic neurons changing their neurotransmitter phenotypes, and other exceptions that broaden the view developed by Langley's pharmacological studies. The canon that the ANS is strictly a motor system without an afferent counterpart is challenged by many who argue on functional and molecular biological grounds that "visceral afferents" belong to the ANS (see Box 34.2).

The proposal that functional differences between the SNS and PSNS divisions of the ANS can be attributed to their contrasting patterns of projection (the sympathetic system preganglionics projecting to postganglionics in a one-to-many pattern; the parasympathetic system projecting in a one-to-few pattern) has not been substantiated by modern analyses of divergence (Wang et al., 1995). Continued application of modern technologies and the prospect of continuing developments promise to define an autonomic nervous system quite different from that envisioned by Langley.

Summary and General Conclusions

The autonomic nervous system is the neural circuitry that maintains homeostasis and health and that enables behavior. It is responsible for the physiological adjustments that achieve what Cannon recognized as the "wisdom of the body." With its sophisticated motor repertoire and complexes of reflexes, including local axon reflexes, segmental or oligosynaptic reflexes, and polysynaptic suprasegmental cascades, the ANS continuously adjusts and defends the body's physiology. The importance of these processes was summarized succinctly by Nauta and Feirtag (1986): "Life depends on the innervation of the viscera; in a way all the rest is biological luxury." The processes go on, for the most part, without awareness or cognitive representations.

The hub of the ANS consists of two separate motor outflows, each hierarchically organized with preganglionic neurons stationed in the CNS and postganglionic neurons located in peripheral ganglia. The sympathetic, or thoracolumbar, division facilitates the mobilization of energy, increases catabolism, and promotes physiological responses that support activity, including emergency responses such as "fight" or "flight." The parasympathetic, or craniosacral, division facilitates conservation of energy, increases anabolism, and supports physiological responses that typically promote rest, digestion, and restoration of body reserves. The adrenergic phenotype of sympathetic postganglionic neurons, the cholinergic phenotype of parasympathetic neurons, and distinguishing complements of neuropeptides and receptor specializations provide neurochemical coding for the two divisions of the ANS. A key peripheral pole—and third distinct division of the ANS—is the enteric nervous system found in the wall of the digestive tract.

The motor outflows of the ANS are efferent limbs of reflexes triggered by visceral and, in some cases, somatic afferents. These reflex circuits have second-order visceral afferent nuclei located adjacent to spinal and medullary nuclei of preganglionic motor neurons (laminae I and V and the nucleus of the solitary tract, respectively).

Higher-order CNS circuitry, including the hypothalamus, limbic system, and a variety of cortical sites, provides

hierarchical control and integration of autonomic reflexes. This hierarchy is responsible for coordinating different autonomic reflexes, integrating autonomic function with somatic activity, and executing response programs that anticipate needs and regulate physiology over more extended time scales than those represented by isolated reflexes.

CHAPTER

35

Neural Control of Respiratory and Cardiovascular Functions

Mammals have developed a highly efficient system for tissue delivery of O_2 and removal of CO_2 to support their high metabolic rate. Getting O_2 to the tissues is a two-stage process: a reciprocal pump driven by respiratory muscles exchanges air from outside the body and the lung and a double circulating pump driven by cardiac muscle drives blood through the lungs, where O_2 enters and CO_2 leaves the pulmonary circulation, and then throughout the body, where O_2 leaves and CO_2 enters the systemic circulation. In order to avoid the brain injury that can be triggered by even brief O_2 deprivation, the respiratory and cardiac pumps must work continuously in mammals, from birth until death, without lapses of more than a few minutes.

The role of the brain in assuring O_2 delivery is preeminent. For respiration, the brain generates the rhythmic motor outflows that drive the contraction and relaxation of skeletal muscles that pump the lung and modulate the tone of skeletal and smooth muscles in the upper airways and bronchi to control resistance to air flow. For the circulation, the brain generates the autonomic motor activities that maintain vascular resistance and arterial pressure and that modulate cardiac contractility and heart rate to ensure an appropriate perfusion of all the tissues under a wide range of whole body and local metabolic demands. Through these mechanisms, the brain supports body function over a twenty-fold range in metabolism (in humans from ~0.25 liter × min^{-1} O_2 consumed at rest to ~3–6 liter × min^{-1} O_2 consumed during maximal exercise). Although respiratory muscles account for ≤5% of body metabolism at rest, the brain must drive them efficiently and without serious respiratory muscle fatigue. During exercise in humans, for instance, the brain must increase air exchange from a resting value of 5 up to 200 liters × min^{-1} (maximal performance in world-class athletes) while minimizing the energy costs of breathing to maximize the O_2 available to other working muscles. This chapter summarizes the distinct neural mechanisms underlying the brain's key roles in controlling respiratory and cardiovascular functions and then describes how these markedly different systems work in tandem.

The drive for continuous ventilation in humans is strong. Typically, breathing is the last consequential movement (the "dying" gasp) to disappear following generalized depression of higher brain function, such as during surgical anesthesia or following insults to the brain—for example, hypoglycemic coma or global brain anoxia following a heart attack. Automatic, homeostatic breathing can remain in people who have lost cortical but maintain brainstem and spinal cord function, resulting in ethical and emotional dilemmas in individuals considered "brain dead."

Neuroscientists take advantage of this robustness of breathing to study synaptic, neural, and network mechanisms in anesthetized or decerebrate mammals that continue to breathe. These mechanisms are so robust and sufficiently self-contained that a thin *in vitro* tissue

© 2013 Elsevier Inc. All rights reserved.

slice (~500 μm thick) at an appropriate medullary level in neonatal or late fetal rodent brainstem continues to generate respiratory-related patterns of motor nerve activity.

The cardiovascular system, in addition to carrying O_2 and CO_2, delivers nutrients and removes waste products from the diverse and widely separated tissues of the body. The circulatory system is a conduit for hormonal and metabolic signals arising in the hypothalamus, adrenal cortex, and gut, and for immune cells from, for example, bone marrow, to sites of infection or injury. The central neural regulation of the cardiovascular system provides the overarching coordination among the various aspects of cardiovascular function required not only to maintain a homeostatic cellular environment for all tissues at rest, but especially to meet the enhanced tissue demands during the challenges of behavior, disease, and environmental adversity. The brain regulates the cardiovascular system primarily through the sympathetic and the parasympathetic divisions of the autonomic nervous system (see Chapter 33) and secondarily via hormones, in particular the sympathetically-driven secretion of epinephrine from the adrenal gland.

BREATHING

A Brief Neuroscience-Oriented History

Although the purpose of breathing—to move air into and out of the lungs—was not established until the late eighteenth century, the sites within the body that control breathing have been a constant source of speculation in Western culture (Feldman, 1986). Perhaps the earliest suggestion that the brain was involved came from Galen (ca. A.D. 131–201), who observed that gladiators and animals injured below the neck continued to breathe, but those injured in the neck stopped breathing. Lorry (1760) showed that cerebellectomized rabbits continued to breathe and suggested that the critical circuits lay within the brainstem and upper spinal cord, essentially the contemporary view. Legallois (1813) "extracted" brain tissue to determine what was necessary for breathing; presciently, he localized critical regions to the rostral ventrolateral medulla, close to the *preBötzinger Complex* (preBötC; Figs. 35.2, 35.7), which we recognize today as a key brain site for generating respiration.

Ramon y Cajal (1909) provided an anatomic rationale for the critical role of the medulla in breathing. Examining the afferent/efferent projections of respiratory-related nerves, he focused on two brainstem nuclei: the nucleus of the solitary tract (NTS), the target of pulmonary afferents, and the nucleus ambiguus, which contains cranial motoneurons that innervate upper airway muscles. His network model for breathing is prescient: afferents containing information about lung volume or blood gases combined with intrinsic properties of brainstem neurons to produce a rhythmic outflow to spinal and cranial respiratory motoneurons (Fig. 35.1). In brainstems isolated from goldfish, Adrian and Buytendijk (1931) recorded slow, rhythmic potentials that were similar in timing to the fish's gill movements when intact, physiological evidence that the brainstem contained the critical circuits. Gesell and colleagues (1936) subsequently recorded individual medullary neurons discharging bursts of activity in phase with the breathing rhythm. This finding initiated a concerted effort to identify neurons that generate respiratory rhythm (Box 35.1).

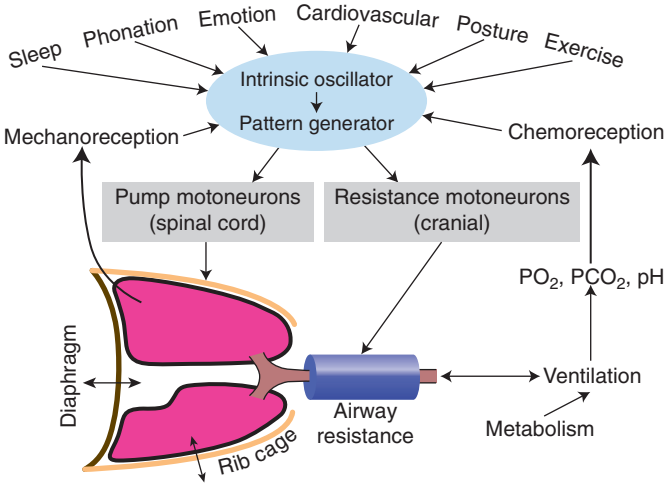

FIGURE 35.1 Functional organization of the CNS control of breathing. Circuitry centered within the medulla oblongata of the brainstem (blue oval) generates an oscillating inspiratory–expiratory rhythm. Neurons within the oscillator circuit generate rhythmic respiratory motor output without requiring sensory signals related to lung inflation. The rhythm is relayed to networks of premotor and interneurons constituting pattern generators that sculpt the detailed firing patterns relayed to spinal and cranial motoneurons. Spinal respiratory motoneurons innervate skeletal muscles, including the diaphragm and muscles of the rib cage, producing the pumping action of the lungs. Cranial motoneurons, e.g., hypoglossal (cranial nerve XII) motoneurons innervating the tongue and vagal motoneurons (cranial nerve X) innervating the glottis, trachea, and bronchi also receive respiratory input that adjusts airway caliber (and hence the resistance to airflow) over the course of each respiratory cycle. The levels of oxygen (PO_2) and carbon dioxide (PCO_2) are sensed by chemoreceptors located in the brain and major arteries. If a low PO_2 or elevated PCO_2 is detected, there is an increase in afferent signals sent to the oscillator and pattern generating circuits to increase breathing. Also, mechanoreceptors located in the airways sense the magnitude of lung inflation and send signals to the central rhythm and pattern generating circuits to modulate the pattern of breathing. Maintenance of appropriate ventilation also requires that breathing be adjusted during a variety of behaviors such as phonation and sleep as well as in response to exercise or changes in posture. These adjustments are mediated via inputs to brainstem rhythm and pattern forming circuits.

BOX 35.1

EXPERIMENTAL ANALYSIS OF VENTILATION

Neuroscientists are constrained by what they can measure. Noninvasive experiments in humans reveal the phenomenology of breathing—for example, the relationship between ventilation and blood CO_2 levels. Brain imaging may reveal which regions are involved, but at present, spatiotemporal resolution is too coarse to show networks, much less neurons or synapses. Respiration lends itself to study because mammals suitable for experimentation breathe much like humans. Breathing continues following anesthesia or decerebration, and the neural patterns remain following paralysis (and mechanical ventilation), making possible experimental procedures requiring highly invasive techniques, such as single neuron recording. Compared to studies of neurons in culture or in tissue slices, experiments in whole mammals have serious limitations: (1) movements of the heart and lungs make certain types of single neuron recording, as well as modern imaging techniques such as fMRI, difficult in the brainstem and spinal cord; (2) the blood–brain barrier is intact, making precise control of brain extracellular fluid impossible; and (3) acute experiments in large mammals, such as cats, dogs, and goats, are expensive and can last 36 h or more, requiring the dedicated and concurrent efforts of several investigators. Fortunately, the robust features of breathing that allow it to persist when other behaviors are suppressed by anesthesia or decerebration permit further reduction in the experimental preparation that removes these limitations. Moreover, a respiratory-related rhythm persists in the brainstem and spinal cord removed from a neonatal rodent and even in a particular slice of brainstem isolated from this preparation. Using such slices, one can correlate exquisite measures of a neuron's intrinsic and synaptic properties and projections with measures of endogenous behavior, such as its firing pattern. With many common and otherwise useful *in vitro* preparations, such as the hippocampal slice, such correlations cannot be made because no endogenous behavior *in vitro* relates to known behavior *in vivo*. In general, en bloc *in vitro*, or slice, preparations play an important role in the study of basic cellular, synaptic, and integrative mechanisms underlying respiratory motor behavior.

Jack L. Feldman and Donald R. McCrimmon

WHERE ARE THE NEURONS GENERATING THE RESPIRATORY PATTERN?

Three distinct functional classes of respiratory neurons underlie the generation of the discharge pattern on the motor nerves innervating skeletal muscles of the respiratory pump and airways: respiratory muscle motoneurons, rhythm-generating neurons, and premotoneurons that link and coordinate rhythm-generating neurons to motoneurons and transform that rhythm into a mechanically efficient pattern of respiratory muscle activity. Nonrhythmic neurons that modulate the behavior of these respiratory neurons are also important. These include neurons involved in sensing blood and brain levels of O_2 and CO_2—that is, chemoreceptors—or may reflect sleep-wake state, such as serotonergic or (nor)adrenergic neurons. Brainstem respiratory neurons are concentrated within three regions (Fig. 35.2).

The *dorsal respiratory group (DRG)* is located within the caudal half of the NTS, the primary target of afferent input from the glossopharyngeal and vagus nerves. DRG neurons are optimally located to receive respiratory-related sensory input. DRG neurons provide input to other groups of respiratory neurons within the *ventral respiratory column* (VRC) of the ventral medulla, the *pontine respiratory group* (PRG), as well as respiratory motoneurons in the spinal cord.

The VRC forms a continuous rostrocaudal field in the ventrolateral medulla with multiple, physiologically distinct subregions, extending from the facial nucleus to the spinomedullary junction. The caudal half of the VRC, termed the ventral respiratory group (VRG), contains respiratory-modulated bulbospinal premotoneurons. Inspiratory neurons in the rostral VRG (rVRG) provide mainly excitatory premotor drive to interneurons projecting to inspiratory muscle motoneurons, including phrenic motoneurons innervating the diaphragm (the principal inspiratory muscle) in the midcervical (C3-C5 in humans) spinal cord and external intercostal muscles of the rib cage in the thoracic spinal cord. Expiratory bulbospinal neurons in the caudal VRG (cVRG) are mainly excitatory and project to interneurons innervating spinal motoneurons that drive internal intercostal and abdominal expiratory pump muscles in the thoracic and lumbar spinal cords, respectively. Inhibitory expiratory premotor neurons in the cVRG and in the *Bötzinger complex* (BötC) inhibit spinal inspiratory motor pools.

In the rostral VRC, rostral to the rVRG, are the preBötC (an essential structure for normal rhythm generation); the BötC; the *retrotrapezoid nucleus* (RTN) that contains central chemosensory cells whose activity increases in parallel with increasing local tissue acidity and provides an important source of respiratory drive; and finally, the *parafacial respiratory group* (pFRG) which plays an important role

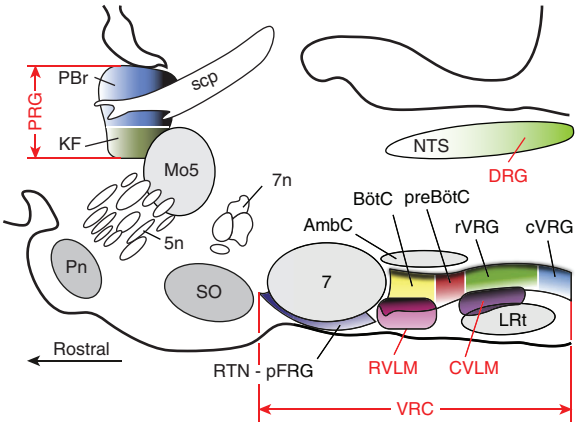

FIGURE 35.2 Respiratory and cardiovascular cell groups in a sagittal view of the rat brainstem. Functionally distinct brainstem compartments related to breathing or cardiovascular control are indicated by shaded regions of different colors. Red text indicates the three primary respiratory and two primary cardiovascular cell groups. Subregions of two of the primary respiratory groups, the ventral respiratory column (VRC) and pontine respiratory group (PRG), are indicated with black labeling. Nearby brainstem structural landmarks are indicated in gray for prominent neuronal nuclei, or outlined without shading for major fiber bundles. 7, facial nucleus; 7n, facial nerve; AmbC, compact part of nucleus ambiguus; BötC, Bötzinger complex; cVRG, caudal division of ventral respiratory group; DRG, dorsal respiratory group; KF, Kölliker–Fuse nucleus; LRt, lateral reticular nucleus; Mo5, motor nucleus of the trigeminal nerve; NTS, nucleus of the solitary tract; PBr, parabrachial region; Pn, basilar pontine nuclei; preBötC, preBötzinger complex; RTN - pFRG, retrotrapezoid nucleus and parafacial respiratory group; rVRG, rostral division of ventral respiratory group; scp, superior cerebellar peduncle; SO, superior olive; VRG, ventral respiratory group. *Modified from Alheid and McCrimmon (2008).*

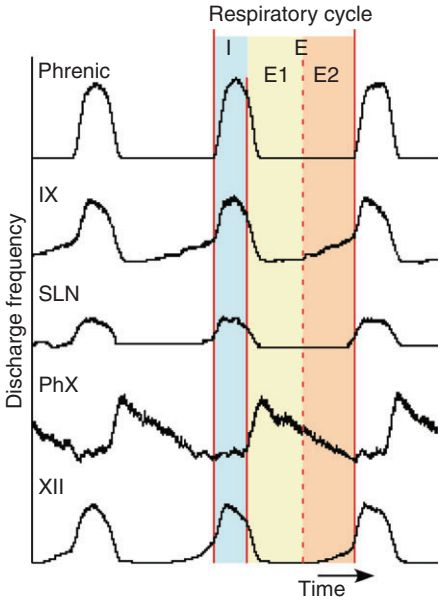

FIGURE 35.3 A diverse pattern of respiratory motor activity is exhibited on spinal (phrenic) and cranial nerves innervating the diaphragm and airways in an anesthetized rat. Low-pass filtered traces of nerve activity show the overall pattern of discharge. Red vertical lines indicate phase transitions between inspiration (I) and expiration (E), which itself is divided into two subphases: E1 (postinspiration) and E2. Note that the onset of inspiratory activity on cranial nerves precedes the onset of activity on the phrenic nerve. IX, glossopharyngeal nerve; PhX, pharyngeal branch of vagus nerve; SLN, superior laryngeal nerve XII, hypoglossal nerve. Traces depict activity in a rat, but activity is similar in other mammals although respiratory frequency varies from greater than 100 × min^{-1} in mice to about 3 × min^{-1} in giraffes. *Adapted from Hayashi and McCrimmon (1996).*

in the generation of expiratory motor output (Feldman & Del Negro, 2006).

The PRG in the rostral dorsolateral pons encompasses portions of the parabrachial complex and the ventrally adjacent Kölliker-Fuse nucleus. PRG neurons may be necessary for the full expression of the normal breathing pattern, but do not seem essential for rhythm generation *per se*. Further, they contribute to the reflex changes in breathing elicited by sensory afferents sensitive to lung volume. They also contribute to the reflex changes in breathing induced by input from chemoreceptors sensitive to the levels of arterial blood O_2, CO_2, and pH. PRG neurons may also contribute to the coordination of respiration with the cardiovascular system, and mediate the effects of breathing rhythm on suprapontine structures and vice versa.

DISCHARGE PATTERNS OF RESPIRATORY NEURONS

Although inspiration and expiration constitute two obvious phases of the mammalian respiratory cycle, the discharge patterns of inspiratory (diaphragm) and expiratory—for example, internal intercostal—muscle activity suggest two expiratory phases. During the first expiratory phase (E1, termed postinspiration), the diaphragm often exhibits a low level of "postinspiratory" activity that slows diaphragm lengthening at the onset of expiration, thus reducing the initial rate of expiratory airflow (Fig. 35.3). Postinspiratory activity typically declines rapidly, ending by midexpiration. In a healthy individual under resting conditions there is little or no activity of expiratory pump muscles, with expiration occurring via the passive recoil of the lung. At higher levels of ventilation, such as during exercise (note: here exercise means sustained activity of large muscles, such as would be involved in fleeing a predator or chasing prey, or running on a treadmill!), an augmenting pattern of expiratory muscle activity in the second (E2) phase increases the expiratory airflow. These motor patterns are generated by interactions among respiratory neurons primarily localized in the respiratory cell groups illustrated in Figure 35.2.

MODELS FOR RESPIRATORY PATTERN GENERATION

Oscillations such as the respiratory motor patterns shown in Figure 35.3 are a common form of dynamic activity in physical and biological systems that have

attracted modelers since the early seventeenth century when philosopher René Descartes used analytic reasoning to model the mind. Since the 1960s, computational models to explain how rhythm-generating neurons in the preBötC, RTN/pFRG interact with the rest of the network, including premotor and motoneurons, to produce appropriate motor patterns have successfully reproduced human and animal breathing patterns. These models are useful for summarizing interaction mechanisms among components of the respiratory system, but modeling efforts still seek the elusive goal of nontrivial, testable predictions. Although current modeling elucidates plausible mechanisms, further data on network connections, intrinsic membrane properties, and synaptic interactions are needed so models are sufficiently constrained to provide novel insights into the underlying mechanisms.

A Respiratory Rhythm Generator is Discovered in the preBötC

Since the late eighteenth century, the brainstem has been recognized as the source of respiratory rhythm, but only in the past 25 years has the precise locale of the obligate structures been determined. A critical step in this advance was the development of novel *in vitro* preparations (see Box 35.1). In the 1980s, Suzue and colleagues (Suzue, 1984) noted that the isolated neonatal rat brainstem and spinal cord, termed the "en bloc" preparation, generated a respiratory rhythmic motor output in spinal nerves that innervate muscles of the respiratory pump, as well as in cranial nerves innervating the airways, which control airway resistance. This *in vitro* preparation permitted a refinement of the "blunt spatula" brainstem transection approach used almost 200 years earlier by Legallois (1813) to identify structures critical for respiratory rhythm generation. In the contemporary case, removing thin (50–75 μm) sections from either rostral or caudal ends of the *en bloc* preparation, while recording respiratory activity from spinal or cranial nerves resulted in the isolation of a small, ventral medullary region, named the preBötC, as an essential component in the rhythm generating circuitry (Smith, Ellenberger, Ballanyi, Richter, & Feldman, 1991). Several experimental observations indicate that neurons within the preBötC provide a minimum essential circuitry for respiratory rhythm generation (Feldman & Del Negro, 2006). (1) Slices containing the preBötC generate a rhythm indistinguishable from the respiratory-related rhythm *en bloc*, although this pattern differs from that seen *in vivo*. (2) In intact adult *awake* rats, neurotoxic lesions of a subset of preBötC neurons containing the receptor for substance P (i.e., neurokinin-1 receptor), irreversibly induces a pathological, ataxic breathing pattern quite different from normal breathing (Fig. 35.4 and see Box 35.2). (3) Essentially normal inspiratory motor pattern persists after transection of the rat brainstem just rostral to the

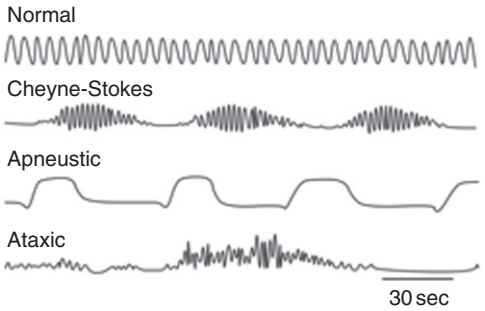

FIGURE 35.4 Abnormal breathing patterns resulting from CNS disorders. The ordinate is lung volume. *Adapted from Plum and Posner (1980).*

BOX 35.2

CNS LESIONS PRODUCE ABNORMAL BREATHING PATTERNS

Many brain injuries and diseases produce abnormal breathing patterns (Plum & Posner, 1980). Because many brain regions provide afferent input to the neurons generating the breathing rhythm, pathology in regions not normally associated with the generation of breathing can produce abnormal breathing patterns. Despite the diffuse nature of many pathologies that give rise to abnormal breathing patterns, Plum and colleagues systematically characterized several breathing disorders (Fig. 35.4) arising from specific CNS pathologies.

Apneustic breathing is marked by prolonged inspiratory periods. In humans, the most frequent pattern is inspirations lasting 2–3 s alternating with prolonged expiratory pauses. In cats, the prolonged inspiratory periods are associated with plateaus in inspiratory drive that can last minutes (leading to death in the absence of mechanical ventilation). Apneusis is observed in people with lesions of the pons, including, or just ventral to, the pontine respiratory group. In experimental animals, apneusis requires not only lesions of the pontine respiratory group, but also interruption of vagal afferent input.

Lesions of the corticobulbar or corticospinal tracts can lead to *Cheyne–Stokes respiration*, a rhythmic waxing and waning of breathing. Periods of no breathing (apnea) follow each period of waning inspiratory depth. Lesions of the corticobulbar and corticospinal tracts can also result in loss of voluntary control of breathing. In pseudobulbar palsy, for example, voluntary control of breathing and of cranial

BOX 35.2 *(cont'd)*

motoneuron function is lost secondary to a lesion often located dorsomedially in the base of the pons.

Extensive bilateral damage to the medullary respiratory groups can severely disrupt or abolish respiratory rhythm, resulting in death unless artificial ventilation is initiated immediately. Fortunately, unilateral damage does not appear to be sufficient to cause severe disruption of respiratory rhythm- and pattern-generating mechanisms. Because two vertebral arteries supply blood to the medulla, bilateral damage from an infarct or embolism is unlikely.

Less extensive damage to medullary respiratory structures can produce *ataxic breathing*, an irregular pattern of breathing with randomly occurring large and small breaths, periods of apnea and low breathing frequency.

Spinal injuries that affect the long axons of bulbospinal premotoneurons that transmit respiratory drive to spinal motoneurons can be life-threatening. Damage between C3 and S1 can diminish the ability to generate inspiratory or expiratory movements of abdominal and intercostal muscles, with the effects more pronounced the more rostral the injury. Injuries between the lower brainstem and C3 will also affect the diaphragm. Such injuries require immediate artificial support of ventilation to maintain life. This type of cervical injury is more common in young, active individuals, resulting from dives into shallow water or being thrown from a horse.

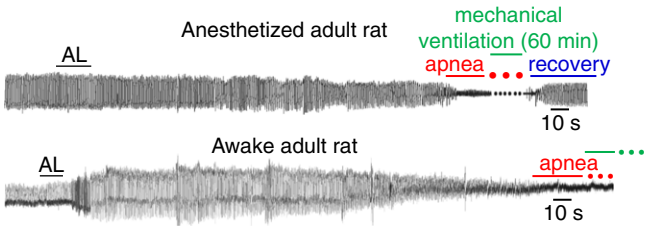

FIGURE 35.5 PreBötzinger complex (preBötC) is essential for breathing in adult rats. Rapid silencing of allatostatin receptor (AlstR)-expressing, preBötC somatostatin (Sst) neurons induces persistent (>45 min when mechanically ventilated) apnea in anesthetized or awake adult rats. Traces are plethysmographic recordings of breathing movements. Allatostatin (AL) administered intracerebrocisternally induces a gradual decline in frequency and tidal volume until apnea develops after several minutes. After ~60 minutes of mechanical ventilation, rats resume spontaneous breathing. The ordinate is lung volume. *From Tan et al. (2008).*

preBötC, which removes all pontine circuits and the RTN/pFRG although phasic expiratory motor activity is abolished. (4) Rapid transient silencing of a subpopulation of preBötC neurons, those glutamatergic neurons that also produce the peptide somatostatin (~500 neurons/side), leads rapidly to a persistent apnea in awake rats (Fig. 35.5). Taken together, these experimental results underlie the now widely accepted view that the preBötC is an essential component of the circuitry generating breathing rhythm.

A Second Respiratory Rhythm Generator is Unveiled

The RTN/pFRG (Fig. 35.2), a region rostral to the preBötC, is now thought to play a critical role in generating respiratory rhythm as well as in its ontogeny and in chemoreception (see Box 35.3). Functional evidence for the presence of this second oscillator initially came from experiments exploiting differences in the opioid sensitivity of preBötC neurons, which are inhibited by opioid agonists, and RTN/pFRG neurons, that appear unaffected. In *in vitro* slices that contain only the preBötC, opioids slow the inspiratory rhythm in a graded fashion, gradually increasing the interval between inspiratory bursts (Fig. 35.6A, top). In the more intact *en bloc* preparation that contains both the preBötC and the RTN/pFRG, opioid agonists also cause a slowing of inspiratory rhythm, but instead of progressively lengthening the interval between inspiratory bursts, some inspiratory bursts are skipped. This results in a stepwise lengthening of the interval between inspiratory bursts (termed "quantal slowing" (Mellen, Janczewski, Bocchiaro, & Feldman, 2003)), with the amount of slowing dependent on how many inspiratory bursts were skipped (Fig. 35.6A, bottom). While this is happening in the motor output, RTN/pFRG expiratory neurons continue to burst at the control frequency with no skips and remain phase-locked to motor nerve output when it occurs, whereas preBötC neurons only burst when there is a motor output (Fig. 35.6B). Quantal slowing of the inspiratory rhythm also occurs *in vivo*, where, the frequency of expiratory motor nerve bursts is unaffected! This is unlikely to be due to a simple block of inspiratory motor output, as the pattern of expiratory motor activity is quite different in cycles with and without inspiration (Fig. 35.6C, right). Excitation or disinhibition of RTN/pFRG neurons can transform a breathing pattern with no active expiratory activity into one with considerable expiratory motor activity (Fig. 35.6D) (Pagliardini, Janczewski, Tan, Dickson, Deisseroth, & Feldman, 2011). Finally, lesions or transections can be used to separate

BOX 35.3

WHY TWO DISTINCT OSCILLATORS?

Two key events characterize the evolution of breathing from fish to mammals. The first includes transformations that support the transition from aquatic to terrestrial breathing in vertebrates. "Breathing" in fish is driven by cranial nerve innervation of the gills. As primitive fish (such as the ancestors of the lungfish) ventured onto land, rhythmic activity of muscles used for other purposes evolved to drive the emerging lung, and this activity might have had a neural origin that was independent of the rhythm driving the gill muscles. This speculative hypothesis is supported by observations in amphibians. Developing frogs have two distinct breathing patterns driven by different muscles and nerves: a buccal pattern that uses cranial nerve-innervated muscles to essentially swallow air and a lung pattern that uses respiratory muscles to pump the lung. Either the buccal or the lung pattern can be suppressed without abolishing its counterpart, but when both are active they appear to be phase-locked. Notably, the lung rhythm is depressed by opioids (like the mammalian preBötC neurons and inspiration), whereas the buccal rhythm is not (like pre-I neurons and expiration). A prediction from this hypothesis is that the preBötC is absent in fish.

The second key event was the emergence of the diaphragm in mammals. Respiratory physiology in vertebrates has evolved to support higher resting and peak ventilation. For example, lizards have gular pumps that uncouple respiration from locomotor musculature, which enhances O_2 consumption to support high-speed locomotion. Birds utilize sacs to pump O_2-rich air through noncompliant lungs, in support of flight. Uniquely, mammals have muscular diaphragms, a profoundly important ventilatory advance as it allows for continuous high basal rates of ventilation and for the very high levels of ventilation necessary to support substantial increases in metabolism. The improvement in gas exchange associated with the development of the diaphragm was probably crucial for brain evolution, as it was a platform for evolution of a brain that consumes extraordinary amounts of O_2 and is generally intolerant of even transient anoxia. The neural circuits driving the primitive diaphragm could have evolved independently of preexisting circuitry driving the rhythmic pumping machinery of the rib cage, abdominal muscles, or upper airway muscles, or it could have been based on the opioid-sensitive oscillator driving lung breathing in amphibia. Nonetheless, a respiratory movement pattern consisting of alternating inspiratory activity to lower the diaphragm with expiratory motor activity has considerable mechanical advantages for efficient ventilation over a broad range of metabolic demand. Therefore, the neural oscillators for breathing, which may have arisen independently, might be expected to evolve to be coupled.

There may be a special role for two oscillators at birth. In mammals there is a surge of endogenous opioids at birth. This postnatal increase in opioid release would depress the excitability of the preBötC but not the RTN/pFRG, thereby allowing the latter to promote breathing immediately after birth, either by rhythmically driving breathing or by providing a drive necessary to keep the preBötC rhythmic. This view is supported by experiments in Krox-$20^{-/-}$ mice that have neuroanatomical defects that result in deletion of the brainstem region containing the RTN/pFRG but do not affect the preBötC. These mutant mice die of fatal apneas within 18 hours after birth, but brief postnatal administration of naloxone (an opioid receptor agonist which has no effect in control mice) rescues these pups by eliminating their apneas. Thus, without the RTN/pFRG to provide respiratory drive, the opioid surge at birth could fatally depress preBötC function. We suggest that in Krox-$20^{-/-}$ mice, in the absence of the RTN/pFRG, the opioid-induced depression of the preBötC causes prolonged and ultimately fatal apneas; naloxone would reverse this depression, which is developmentally relieved within two days, allowing the preBötC to function adequately for survival. This special role for the RTN/pFRG at birth is consistent with the two-oscillator model.

Jack L. Feldman and Donald R. McCrimmon

the regions that generate inspiratory and expiratory activity. In vagotomized and anesthetized juvenile rats, complete brainstem transections rostral to the VII nucleus that leave the RTN/pFRG and preBötC intact do not markedly affect inspiratory or expiratory motor bursting activity, whereas transections that disconnect the rostral portion of the RTN/pFRG from the more caudal preBötC abolish expiratory motor activity without affecting inspiratory rhythm. Additionally, continuous lung inflation suppresses inspiratory activity and enhances expiratory drive, whereas lung deflations increase the rate of inspiration, while minimizing rhythmic expiratory efforts.

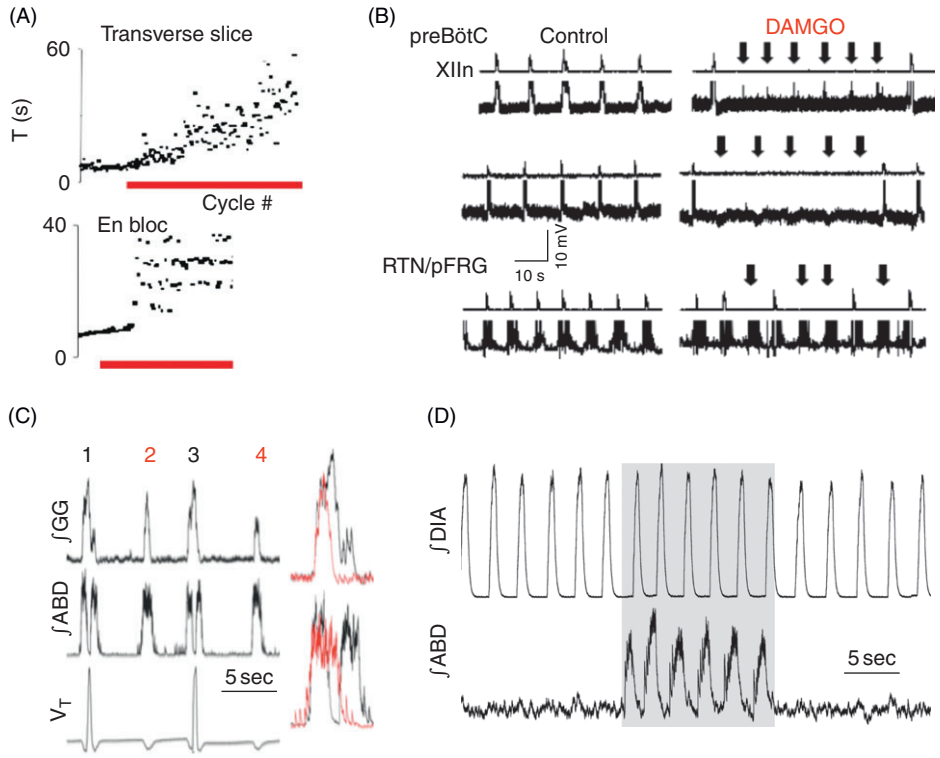

FIGURE 35.6 Evidence for two respiratory oscillators. (A) Slowing of the inspiratory period *in vitro* in a slice (top) and en bloc (bottom), before and after DAMGO, an opiate agonist (red bar): top—continuous slowing of rhythm in the slice; bottom—quantal slowing of rhythm *en bloc*. T(s), time in seconds between successive bursts of inspiratory neuronal activity recorded either from the preBötC (top) or a cervical ventral root (bottom). (B) Simultaneous recordings of inspiratory burst activity in XII nerve and preBötC inspiratory neurons (top two pairs of traces) and pre-I neuron in RTN/pFRG (bottom pair). Arrows in DAMGO traces indicate subthreshold events in preBötC neurons during skipped bursts, which occur at the approximate expected time of inspiratory bursts at control frequency, or unperturbed bursting in pre-I neurons. (C) *In vivo* recordings (juvenile rat) following fentanyl, an opiate agonist, injection. Left: typical recording with normal cycles (1, 3) interspersed with cycles without inspiratory activity (2, 4). Traces from top: integrated genioglossus muscle EMG; integrated abdominal muscle EMG, tidal volume (V_T). Right: Superposition of $\int EMG_{GG}$ and $\int EMG_{ABD}$ in a normal cycle (black) compared to an inspiratory skipped cycle (red). Note the marked differences, especially in the $\int EMG_{ABD}$ burst. (D) Optogenetic stimulation of RTN neurons turns on abdominal (expiratory) nerve activity, with minimal effect on inspiratory activity. *A, B adapted from Mellen et al. (2003); C adapted from Janczewski and Feldman (2006); D adapted from Pagliardini, et al. (2011).*

Summary

The working paradigm for the core engine of breathing is that the preBötC generates inspiratory rhythm and the RTN/pFRG generates expiratory activity, and these two oscillators are coupled (Fig. 35.7).

MECHANORECEPTORS IN THE LUNGS ADJUST BREATHING PATTERN AND INITIATE PROTECTIVE REFLEXES

Many different patterns of muscle activity can produce appropriate ventilation; however, the specific pattern should minimize energy expenditure. Mechanical efficiency, in turn, depends on factors such as posture, and lung and chest wall mechanics; for example, lung injury can lead to an increase in fibrous tissue in the lung, making it harder to inflate than a normal lung, and thus for this condition, rapid, shallow breathing is more efficient. Feedback about the mechanical status of the lungs and chest wall is provided by mechanoreceptors. Protective respiratory reflexes, such as sneezing and coughing, are also generated by pulmonary receptors.

There are three distinct groups of lung afferents, and all of them have axons in the vagus nerve that terminate in the NTS (Kubin, Alheid, Zuperku, & McCrimmon, 2006). Two groups have large, myelinated A fibers. These include slowly adapting and rapidly adapting pulmonary stretch receptors. The third group has unmyelinated C fibers and responds to inhaled irritants such as smoke. Most natural stimuli—for example, pulmonary edema or alveolar collapse—probably activate multiple receptor types.

Slowly Adapting Pulmonary Stretch Receptors

Located in airway smooth muscle, slowly adapting pulmonary stretch receptors (SARs) are activated when the airways stretch during lung inflation (Kubin et al., 2006) providing the central pattern generator with information

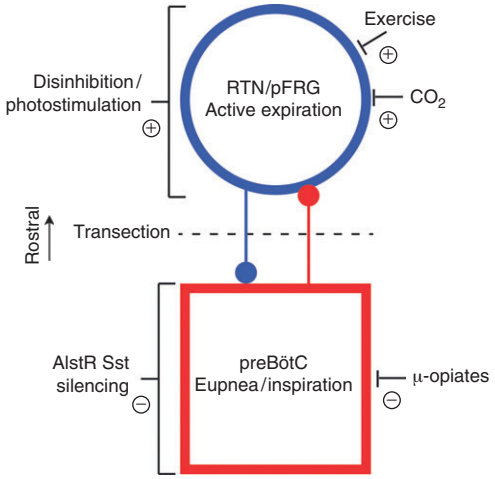

FIGURE 35.7 At the core of current models for respiratory rhythmogenesis are two medullary nuclei, the preBötC and the RTN/pFRG. The preBötC is essential for the generation of inspiratory motor activity, sufficient for breathing at rest. Endogenous stimulation of the RTN/pFRG by elevated CO_2, or perhaps exercise, is hypothesized to produce active expiration (absent at rest in adult mammals). The above figure summarizes results discussed in the text.

about lung volume. Their activation drives reflexes by which lung inflation shortens inspiration and prolongs expiration (Breuer–Hering reflex), which is an important determinant of inspiratory duration during normal relaxed breathing in most mammalian species, with the notable exception of humans. The activation of these receptors shortens inspiration and increases breathing frequency. In humans, activation of SARs by normal breaths only modestly alters inspiratory timing. Their activation also relaxes airway smooth muscle, dilating the airways to make breathing easier.

Rapidly Adapting Pulmonary Stretch Receptors

Located in airways, rapidly adapting pulmonary stretch receptors (RARs) initiate protective reflexes in response to a variety of stimuli, including large or rapid lung inflation or deflation, inhaled irritants, and, possibly, airway edema (Canning & Spina, 2009). Cigarette smoke activates RARs and elicits a cough to rid the airway of the offending material. RARs elicit a larger than normal inspiration (sigh) in response to alveolar collapse (atelectasis), inflating the lung and popping open the collapsed alveoli. Also contributing to cough is a recently identified group of airway receptors, termed cough receptors, with small myelinated fibers (A-∂ fibers).

Bronchopulmonary C Fibers

C fiber afferent activation elicits apnea followed by rapid shallow breathing. Like RARs, C fibers are polymodal, activated by chemical and mechanical stimuli. Their activation also enhances airway mucus secretion. Inhaled particles are trapped in the mucus and removed from the airways by the action of cilia, which continuously (in the nonsmoker) move the mucus and trapped particles toward the mouth to be swallowed or expectorated.

Summary

Mechanoreceptors, especially those in the lungs, are essential for the precise regulation of the timing and amplitude of breathing. They also participate in reflexes, such as those eliciting coughing and mucous secretion, that protect the airways and lungs from compromises in airflow and inhaled irritants.

CARDIOVASCULAR

Organization and Functions of the Innervation of the Cardiovascular System

The heart, unlike skeletal muscle, can beat rhythmically in the absence of its neural input. However, neural inputs are essential for modulating cardiac contractility—that is, force of contraction—and heart rate. Sympathetic and parasympathetic nerves innervate the heart (Fig. 35.8), regulating cardiac function in a push-pull manner. Increasing the sympathetic input to the heart increases heart rate and its contractility, thereby increasing the amount of blood pumped—that is, cardiac output. The sympathetic innervation is via the cardiac nerve that arises from noradrenergic sympathetic ganglion cells (primarily in the stellate ganglion) driven by cholinergic preganglionic neurons in the intermediolateral nucleus of the upper thoracic spinal cord. Increasing the parasympathetic input to the heart decreases the heart rate. The parasympathetic, cholinergic postganglionic neurons are within adipose tissue apposing the heart, driven by cholinergic vagal preganglionic neurons whose somata are in the nucleus ambiguus and the dorsal motor nucleus of the vagus.

Blood vessels, which have only a low contractile tone in the absence of neural input, generally receive only a sympathetic innervation that mediates vasoconstriction (although several notable exceptions are described in the next paragraph). Increased vascular sympathetic activity increases the tone of vascular smooth muscle, resulting in vasoconstriction that increases arterial blood pressure. Decreased vascular sympathetic activity allows the blood vessels to dilate, decreasing blood pressure. Sympathetic input to veins increases venous wall tension, which increases cardiac filling and cardiac output. The sympathetic vascular innervation is from noradrenergic sympathetic ganglion cells in prevertebral (visceral blood

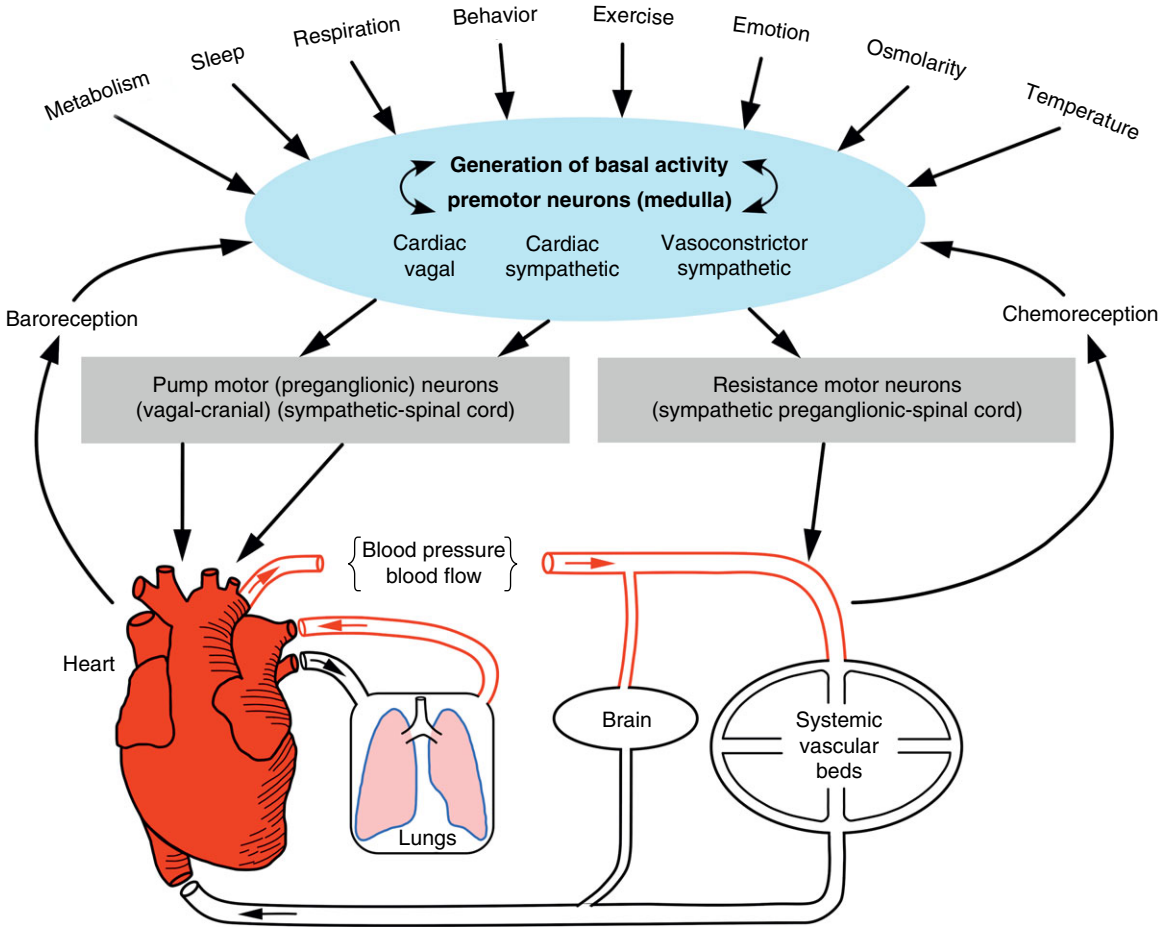

FIGURE 35.8 Functional organization of the CNS regulation of cardiovascular function. The medulla contains sympathetic neurons, including sympathetic premotor neurons that are responsible for the significant level of basal sympathetic nerve discharge to the heart and vasculature. Although the medullary mechanisms underlying the generation of basal sympathetic tone remain to be identified, they result in the activity of medullary sympathetic premotor neurons that provides the essential excitation to spinal sympathetic preganglionic neurons that maintains the basal sympathetic tone to the heart and vasculature. The basal activity of sympathetic nerves maintains a release of norepinephrine in the heart and vascular beds that supports, respectively, the rate and strength of cardiac pumping and the constriction of blood vessels that produces the resistance to blood flow required to maintain blood pressure at a level sufficient to ensure adequate blood flow to the brain, even against the pull of gravity. Selective activation or inhibition of the sympathetic outflow to the vascular beds in different tissues allows relative reductions or increases in blood flow to those tissues as needed to support a wide range of behaviors and of homeostatic adjustments to environmental challenges. Many of the stimuli for changes in sympathetic and vagal outflow to the cardiovascular system, from homeostatic reflexes, to diseases, dehydration, drugs, and metabolism, elicit their responses through inputs, including those from the hypothalamus, to the medullary networks, including the premotor neurons, that generate sympathetic tone.

vessels) and paravertebral (vessels in the skin and skeletal muscle) ganglia close to their target tissues. Their preganglionic neurons are in the intermediolateral nucleus throughout the thoracolumbar spinal cord segments.

Sympathetic activation can be highly localized or global in effect. Sympathetic preganglionic neurons and ganglion cells are target-specific, providing a substrate for selective CNS regulation of the heart and of the blood vessels in each tissue. Chromaffin cells in the adrenal medulla, driven by adrenal sympathetic preganglionic neurons in the thoracic spinal cord, secrete the catecholamines, epinephrine and norepinephrine, into the circulation as part of the stress response. Although normally at a low level, circulating epinephrine stimulates β1 adrenergic receptors on cardiac tissue to increase cardiac output and β2 adrenergic receptors to dilate skeletal muscle blood vessels, both supporting the "fight-or-flight" response to danger, as well as the muscle hyperemia needed for exercise.

There are several notable exceptions to the concept that blood vessels only receive a sympathetic postganglionic innervation. Innervation of arteries supplying the penis or the clitoris includes a parasympathetic component underlying an active vasodilation that maintains penile erection or clitoral engorgement and determines the success of reproductive behavior. Indeed, the role of nitric oxide as the mediator of this parasympathetic vasodilation

is the basis for a variety of successful pharmacological agents to combat erectile dysfunction. Parasympathetic inputs to the eye produce a nitric oxide-mediated vasodilation in the uveal vasculature that contributes both to the fine control of the availability of metabolic fuels to parts of the eye that lack an intrinsic blood supply and to optimizing the retinal image through variations in uveal light absorption. In humans, sympathetic vasodilator nerves to the skin are principally responsible for an acetylcholine-mediated relaxation of vascular smooth muscle that increases cutaneous blood flow for increased heat loss in hyperthermic environments. The parasympathetic innervation of the salivary glands elicits a local vasodilation that supports an increase in salivary secretion. Norepinephrine released from sympathetic nerve terminals innervating brown adipose tissue acts not only on brown adipocytes to induce thermogenesis, but also on local vascular endothelial ß-adrenoceptors to induce nitric oxide synthase and thereby provide the increase in tissue blood flow that distributes the heat throughout the body. Similarly, the increase in adrenal medullary blood flow that accompanies the sympathetic stimulation of adrenal catecholamine release is dependent on a sympathetic preganglionic, cholinergic stimulation of nitric oxide production.

Basal Neural Tone to the Cardiovascular System

The sympathetic and parasympathetic nerves to the heart and the sympathetic nerves to the vasculature all have a basal level of discharge ultimately controlled by central neural circuits innervating the various populations of preganglionic neurons (Fig. 35.8). Due to the intrinsic rhythmicity of cardiac pacemaker cells, the heart beats without extrinsic innervation (as is the case for human heart transplants). Heart rate is modulated by the combined sympathetic, parasympathetic, and adrenal epinephrine effects on cardiac pacemakers. For instance, resting heart rate is slower in trained athletes due to an increased vagal (parasympathetic) tone—a reflex that maintains a constant resting cardiac output in the face of the increased stroke volume resulting from the stronger cardiac muscle produced by training. In contrast, although there are a variety of chemical signals that affect vascular smooth muscle contraction, under normal conditions, the level of sympathetic nerve activity to blood vessels is the primary factor determining vascular diameter and, in turn, the resistance to blood flow throughout the vascular network. Vascular smooth muscle, in the absence of sympathetic input, has insufficient tone to provide enough resistance to keep arterial blood pressure at a level sufficient to provide adequate blood flow to meet the metabolic needs of the brain and other tissues in the body. Thus, a basal level of sympathetic tone is essential.

Sympathetic Premotor Neurons and Generation of Basal Sympathetic Tone

The cardiovascular sympathetic preganglionic neurons receive their primary excitatory drive from premotor neurons in the rostral ventrolateral medulla (RVLM). These bulbospinal neurons (Fig. 35.9) are glutamatergic, but many also contain the enzymes for catecholamine synthesis (C1 cell group). Silencing these neurons with local injections of muscimol (a $GABA_A$ receptor agonist), or transection of their bulbospinal axons as in spinal cord injury, results in a precipitous fall in arterial pressure due to marked reductions in cardiac output and in vascular resistance. RVLM neurons have a significant basal discharge rate that supports basal cardiovascular sympathetic nerve activity. Modulation of this activity underlies a variety of reflex- and centrally-evoked changes in sympathetic nerve activity, including the baroreceptor and chemoreceptor reflexes and the response to physical exercise, which are described below. Other brainstem and hypothalamic neurons also project to the intermediolateral nucleus in the

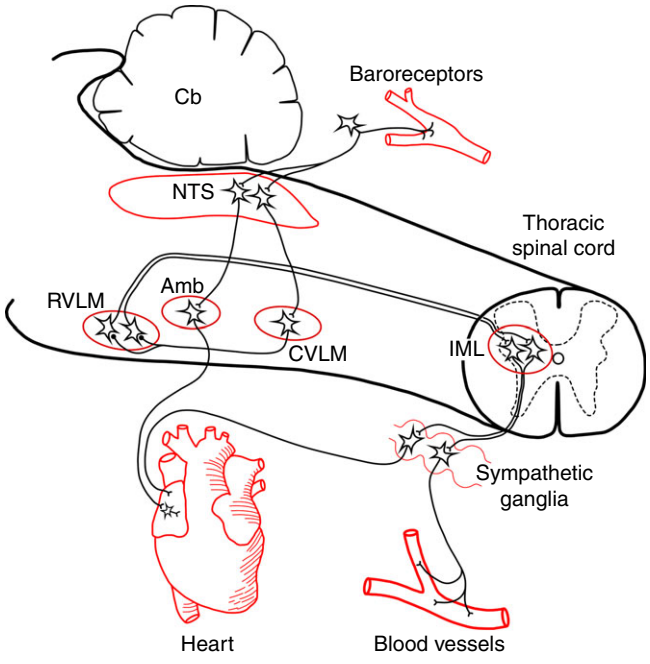

FIGURE 35.9 Anatomical schematic of the organization of the arterial baroreceptor reflex pathways providing short-term stabilization of arterial pressure through feedback control of cardiac and vascular performance (see text for description). Amb, nucleus ambiguus, containing cardiac vagal preganglionic neurons; Cb, cerebellum; CVLM, caudal ventrolateral medulla, containing GABAergic, inhibitory interneurons; IML, intermediolateral nucleus of the thoracic spinal cord, containing cardiac and vasoconstrictor sympathetic preganglionic neurons; NTS, nucleus of the tractus solitarius, containing second-order, barosensory neurons; RVLM, rostral ventrolateral medulla, containing sympathetic premotor neurons projecting to the spinal cord to control the heart and blood vessels.

thoracic spinal cord and thus also act as sympathetic premotor neurons. However, interruption of their activity does not eliminate basal sympathetic tone.

How and where is basal sympathetic tone generated? Understanding the generation and regulation of the basal sympathetic tone to the cardiovascular system is highly relevant, since exaggerated sympathetic outflow to the vasculature contributes to the elevated blood pressure in several forms of hypertension and an enhanced sympathetic outflow to the heart is a precipitating factor in cardiac arrhythmias leading to sudden cardiac death (Box 35.4). Blockade of various RVLM inputs has not been fruitful in identifying the primary sources controlling their activity, a key mystery in explaining the generation of the tonic cardiovascular sympathetic nerve activity. Although the RVLM neuronal pacemaker-like discharge seen under certain *in vitro* conditions was once proposed to provide the tonic drive, this does not appear to be the case because, under normal conditions, their rhythmic discharge is not endogenous, but rather is due to synaptic drive. Thus, although the RVLM sympathetic premotor neurons are essential elements in the circuit generating the basal cardiovascular sympathetic outflow (Fig. 35.8), the network or cellular mechanisms responsible for their basal activity remain unknown.

The parasympathetic (vagal) preganglionic neurons influencing cardiac function are strongly excited by inputs from the NTS which has neurons receiving input from arterial baroreceptors that sense pressure in the major arteries, thereby providing the afferent drive for vagal baroreceptor reflex bradycardia (Fig. 35.9). Although the central circuits underlying the parasympathetic vasodilatory control of certain vascular beds (see above) remain relatively unknown, this parasympathetically mediated redistribution of blood flow is critical for the successful performance of certain physiological functions, such as reproduction.

Summary

Neural circuits, primarily within the brainstem, are responsible for generating the modest level of vasoconstrictor sympathetic nerve activity to blood vessels that must be sustained to provide the vascular tone necessary to maintain a sufficient level of arterial pressure to perfuse all the capillary beds in the body, but especially those in the brain and heart, with the O_2- and nutrient-rich blood necessary for survival. Although the cellular and neural network mechanisms through which this basal sympathetic nerve activity is generated remain unknown, the vasoconstrictor sympathetic premotor neurons in the RVLM are the key medullary output neurons of this generating network, providing the glutamatergic excitation necessary to drive the spinal sympathetic circuits whose activity maintains vascular tone. Similarly organized, but distinct brainstem and spinal circuits generate and control the cardiac and other sympathetic outflows, contributing to the optimized tissue function necessary for homeostasis, the support of behavior and organismal survival.

BOX 35.4

CARDIOVASCULAR DISEASE

Alterations in the autonomic neural regulation of the cardiovascular system characterize the major cardiovascular diseases—contributing significantly to the etiology of the disease and to exacerbation of the symptoms and morbidity. Elevated sympathetic vasoconstrictor outflow plays a role in the increased vascular resistance seen in essential (primary) hypertension, the most prevalent form of high blood pressure and a major risk factor for stroke and congestive heart failure. Although the cause or trigger for this augmented stimulation of the CNS circuits generating vasoconstrictor sympathetic nerve activity is unknown, elevated dietary salt or increased central production of the hormone angiotensin II, both of which increase the discharge of RVLM sympathetic premotor neurons, are thought to contribute. Following myocardial infarction (heart attack), the cardiac sympathetic outflow is increased, at least partially the result of reflex drive to compensate for the reduced cardiac output, and this sympathetic drive to increase heart rate and cardiac contractility increases the stress on the weakened cardiac muscle, contributing to congestive heart failure and predisposing to arrhythmias. An imbalance in the neural regulation of the heart beat, with exaggerated cardiac sympathetic nerve activity and reduced cardiac vagal outflow, is a main cause of lethal arrhythmias and sudden cardiac death. Attempts to reduce mortality in such patients include surgical removal of the right stellate ganglion which contains the sympathetic ganglion neurons controlling heart rate. Increased understanding of the neural circuits and neurotransmitters controlling and generating sympathetic nerve activity to the cardiovascular system holds the promise of improved therapeutic approaches to a variety of cardiovascular diseases.

Shaun F. Morrison

SENSORY REGULATION OF RESPIRATORY AND CARDIOVASCULAR SYSTEMS

The principal homeostatic goal in the control of breathing is the regulation of the pressures of O_2 and CO_2 and pH in arterial blood—that is, arterial PO_2 = 80–100 mmHg, PCO_2 = 35–45 mm Hg and pH = 7.35–7.45. Such regulation requires their constant measurement by sensors connected in a feedback network to control breathing. Decreases in either PO_2 or pH or an increase in PCO_2 stimulate breathing, whereas increases in PO_2 or pH or a decrease in PCO_2 depress breathing. Similarly, a principal homeostatic goal in the regulation of the cardiovascular system is the maintenance of adequate blood flow to the brain. To meet this requirement, the CNS receives baroreceptor sensory input related to the stretch in the walls of the major arteries and modifies cardiovascular performance to sustain an arterial pressure sufficient to perfuse the brain with oxygenated blood.

Controlling Breathing and Cardiovascular Function; O_2 and CO_2 Are Measured By Chemoreceptors

The consequences of anoxia are catastrophic (particularly for the brain), but the effects of modestly depressed or elevated PO_2 are benign (due in part to the unique way blood hemoglobin reversibly binds O_2). However, small changes in PCO_2 (with consequent changes in pH) can profoundly affect cellular metabolism. Ventilation is very sensitive to small changes in PCO_2: a 1 mmHg increase in PCO_2 leads to a 2 liter × min^{-1} increase in ventilation at rest (~5 liter × min^{-1} in an adult human). In other words, a 2.5% increase in PCO_2 at rest leads to a 40% increase in ventilation! Thus, at rest and typically in exercise, ventilation is controlled mostly to regulate CO_2; however, in severe hypoxia, everything else is ignored. For example, compared to the normal ambient PO_2 at sea level (~160 mmHg), the exceptionally low PO_2 (~40 mm Hg) at the top of Mount Everest results in such a strong ventilatory drive that PCO_2 in climbers without supplemental O_2 is exceptionally low (~10 mm Hg compared with normal ~40 mm Hg). The sites and mechanisms of CO_2 chemoreception are the subject of intense scrutiny (Feldman, Mitchell, & Nattie, 2003). While the carotid bodies are sensitive to changes in PCO_2, a robust CO_2 response remains in peripherally chemo-denervated, vagotomized mammals, indicating the existence of intracranial sensors for CO_2 or related variables (pH, HCO_3^-). A number of structures are implicated in intracranial chemotransduction (Feldman et al., 2003; Huckstepp & Dale, 2011). Among these, neurons within the RTN (Guyenet et al., 2010) and in the raphe (Richerson, 2004; Ray et al., 2011) respond robustly to changes in CO_2/pH within the physiological range and project to respiratory nuclei.

The mammalian brain is extremely sensitive to O_2 deprivation: several minutes of anoxia can initiate a cascade leading to loss of consciousness and neuronal death. Accordingly, the arterial chemoreceptors, the principal O_2 sensors for the entire body, are located in the carotid bodies in the bifurcation of the common carotid artery, the main portal through which O_2-enriched blood is transported to the brain. Arterial chemoreceptor afferents enter the brain via the glossopharyngeal nerve (cranial nerve IX) and terminate on second-order sensory neurons located primarily in the commissural region of the NTS.

Arterial chemoreceptor signals account for only a small part of the chemical drive to breathe during wakefulness, as breathing 100% O_2 reduces peripheral chemoreceptor discharge to near zero but only decreases ventilation by ~15% in awake mammals. Decreasing PO_2 has relatively little influence on chemoreceptor activity and ventilation until it falls to ≤60 mm Hg. With further reductions in PO_2, chemoreceptor discharge and ventilation increase exponentially.

In contrast to the global effects of hypoxia on breathing, the cardiovascular response is compartmentalized, directed toward conserving the O_2 availability for the brain by increasing brain blood flow while simultaneously reducing blood flow to other tissues. This is accomplished primarily by a widespread sympathetically induced vasoconstriction, which is driven by the arterial chemoreceptors and mediated by a strong activation of RVLM sympathetic premotor neurons. Although the brainstem circuitry underlying arterial chemoreceptor-stimulated excitation of RVLM sympathetic premotor neurons remains to be identified, a role for the RTN has been strongly implicated (Moreira, Takakura, Colombari, & Guyenet, 2006). In extreme cases, vasoconstriction evoked by severe hypoxia can reduce blood flow sufficiently to cause organ damage—for example, renal failure. Interestingly, although diving mammals such as seals also conserve brain O_2 availability by slowing their heart rate (by vagal activation) and maximally constricting their muscle blood vessels during their dives (hypoxic breath-holding), they avoid hypoxic tissue damage and maintain use of skeletal muscle through adaptations that include a prominent increase in myoglobin concentration.

Baroreceptor Reflex Regulation of Cardiovascular Performance

With the primary goal of maintaining adequate perfusion of the brain with sufficient O_2-rich arterial blood to support its continuous and high level metabolism, two regulatory circuits are critical for the maintenance of blood pressure (via the baroreceptor reflex) and for the distribution of blood flow (via the arterial chemoreceptor

reflex). The baroreceptor reflex can be modeled as a simple negative feedback circuit in which changes in arterial pressure evoke compensatory changes in cardiovascular sympathetic nerve activity and cardiac parasympathetic vagal nerve activity to affect cardiac output and vascular resistance in an effort to return arterial pressure toward its baseline level. Figure 35.9 illustrates the pathways mediating the baroreceptor reflex-mediated changes in autonomic outflows. The sensors in the baroreceptor reflex are stretch receptors (baroreceptors), sensitive to changes in the pressure across the walls of the major arteries, and with axons in the vagus and glossopharyngeal nerves that project to second-order NTS neurons (Fig. 35.9). Thus, the activity of NTS barosensory neurons tracks increases and decreases in arterial pressure, including the rapid rise and fall in arterial pressure that occurs during the systolic phase of each cardiac cycle. Second-order glutamatergic barosensory neurons in the NTS project to GABAergic neurons in the caudal ventrolateral medulla (CVLM) that, in turn, project to the RVLM to inhibit cardiovascular sympathetic premotor neurons (Fig. 35.9). Thus, for example, a fall in arterial pressure will induce the following sequence: decreased activity of barosensory NTS neurons leading to disfacilitation of CVLM inhibitory interneurons and subsequent disinhibition of RVLM sympathetic premotor neurons causing increased preganglionic activity resulting in cardiac stimulation and vasoconstriction, acting together to counter the fall in arterial pressure. Concurrently, the reduced firing of NTS barosensory neurons decreases the excitation of cardiac vagal preganglionic neurons in the nucleus ambiguus (Fig. 35.9), thereby diminishing their inhibitory influence on the heart, effectively amplifying the effects of increases in cardiac sympathetic nerve activity. Each of the synaptic integration sites in the baroreceptor reflex pathway present the potential for other inputs to modulate the effectiveness of the reflex. For instance, both arterial pressure and heart rate must rise to provide adequate perfusion of skeletal muscle during escape behavior (or exercise, see below) and this is accomplished, in part, by presynaptic inhibition of the baroreceptor afferent inputs to second-order barosensory NTS neurons from hypothalamic neurons activated during these behaviors.

Summary

Chemoreceptors in the carotid bodies and in the brain provide sensory input to the central circuits controlling breathing and cardiovascular function. PCO_2 is normally regulated within narrow limits over a wide range of metabolic demands and this usually assures an adequate O_2 supply to the brain. However, during significant hypoxia, arterial chemoreceptors sensitive to O_2 can provide a powerful stimulus to increase breathing. Central chemoreceptors are exquisitely sensitive to changes in PCO_2 and in pH and can evoke large and rapid increases in respiration. Baroreceptors transduce the pressure in the major arteries to neural signals that modulate the autonomic outflows to the cardiovascular system, thereby stabilizing arterial pressure and maintaining adequate blood flow to the brain.

MODULATION AND PLASTICITY OF RESPIRATORY MOTOR OUTPUT

In meeting the homeostatic goal of maintaining normal arterial PO_2 and PCO_2, breathing must continually be adapted to meet changes in the state of the body—for example, posture—and in the environment (e.g., sojourning to or living at high altitude), and, in particular, to compensate for a variety of chronic cardiopulmonary diseases that result in low arterial PO_2.

Adaptations in the control of breathing in response to hypoxemia are examples of neural plasticity (Feldman et al., 2003). Inhaling an hypoxic gas mixture for 10–20 min elicits a progressive increase in ventilation. This slow increase in breathing at the onset of hypoxia is matched with a slow posthypoxic decline back to normal ventilation that is termed *short-term potentiation* (arrowheads in Fig. 35.10). Thus, even though the afferent input to the respiratory system from arterial and central chemoreceptors can change abruptly, the respiratory response consists of slower, smoother changes. This is important since abrupt changes can result in an unstable breathing pattern such as Cheyne-Stokes respiration (Fig. 35.4 and see Box 35.2), often seen in patients with severe congestive heart failure.

A longer-lasting plasticity is revealed following a repetitive series of brief episodes of hypoxia, as may occur in a patient with sleep apnea (see Box 35.5). As illustrated in Figure 35.10, following the final hypoxic episode, ventilation transiently returns toward control levels, but is followed by a progressive augmentation that lasts for several hours termed *respiratory long-term facilitation.* Like other forms of neural plasticity in the brain, respiratory long-term facilitation is dependent on activation of serotonergic and noradrenergic inputs to respiratory motoneurons. This activates protein kinases, such as protein kinase C, thereby initiating an intracellular signaling cascade that amplifies the synaptic currents arising from glutamatergic respiratory premotoneurons. In response to a single prolonged hypoxic exposure, protein phosphatases constrain activity in this pathway and prevent long-term facilitation. However, repetitive bouts of hypoxia decrease the activity of phosphatases such as the serine/threonine phosphatases, thereby removing this constraint and permitting the development of long-term facilitation (Wilkerson, Macfarlane, Hoffman, & Mitchell, 2007).

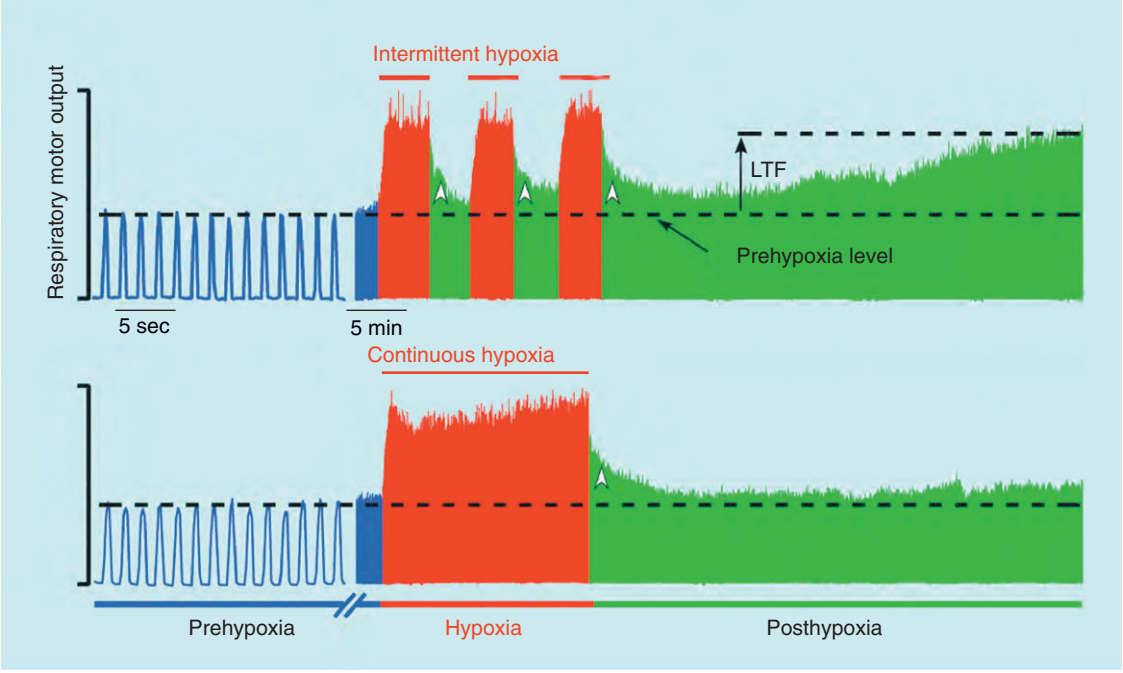

FIGURE 35.10 Respiration-related neural activity in an anesthetized and artificially ventilated rat exhibits *respiratory long-term facilitation*. Peak electrical activity in the phrenic nerve corresponds to the magnitude of inspiration. When arterial O_2 and CO_2 are normal (prehypoxia), the phrenic bursts are rhythmic and consistent (shown with expanded time scale). Upon exposure to intermittent (upper trace) or continuous (lower trace) hypoxia, phrenic bursts increase in amplitude, reflecting the drive to take deeper breaths when hypoxia-sensitive chemoreceptors are activated. In both patterns of hypoxia, phrenic nerve activity slowly returns nearly to baseline over a period of several minutes in a process termed short-term potentiation (STP; open arrowheads). Following intermittent, but not continuous hypoxia, phrenic burst amplitude progressively increases over an hour. This slow increase reflects respiratory long-term facilitation (LTF). *Courtesy of T. L. Baker and G. S. Mitchell.*

BOX 35.5

DISORDERS OF BREATHING ARE WIDESPREAD AND SERIOUS

Breathing at rest is normally controlled to maintain arterial PCO_2 at 40±2 mm Hg. However, cardiopulmonary pathology can increase PCO_2 markedly. Narcotics, barbiturates, and most general anesthetics depress breathing and at high doses, as can happen when self-administered, these drugs can cause death by respiratory failure. For opioids, respiratory depression appears to be due to depressant actions directly on preBötzinger complex neurons.

Sleep apnea. Sleep is associated with a modest decrease in ventilation and a reduced responsiveness to deviations in PCO_2 and PO_2. With the onset of sleep, the breathing pattern can become unstable, and apnea (defined as at least 10 s without breathing) can occur. In the most common form, *obstructive sleep apnea*, there is a loss of tone in airway muscles and tongue, so that the reduction in airway pressure during inspiration can pull in on the walls of the upper airway sufficiently to cause vibration—that is, snoring, even airway obstruction. Obstruction reduces or abolishes ventilation, raising CO_2 and lowering O_2. This in turn can cause arousal, and with it restoration of airway muscle tone and airway patency. In serious cases, the cycle of sleep, airway obstruction, and hypoxia-induced waking repeats hundreds of times every night. The marked disruption of sleep can cause debilitating hypersomnolesence, and severe obstructive sleep apnea can also have other sequelae, such as hypertension. In *central sleep apnea*, pauses in breathing result from the failure of respiratory drive. Mechanisms underlying central apneas are not understood, but the problem is prevalent during sleep at the end stages of a variety of neurodegenerative diseases, including amyotrophic lateral sclerosis, Parkinson's disease, and multiple systems atrophy (where there is evidence of loss of preBötC neurons).

Sudden infant death syndrome (SIDS). SIDS is defined as the unexpected sudden death of an infant or young child that cannot be explained by a postmortem examination. SIDS is the leading cause of death of infants between 1 month and 1 year of age in the United States. Although a

BOX 35.5 *(cont'd)*

number of etiologies are likely to contribute to SIDS, current hypotheses tend to focus on abnormalities of cardiorespiratory control. The apnea hypothesis of SIDS attributes apnea to disorders of both the chemical control of breathing and the arousal response to insufficient ventilation. Infants who later succumb to SIDS have been described as exhibiting irregular breathing patterns, including periods of apnea, and depressed arousal responses to hypoxia or hypercapnia. Epidemiologically, SIDS has been associated with infants sleeping face down, where pillows, blankets, and mattress can limit the diffusion of expired air, resulting in elevated CO_2 and lower O_2 in inspired air and, consequently, in arterial blood. This in turn could depress breathing sufficiently to cause respiratory arrest and death.

Genetic Diseases Affecting Breathing

Congenital Central Hypoventilation Syndrome (CCHS; Weese-Mayer et al., 2009). CCHS is a potentially life-threatening genetic disorder typically presenting in newborns and characterized by respiratory insufficiency especially during sleep. This breathing phenotype is the consequence of an impaired ventilatory response to hypercapnia (increased blood PCO_2) and hypoxemia (decreased blood PO_2). Additionally, the disease is often associated with functional impairments of the autonomic nervous system and tumors of neural crest derivatives. The defining mutation in CCHS is a polyalanine expansion in *Phox2b*. The extent of the polyalanine repeat mutation correlates with the severity of the disease, with the most severe cases requiring continuous artificial ventilation. The offspring of mice genetically modified to contain the polyalanine expansion have irregular breathing at birth, do not increase their breathing in response to CO_2 stimulation of chemoreceptors, and die shortly after birth. Postmortem examination of these mice provided a likely explanation for the depression of breathing. Chemoreceptor neurons in the RTN (Fig. 35.2) normally express Phox2b but in mouse pups with the Phox2b polyalanine expansion these neurons were absent. Thus, the *Phox2b* mutation appears to result in a loss of RTN neurons that reduces the normal respiratory drive arising from chemoreceptors.

Rett Syndrome (RTT; Lioy, Wu, & Bissonnette, 2011). RTT is a developmental disorder of the central nervous system resulting from mutations in the X-linked gene methyl-CpG-binding protein 2 (*Mecp2*) and is usually seen in girls. It results in severe neurological symptoms that include speech and movement disorders as well as irregular breathing (e.g., Cheyne-Stokes breathing; Fig 35.4 and Box 35.2) that can include life-threatening periods of apnea. The onset of symptoms typically begins at about 6–18 months of age at which time there is a slowing down of motor skills and then a regression in communication skills.

Exercise: An Example of Cardiopulmonary Integration

Physical activity involving repetitive movement of large muscles significantly increases the metabolic consumption of O_2 and production of CO_2. Even during mild activity, such as walking, the metabolic changes require substantial ventilatory and cardiac output increases to maintain arterial and brain levels of CO_2 and O_2 within normal limits. Impressively, the cardiorespiratory changes are proportional to the changes in metabolism and there is almost no change in arterial PCO_2 or PO_2 with mild or moderate intensity exercise. During high intensity exercise, the increase in breathing can result in a decrease (!) in arterial PCO_2. The primary cardiovascular adjustments accompanying exercise include not only the sympathetically mediated increases in heart rate and cardiac contractility necessary to elevate cardiac output required to support increased muscle metabolism, but also a widespread sympathetic vasoconstriction. This increased sympathetic input to the vasculature plays a significant role in optimizing exercise performance. Blood volume "stored" in the veins at rest is brought into the arterial circulation to increase the capacity for O_2 transport to exercising muscle. Arterial blood pressure is maintained in the face of a marked reduction in total peripheral vascular resistance due to the substantial vasodilation occurring in exercising muscle (driven mostly by local metabolic signals—for example, adenosine—rather than by a selective inhibition of sympathetic tone to exercising muscle). Metabolism and O_2 consumption in nonexercising tissues is significantly reduced—for example, the reduced blood flow to the GI tract accounts for the cramping that occurs with intense exercise immediately after a large meal. Sympathetically driven adrenal epinephrine secretion further supports both the increased cardiac output and the skeletal muscle hyperemia. Because the large amount of heat produced by exercising muscles (and the respiratory muscles engaged to support exercise) must be eliminated to prevent a significant rise in body temperature (potentially lethal hyperthermia), secondary, but critically important cardiovascular changes are engaged as exercise

progresses: a reduction in sympathetic vasoconstrictor tone to the skin increases skin blood flow and heat loss, and sympathetic vasoconstriction to the kidney is increased to retain water and electrolytes that are required to maintain blood volume during the increased sweat production (as much as 1.5 l/h) required to enhance heat loss from the skin.

Despite its utility as a model of neural integration and widespread scientific fascination with the topic, the physiological mechanisms underlying the matching of changes in cardiorespiratory function to exercise remain mysterious. Since there is normally little change in CO_2 or O_2, classic negative feedback from arterial or brain chemoreceptors cannot adequately account for these cardiorespiratory adjustments. Thus, feedforward, descending command from higher brain systems and sensory input from joint and muscle receptors appears to be important.

The volitional initiation of exercise, signaled by suprapontine structures, likely involves activation of spinal pathways for locomotion and concurrent feedforward activation of brainstem mechanisms controlling breathing and cardiovascular function. This allows pulmonary ventilation and gas transport to change appropriately and quickly before there are any significant changes in blood gases (as would occur if the mechanism was strictly based on feedback). Commands for the activation of pulmonary and locomotor muscles presumably arise in similar ways in the motor cortex, thalamus, and basal ganglia. Once the motor command has been initiated, respiratory and locomotor activities are likely coordinated at subcortical levels, including the hypothalamus and periaqueductal gray. Electrical or chemical activation of the hypothalamus in the anesthetized, paralyzed cat elicits fictive locomotion paired with proportional increases in respiratory motor output (suggestive of exercise-related increases in ventilation, termed exercise hyperpnea) and redistribution of blood flow consistent with the induction of locomotion (Waldrop, Eldridge, Iwamoto, & Mitchell, 1996). Because the animals were paralyzed, muscle activation did not occur, and thus the changes in breathing were the result of feedforward control rather than sensory feedback from joint or muscle receptors.

At the level of the brainstem, coordination of the respiratory and cardiovascular responses likely involves circuitry in the dorsolateral pons, in the vicinity of the PRG. Descending inputs from the hypothalamus, periaqueductal gray, and dorsolateral pons activate medullary respiratory circuits to increase both the depth of each breath—that is, tidal volume—and respiratory frequency, which almost certainly involves modulation of the activity of the rhythm generating circuitry in the preBötC. The need for an increase in the size of each breath means there is also a parallel increase in the activity of pattern forming circuits in, for example, the rVRG. There is also an increase in the contribution of expiratory muscles. Expiratory rhythm generating neurons in the region of the pFRG appear to be synaptically inhibited at rest and this inhibition may be removed by signals related to exercise, possibly through the influence of descending inputs from the higher brain structures. Through reciprocal connections between the pFRG and preBötC, activation of the pFRG may contribute to the increase in breathing frequency. Activation of the pFRG will also increase tidal volume through activation of expiratory pattern-forming circuits in the caudal VRG.

The increases in cardiac, vasoconstrictor, and adrenal sympathetic outflows necessary for exercise are mediated by enhanced discharge of the relevant sympathetic premotor neurons in the RVLM. Although the exercise-related stimulus and the source of the increased excitatory drive to these premotor neurons are unknown, their excitatory inputs from central respiratory neurons are likely to contribute significantly. Also contributing to the sympathetic activation is a centrally-mediated reduction in the effectiveness of the inhibitory baroreceptor reflex, due to modulation of the synaptic efficacy in the NTS, which would otherwise inhibit sympathetic outflow as arterial blood pressure increases during exercise. The increased central respiratory drive may also contribute to the activation of adrenal sympathetic premotor neurons in the RVLM during exercise, which leads to secretion of adrenal epinephrine and a potent stimulation of cardiac output and skeletal muscle vasodilation. As the body heat load rises during exercise, warm-sensitive, thermoregulatory neurons in the preoptic hypothalamus increase their inhibitory influence on the cutaneous vasoconstrictor premotor neurons in the raphe nuclei of the ventromedial medulla to dilate skin blood vessels. Simultaneously, these preoptic neurons excite the sympathetic outflow to sweat glands to augment heat loss. As the osmolarity of the blood increases due to sweating, a specialized, osmosensitive neural network in the anterior hypothalamus increases the activity of renal sympathetic premotor neurons in the RVLM to augment the sympathetic outflow to the kidney to reduce renal filtration and help sustain blood volume.

Summary

Breathing and cardiovascular function are fundamental and intertwined physiologic functions that must be controlled vigilantly by the brain. This chapter has explored the basic mechanisms underlying rhythm generation, sensory processing, and motor output for these regulatory systems.

CHAPTER

36

Food Intake and Metabolism

Eating is a familiar behavior. In humans, it is strongly influenced by cultural, social, and experiential factors. Consequently, eating has been a subject of considerable interest to social and behavioral scientists. In mammals, including humans, food intake is also a regulatory behavior with the primary function of supporting the continuous energy demands of body tissues. When considered from this biological perspective, food intake is influenced by hunger, satiety, and the physiological mechanisms that couple eating with internal caloric supplies and a stable body weight. This chapter discusses the signals important for the central nervous system's control of food intake and glucose homeostasis, and also describes mechanisms thought to integrate those signals.

Despite decades of investigation, considerable differences of opinion still exist about how food intake is controlled. The multiple views follow one of two principles. The first considers eating to be a consequence of depleted energy stores in adipose tissue, reduced use of energy-rich *metabolic fuel* (glucose or lipid) in some critical tissue, or both. In this schema, the purpose of eating is to restore energy reserves in adipose tissue or to increase fuel utilization to some desired level, thereby eliminating the signal to eat. This traditional negative feedback model is not the approach taken in this chapter. Rather, we subscribe to a second principle, in which hunger is thought to be initiated in part by the gradual disappearance of inhibitory satiety stimuli that were generated by the previous meal. In addition, meal initiation may occur based on learning, habits, and various social and other situations, which allow animals to take maximal advantage of their environment. According to this view, *caloric homeostasis* influences meals, albeit indirectly, and eating contributes to caloric homeostasis by providing nutrients. The storage and use of those nutrients are regulated independently by physiological mechanisms described later. We describe the properties of caloric homeostasis before we consider the control of food intake.

CALORIC HOMEOSTASIS

Homeostatic Mechanisms Provide a Continuous Supply of Metabolic Fuels to Cells

The purpose of caloric homeostasis is to preserve cellular metabolism. Cells oxidize metabolic fuels to drive all cellular processes; thus, the higher the cellular activity, the greater the demand for energy. Because most cells have limited amounts of stored energy, they rely on a steady supply of calories and oxygen from the bloodstream. Oxygen is dependably and instantaneously available via the respiratory system and is not stored in the body. In contrast, food calories can be scarce and require time after ingestion to become available to cells in significant quantities. One consequence of this functional organization is the capacity of animals to store sufficient energy to bridge long intervals during which no food is eaten.

Three categories of macronutrients—carbohydrates, lipids, and proteins—provide usable energy, but the use of specific macronutrients by the body varies depending on the tissue. Most tissues can oxidize carbohydrates in the form of *glucose* or lipids in the form of *free fatty acids*, depending on the availability of these nutrients and the levels of certain hormones in the blood. Notable exceptions are the liver, which requires lipids for proper functioning, and the brain, which has a large, continuous need for glucose despite the ability to oxidize lipids in the form of *ketone bodies*. When the supply of glucose to the brain is compromised, neurons cease to function and in a few minutes consciousness is lost. Death will ensue unless glucose delivery to the

© 2013 Elsevier Inc. All rights reserved.

brain is restored. Therefore, maintenance of circulating glucose in sufficient amounts to support normal brain function is a critical goal of caloric homeostasis.

Two distinct metabolic states are defined by the availability of recently consumed food to cells. The *prandial*, or fed, state is characterized by an abundance of newly ingested and absorbed nutrients in the blood. These molecules are sequestered rapidly in tissues to prevent them from being excreted wastefully in urine. The *postabsorptive*, or fasted, state is characterized by the absence of calories entering the circulation from the gastrointestinal tract and a consequent reliance on energy from metabolic fuels less recently consumed and stored. These stores are released gradually into the blood during a fast. In both states, tissues take nutrients from the blood as needed for cellular metabolism.

Many tissues store carbohydrates in the form of *glycogen*, a polymer of glucose; the liver and skeletal muscles have the largest depots. Energy is stored more efficiently, mainly in adipose tissue, as *triglyceride*, each molecule of which consists of glycerol with three attached fatty acids. During the prandial period, newly ingested food is used immediately by the body or is stored as glycogen or triglyceride. Excess carbohydrate is largely converted to lipid (*lipogenesis*) because glycogen storage capacity is limited. During the fasting period, liver glycogen is converted back to glucose (*glycogenolysis*), which enters the blood and is available to all tissues. Similarly, stored triglycerides are mobilized from adipose tissue (*lipolysis*) and enter the circulation as fatty acids and glycerol. The fatty acids are used by tissues as needed or are converted to ketone bodies (*ketogenesis*), whereas glycerol is converted to glucose (*gluconeogenesis*) (Fig. 36.1).

The liver is the key organ of energy traffic. Lipogenesis (which also occurs in adipose tissue) and glycogen formation (which also occurs in skeletal muscle) occur in the liver during the prandial period, and glycogenolysis, ketogenesis, and gluconeogenesis occur during the fasting period. These processes are regulated (discussed later), as are delivery of metabolic fuels (from the small intestine into the circulation), storage of excess fuels, and mobilization of stored energy. The control system involves interplay among several hormones and the sympathetic and parasympathetic divisions of the autonomic nervous system.

Insulin is the Key Hormone Affecting Caloric Homeostasis

Secretion of the peptide hormone *insulin* from B cells of the pancreatic islets is influenced by several factors, among which interstitial glucose is critical. Insulin secretion increases in direct proportion to the concentration

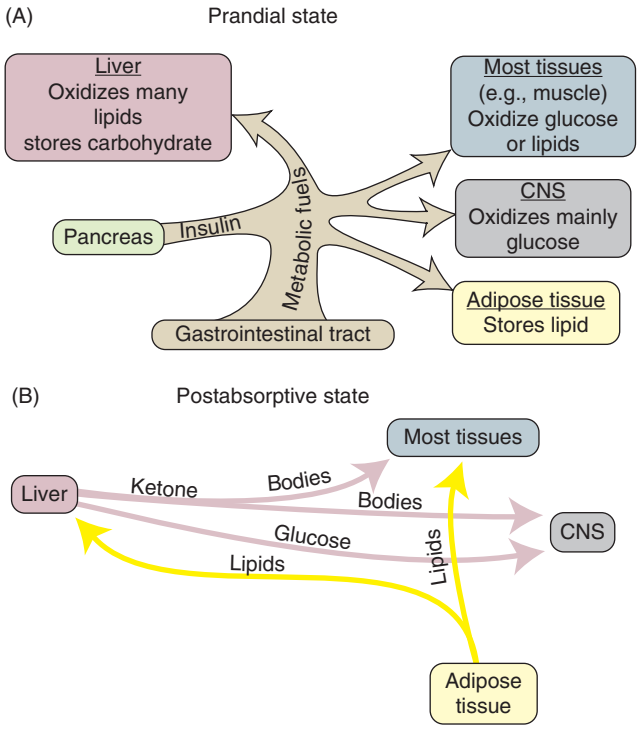

FIGURE 36.1 Schematic diagram of the fluxes of metabolic fuels in the (A) prandial and (B) postabsorptive states. Note the absence of insulin in the postabsorptive state, which greatly facilitates the mobilization of energy stores from the liver and adipose tissue. The adult human liver stores sufficient fuel to support metabolism during fasting for about 7 h, whereas the adipose mass has a far greater capacity.

of glucose in the blood. Other substrates, such as amino acids and ketone bodies, also stimulate insulin secretion. In addition, autonomic nerves innervate the pancreatic islets: cholinergic parasympathetic activity stimulates secretion of insulin, and α-adrenergic sympathetic activity inhibits it.

When a hungry person anticipates a meal, the aroma and, subsequently, the taste of food initiate the secretion of insulin and many other pancreatic and gastrointestinal signals via neural activity. Neural signals descend from the forebrain (where the smell and taste of food are recognized) through the hypothalamus to the dorsal motor nucleus of the vagus in the caudal brainstem and then to the pancreas and gastrointestinal tract by way of cholinergic fibers of the vagus nerve. This *cephalic phase* of secretion of insulin and gastrointestinal hormones such as glucagon-like peptide-1 (GLP-1) helps reverse the mobilization of fuels that occurs during fasting and prepares the body for the entry of fuels from the gut. As ingested food enters the stomach and duodenum, several gastrointestinal hormones, which also are important in digestion, continue to stimulate pancreatic B cells to secrete more insulin. This *gastrointestinal phase* of insulin secretion ensures that the level of insulin in the circulation is high by the time digested nutrients first appear

in the bloodstream. Finally, nutrients absorbed from the small intestine cause even greater stimulation of insulin secretion by their direct effect on the pancreas. This *substrate phase* of insulin secretion increases insulin levels further, and that effect lasts well beyond the cessation of eating. As a result of these coordinated meal-related events, prandial insulin secretion is rapid and appropriate to the caloric load, and ingested fuels are efficiently used and stored (Fig. 36.2).

Neural and endocrine factors control the ebb and flow of metabolic fuels from body stores. Circulating insulin is the most important factor that promotes storage. Insulin enables most tissues to take up glucose from the blood for immediate oxidation or for storage during the prandial period. Conversely, the most important factor for fuel mobilization is the near disappearance of insulin from the circulation during the postprandial, postabsorptive period, when fuel delivery from the small intestine has ended and parasympathetic activity to the pancreas is no longer elevated. Insulin secretion at this time is reduced greatly but is not inhibited and therefore can be stimulated immediately if necessary. For example, when more than the needed amount of stored fuels is mobilized, substrates directly stimulate the pancreas to secrete insulin, thereby slowing substrate mobilization to a rate appropriate to need. Thus, insulin is pivotal for storing calories in the fed state and for allowing stored calories to be mobilized in measured amounts during the postabsorptive state.

The amount of body fat (*adiposity*) is superimposed on other factors that influence insulin secretion. People with low adiposity have a relatively large number of active insulin receptors on adipose tissue, whereas obese individuals have fewer active insulin receptors. Consequently, in response to a given stimulus, secretion of insulin is lower in people who are lean than in those who are obese, but its net effects on adipose and other tissues are comparable. In healthy, nondiabetic people, this reciprocal relationship between the secretion of insulin and the sensitivity of most tissues to insulin ensures efficient storage and use of fuels independent of body fat. In these individuals, plasma insulin levels in the prandial and the postprandial periods are reliable correlates of adiposity.

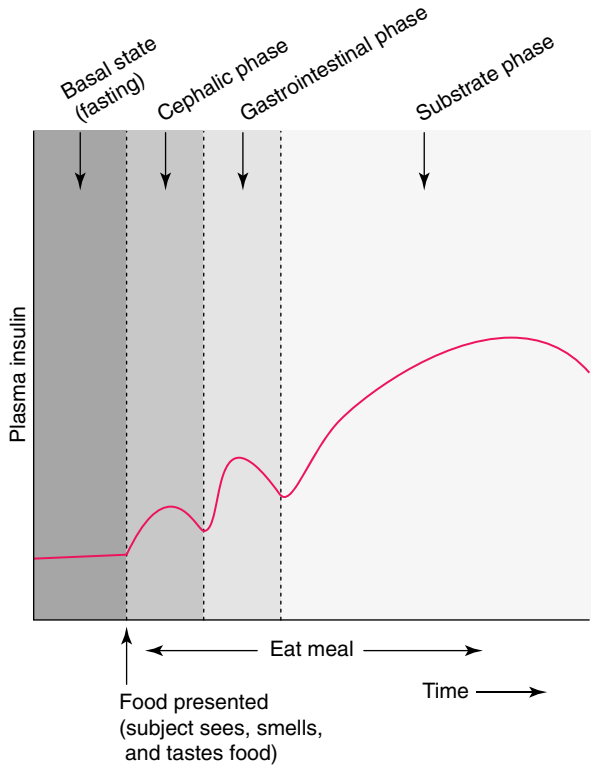

FIGURE 36.2 The three phases of meal-related insulin secretion. The cephalic phase, during which parasympathetic vagal activity stimulates the pancreas, is initiated when food is seen, smelled, and tasted. The gastrointestinal phase is mediated by the direct action of digestive hormones on the insulin-secreting B cells. The prolonged substrate phase is caused by metabolic fuels (mainly glucose) directly stimulating pancreatic B cells. When meals are prolonged, the three stimuli operate simultaneously and have additive effects.

Summary

All cells require continuous supplies of metabolic fuels to support ongoing activity. The fuels enter the circulation from the small intestine during the prandial period and from storage depots during fasting. The availability of fuels to tissues is controlled primarily by the liver and by the hormone insulin. Hepatic function and insulin secretion are in turn controlled in large part by the autonomic nervous system.

ROLE OF CALORIC HOMEOSTASIS IN CONTROL OF FOOD INTAKE

Meals Generate Biological Satiation Signals

The traditional view of caloric homeostasis is that animals eat when they need calories. However, as discussed earlier, the delivery of metabolic fuels to cells is continuous, and animals may experience urgent needs for calories to support cellular metabolism only infrequently. Instead, caloric homeostasis can be related to the control of food intake in ways that are unrelated to acute cellular needs.

Animals consume food in distinct bouts (i.e., meals); therefore, daily food intake reflects the cumulative intake of multiple meals. Control factors influence the time when each meal is initiated and the amount of food consumed before the meal is terminated. Satiation signals terminate an ongoing meal whereas satiety signals prolong the interval until a subsequent meal is initiated.

The first comprehensive study of meals was reported in 1966 by Le Magnen and Tallon. They maintained laboratory rats in cages and allowed them to eat *ad libitum* for weeks, during which time intake was recorded by photosensors and electronic relays. They consequently obtained a full record of when meals were initiated, how much was eaten during each meal, how much time passed before the next meal, and so on. No relationship was found between how much a rat ate in a meal and how much time had passed since it had last eaten; in other words, meal sizes were unpredictable. However, the larger the meal, the longer the interval before the next meal, and the relationship was strongest during the night, when rats ate the largest meals. Thus, eating appeared to be inhibited by a satiety signal generated in proportion to the size of a meal, and eating resumed when that signal disappeared. Similar observations have since been made in many laboratories.

Gastric Distension, Cholecystokinin, and Other Satiation Signals

Several meal-related variables might plausibly provide satiation signals. These include signals based on the smell, taste, and texture of food. Signals arising from the stomach could also play a role, as could intestinal and postabsorptive signals that arise after ingested food has left the stomach. In studies of rats, pregastric signals have been ruled out because little satiation is achieved when ingested food is immediately drained out through an esophageal or gastric fistula; these animals eat continuously, as if they had no satiation despite the passage of very large amounts of food through the oropharynx (Fig. 36.3). Because meals end long before significant digestion and absorption occur, gastric signals have been considered a likely source of satiation. Gastric volume is an obvious possibility, and, in fact, meals are known to end when substantial gastric distension occurs. The stomach wall is richly endowed with stretch receptors whose activity increases in proportion to the volume of the stomach. Those signals are communicated by way of the vagus nerve to the nucleus of the solitary tract (NST) and adjacent area postrema in the brainstem. The signals travel to the hypothalamus and, ultimately, to the cortex, where gastric distension is perceived.

Gastric stretch that accompanies meals presumably interacts with other signals to produce satiation. For example, aside from directly affecting digestion, the intestinal peptide *cholecystokinin* (CCK), which is secreted during meals, acts on receptors located on vagal afferent fibers that carry gastric stretch signals from the pyloric region of the stomach to the brainstem. Thus, relatively small amounts of CCK can inhibit feeding in rats by acting synergistically with gastric distension. When given in larger doses, CCK can inhibit food intake even when the stomach is empty

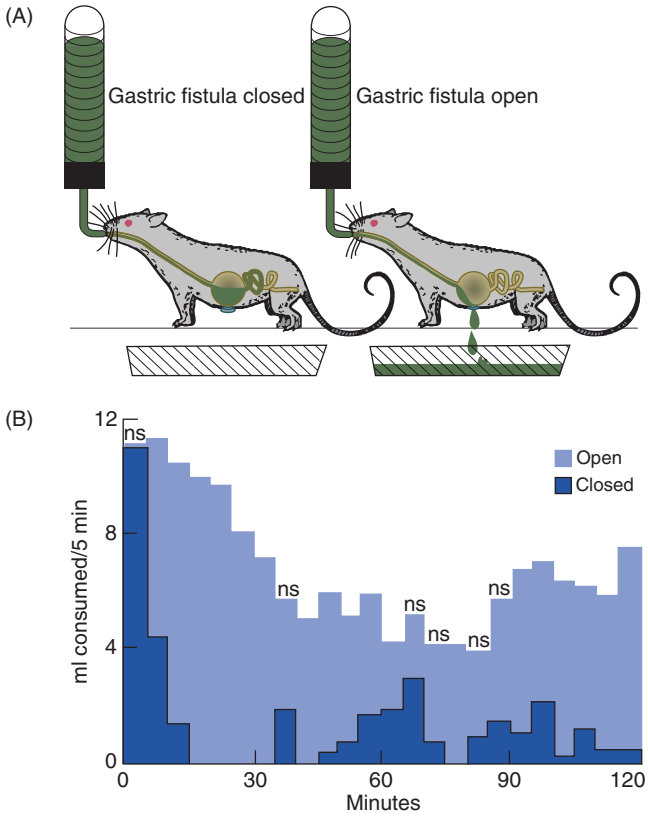

FIGURE 36.3 (A) Rats consuming liquid diet, with gastric fistula closed (real eating) or open ("sham eating"). When the gastric fistula is closed, food passes through the stomach and into the small intestine normally. When the gastric fistula is open, ingested food drains out the open fistula instead of accumulating in the stomach to distend it, and no food enters the small intestine. (B) Mean consumption of liquid diet (ml/5 min) by rats with a gastric fistula after 17 h of food deprivation. The rats consumed food in discrete meals when the fistula was closed. When the fistula was open, they ate continuously throughout the test period and never displayed satiety. Thus, rats consumed significantly more food during the 2-h test period when their fistulas were open than when they were closed. ns, intervals in which the amount of food consumed did not differ significantly between open and closed fistulas. *From Smith, Gibbs, and Young (1974).*

(Gibbs, Young, & Smith, 1973). As might be expected, total or selective gastric *vagotomy* (or ablation of brainstem areas to which the gastric vagus projects) decreases the ability of gastric volume and peripherally administered CCK to reduce meal size. Conversely, systemic administration of CCK receptor antagonists increases the size of meals (Box 36.1).

Gastric distension is one of the factors that control suckling in neonatal rats. The dam controls the timing of meals, and at each meal pups consume as much milk as their stomachs allow; gastric volume, not caloric content, provides the signal to stop. Consistent with the importance of gastric distension to suckling, pups are particularly sensitive to the inhibitory effects of

BOX 36.1

VALIDATING SATIATION FACTORS

Several metabolically important peptides are secreted during meals, including CCK, insulin, leptin, *glucagon-like peptide-1* (GLP-1), *Peptide YY* (PYY) and others. The specific individual nutrients being consumed are thought to determine the specific mix of peptides secreted, and their combination is considered to elicit satiation. Consistent with this perspective, each of these peptides has been found to reduce food intake when administered systemically to laboratory animals. By themselves, these findings do not prove that the peptides normally function as endogenous satiation agents; blood levels of an administered peptide must be within the physiological range. In addition, the behavioral effects of the peptide must be specific to the inhibition of food intake and cannot merely reflect a secondary consequence of illness, behavioral depression, or motor incapacitation. Because investigators cannot be certain what animals sense, they must infer whether animals experience satiation in association with an observed reduction in food intake.

One common approach is to determine whether the peptide causes a *learned flavor aversion* in animals. People readily learn to avoid food or drink that, when ingested, produces nausea. Rats and other animals seem to respond in the same way; moreover, when a toxin that elicits nausea is administered systemically soon after consumption of an uncontaminated drink with a novel flavor, the animals subsequently avoid fluids of that flavor and behave as if the drink had contained the toxic agent that had made them sick. In addition, electrophysiological recording from the first gustatory relay nucleus in the brainstem, the nucleus of the solitary tract, shows that the response elicited by a taste that has been associated with a toxin is similar to the pattern of activity typical of a naturally aversive flavor. Nausea is critical to the process; damage to the "emetic center" in the area postrema eliminates the sensation of nausea and prevents the formation of the learned taste aversion.

Another approach to distinguishing nausea from satiation is to monitor biological variables that occur in association with nausea but not satiation, or vice versa. One such variable is neurohypophyseal hormone secretion. For example, administration of lithium chloride (LiCl) causes nausea in humans and vomiting in monkeys, and elicits a learned flavor aversion in rats. LiCl stimulates vasopressin secretion in humans and monkeys. In this example, elevated plasma vasopressin can be considered a biological marker of nausea because it does not itself cause nausea or vomiting. Curiously, rats secrete the other neurohypophyseal peptide, oxytocin (and not vasopressin), in response to large doses of LiCl and other nauseants. Control experiments have shown that following an ordinary meal, vasopressin is not secreted in primates nor is oxytocin secreted in rats. Thus, when rats are administered a chemical agent that stimulates pituitary oxytocin secretion, nausea, rather than satiation, is the suspected basis of the reduction in food intake.

Such experiments are helpful for interpreting the anorexia that occurs when a peptide is administered exogenously, but insight into the normal effects of endogenously secreted chemical signals requires an alternative experimental approach. For example, a drug that blocks the effect of an endogenous peptide on its receptors could be administered. If the hormone normally functions to reduce food intake, then the blocking agent should increase the size of meals. Such drugs are not yet available for all peptides suspected of mediating endogenous satiation, but increases in meal size were found in experiments using drugs to reduce the activity of CCK, GLP-1, and several other peptides at their respective receptors. These observations strongly suggest that these peptides normally function as endogenous satiation factors.

CCK on food intake, suggesting that a combination of gastric distension and CCK may be the principal signals that inhibit the initiation of spontaneous meals in suckling rats.

As rat pups mature, signals related to the caloric content of food begin to participate in the control of meal size and become integrated with CCK, GLP-1, gastric distension, and other factors as satiation signals. This developmental change allows adults to ingest, assess, and respond to foods whose caloric density is not as constant as that of milk. For example, when liquid food is diluted with water, adult rats compensate by increasing the volume consumed in each meal, allowing daily caloric intake to remain stable. This observation reveals that gastric distension is but one of several possible satiation signals in adult rats and that greater distension can be accommodated in circumstances in which the calorie-related satiation signals have diminished.

The mechanism by which caloric signals are monitored is an area of intense investigation. Although early reports suggested that the stomach monitored caloric nutrients, later findings did not support this hypothesis. For example, when hungry rats were equipped with closed pyloric cuffs to prevent ingested food from entering their small intestine, the rats decreased their food intake in proportion to the volume, and not the caloric

content, of intragastric infusions (Phillips & Powley, 1996). In contrast, when the cuff was open so that gastric contents could empty into the duodenum, caloric nutrients were much more effective in reducing food intake than calorie-free loads of equal volume. These observations suggest that the stomach does not detect caloric nutrients but instead contributes primarily inhibitory signals related to gastric distension.

Postgastric Effects of Meals Provide Additional Satiation Signals

During the course of a meal, some of the ingested food enters the small intestine and is absorbed, thus allowing postgastric signals to contribute to satiation. In this regard, small amounts of specific nutrients infused directly into the duodenum produce a robust suppression of eating that cannot be attributed to gastric factors. It is likely that both the upper small intestine as well as postabsorptive sites are responsible for detecting the administered calories and generating the signals that limit meal size. The luminal surface of the intestine contains mainly enterocytes that absorb digested nutrients and pass them into the blood. Interspersed among the enterocytes are scattered enteroendocrine cells that have tentacle-like projections which extend into the intestinal lumen and express many of the same taste receptors as occur on taste buds on the tongue. As a result, these enteroendocrine cells "taste" specific nutrients (e.g., glucose) that are in the intestinal lumen, and they respond by secreting peptide hormones that contribute to the ongoing process of digestion. There are a dozen or so different types of enteroendocrine cells, each secreting a different peptide or peptides. As an example, I-cells secrete CCK when they "taste" fatty acids in the lumen, and the CCK in turn enters the blood and causes the liver/gall bladder to secrete bile into the intestine to facilitate the digestion of fats. Analogously, L-cells secrete GLP-1 and PYY in response to "tasting" carbohydrates, and GLP-1 increases insulin secretion during the meal. Importantly, many of the peptide secretions of the enteroendocrine cells also double as satiation signals, acting either locally on afferent nerves in the wall of the intestine or else circulating to a distant organ such as the liver or brain to elicit satiation. These peptides include CCK, GLP-1, and PYY.

As discussed earlier, the liver plays a critical role in caloric homeostasis, and the delivery of nutrients absorbed from the small intestine to the liver may be monitored to provide an important postgastric signal for the inhibition of food intake. Consistent with this hypothesis are findings that infusion of glucose or lipids into the hepatic portal vein reduces food intake. Importantly, infusion of fructose (a sugar utilized by the liver but not by the brain) into the general circulation no longer reduces food intake in rats after hepatic vagotomy. Collectively, these findings suggest that like the intestines themselves, the liver provides a satiation signal. All of these signals would diminish as absorption slows and satiation occurs.

Intravenously administered glucose reduces food intake but not by as much as the caloric content of the glucose. In contrast, when glucose solution is consumed orally or fed through a tube directly into the stomach, the compensatory reduction in food intake is equivalent to the caloric load. In this case, gastric and/or intestinal signals such as GLP-1 contribute to the increased satiation and augment insulin secretion above that elicited by the glucose *per se*; that is, more insulin is secreted in response to infusion of glucose into the stomach or intestine than into a vein, which might contribute to the observed reduction in appetite. In fact, intravenously infused glucose reduces food intake by an equivalent caloric amount when insulin is added to the infusate. Together, these observations suggest that insulin contributes to the satiating effect of glucose whether given by gavage or ingested during a meal. Consistent with this possibility, rats made diabetic by destruction of their pancreatic B cells eat discrete meals more frequently as if they experienced less postprandial satiety (Box 36.2).

In addition to providing useful nutrients, consumption of food increases *plasma osmolality*, yet another factor influencing the size of a meal. Increased plasma osmolality stimulates thirst, and for this reason water intake usually accompanies eating. The important point, however, is that less food is consumed during meals when drinking water is not available, a phenomenon known as *dehydration anorexia*. Similarly, increased plasma osmolality caused by systemic injection of hypertonic saline reduces food intake in proportion to the administered osmotic load. The well-described forebrain osmoreceptors that cause thirst and influence vasopressin secretion (Chapter 39) apparently do not mediate this inhibitory effect on food intake, which persists after those osmoreceptors have been destroyed surgically. Instead, osmoreceptors in the viscera or in the caudal brainstem might mediate the inhibitory effect of increased plasma osmolality on food intake.

Body Weight Influences Food Intake

The control of food intake is also associated with the maintenance of body weight (adiposity, actually). For example, after a period of food deprivation and forced loss of body weight, animals (including humans) eat relatively large meals until adiposity returns to pretreatment levels. Conversely, after a period of forced feeding, during which the increased daily intake of calories causes weight gain, animals eat relatively small meals

BOX 36.2

THE GLUCOSTATIC HYPOTHESIS

Almost 60 years ago, Mayer (1955) proposed that the onset and termination of meals are determined by changes in the amounts of glucose used by certain areas of the brain. More specifically, Mayer hypothesized that food intake was controlled by a region of the ventral hypothalamus whose glucose utilization, unlike the rest of the brain, was sensitive to insulin. In diabetic rats, the presence of hyperphagia despite elevated blood glucose emphasized the point that diminished glucose utilization in these insulin-dependent cells (as opposed to a reduction of blood glucose levels *per se*) was the critical factor in removing satiety and stimulating food intake.

At first widely accepted, the glucostatic theory fell into disfavor for several reasons. For one, although eating can be induced by low availability of glucose to the brain, no evidence supports suppression of eating by high glucose availability. In addition, concentrations of blood glucose after administration of large doses of insulin are now known to be far lower than what occurs during a fast or at the normal onset of a meal. Thus, eating in response to insulin-induced hypoglycemia is now considered an "emergency response" that is not relevant to normal feeding. (A similar emergency response occurs after a systemic injection of 2-deoxyglucose induces an acute decrease in cellular glycolysis.) Finally, the prevailing view of the ventromedial hypothalamus as a satiety center has changed considerably since the original formulation of the glucostatic hypothesis. This region of the brain is better regarded as a regulatory control center that influences many aspects of hormonal and autonomic function. Diabetic hyperphagia may therefore represent the ineffectiveness of insulin or leptin to activate neural systems that inhibit food intake. In contrast, the earlier glucostatic hypothesis would have explained diabetic hyperphagia as a consequence of the decreased uptake of glucose into special hypothalamic neurons that mediate satiety.

In recent years, evidence has emerged that neurons in the hypothalamic arcuate nucleus are sensitive to fluctuations of the adiposity signals leptin and insulin. Neurons in the same area also are sensitive to fluctuations of glucose as well as to certain fatty acids (especially oleic acid) and amino acids (especially leucine), and local manipulations of either adiposity signals or nutrients influence food intake, pancreatic insulin secretion, and the release of glucose from the liver. Hence, the view is emerging that the arcuate nucleus integrates long-term energy stores (principally body fat) with acute availability of nutrients to control several aspects of energy homeostasis.

(or no meals at all) until normal adiposity is restored. Long-term stability of adiposity in adult animals is attributed in part to these compensatory responses to weight fluctuations that are caused by acute changes in food intake or energy expenditure.

Adiposity may indirectly influence food intake by modulating how quickly food passes through the gastrointestinal tract, how long nutrients remain in the circulation, or how nutrients interact with the liver. For example, after fasting, less prolonged gastric distension or more rapid absorption and storage of ingested calories would diminish the duration of satiety signals, thereby increasing the frequency of meals. These effects would promote the *hyperphagia* (overeating) associated with the restoration of body weight in animals that have been food restrained and lost weight. Similarly, the satiating properties of ingested food would be reduced by diversions of ingested food calories to the fetus during pregnancy, to milk during lactation, or to skeletal muscle during exposure to cold temperatures, thereby contributing to the hyperphagia associated with each of these conditions.

Alternatively, adipose tissue may directly signal the brain to modulate food intake. Although afferent nerves from adipose tissue to brain have been described, communication from adipose tissue is thought to be mediated primarily by a humoral (circulating) factor. *Parabionts*, created by surgically joining two animals at the flank muscles and skin, support this hypothesis. Vascular interconnection within a parabiont is demonstrated when a dye injected into one animal appears in the blood of its partner. Because the nervous systems of the two animals remain independent, any physiologic communication between the animals must occur through the vascular system. When two lean rats were joined parabiotically, each consumed its normal amount of food and maintained its usual body weight. Similar results were obtained when two obese rats with lesions in the *ventromedial hypothalamus* (see later) were joined together. However, when a lean animal was joined to an obese

animal, the result was striking: The lean animal reduced its food intake markedly and consequently lost a considerable amount of weight. These experiments have been interpreted to mean that a circulating factor, secreted by the obese animal in large amounts proportional to adiposity, enters the blood of the lean animal and reduces food intake, as if the lean animal was receiving a signal that it was too fat (Coleman & Hummel, 1969).

Investigations have identified *leptin*, a hormone synthesized by adipose tissue, as a key circulating adiposity signal that regulates food intake and body weight. Leptin concentration in plasma is directly proportional to adiposity, and a receptor-mediated transport process passes it into the brain. Animals that lack the gene for synthesizing leptin (ob/ob mice) are hyperphagic and obese, and administering leptin to ob/ob mice causes them to eat less and lose weight. Because lower doses of leptin have this action when administered into the ventricles of the brain than when administered systemically, leptin is believed to reduce food intake and body weight via a central site of action. Consistent with this hypothesis, the receptor for leptin has been identified and found to be located within the hypothalamus. Like ob/ob mice, animals with mutated leptin receptors (db/db mice and fatty Zucker rats) are obese, but unlike ob/ob mice, they do not respond to exogenous leptin. Hence, leptin appears to function as a negative feedback signal to the brain. When fat stores increase in adipose tissue, more leptin is secreted and enters the brain, causing greater inhibition of food intake and loss of body fat. When circulating leptin levels are low, feeding and other anabolic responses are disinhibited. In this way, leptin acts to promote the maintenance of relatively stable adiposity over long intervals. The neural circuitry through which leptin inhibits food intake and influences caloric homeostasis is discussed later.

Insulin provides a second circulating signal that informs the brain of body fat levels. Plasma levels of insulin are directly correlated with adiposity, and, like leptin, insulin is transported through the blood–brain barrier where it can act on insulin receptors in the hypothalamus and other sites. Insulin administered into the brain reduces food intake and body weight, whereas animals that do not secrete insulin are hyperphagic. Of course, severe diabetics do not become obese because their adipocytes cannot store fat in the absence of insulin. Mice lacking insulin receptors on brain cells are both hyperphagic and obese. In short, both leptin and insulin provide blood-borne signals that enter the brain and act on their respective receptors to reduce food intake and body fat.

Obesity, the accumulation of greater than normal fat in the body, is increasing throughout the world and creating a major public health problem, in part because it increases the risk for developing cardiovascular disorders, several cancers, type-2 diabetes mellitus, and other metabolic problems, and increases mortality. Obese individuals have both leptin resistance and insulin resistance; that is, although they secrete large amounts of both leptin and insulin in proportion to their adiposity, these signals are relatively ineffective in controlling metabolic parameters. Consequently, considerably more insulin is required to maintain plasma glucose within normal limits, and the brain is insensitive to the catabolic action of both leptin and insulin. The latter is thought to be due to a combination of reduced passage of these hormones through the blood–brain barrier as well as fewer leptin and insulin receptors within the brain itself. See Box 36.3 for more on obesity.

BOX 36.3

TREATMENT OF OBESITY

Obesity, the accumulation of greater than normal fat in the body, results when energy intake exceeds energy expenditure over long intervals. Obesity often is defined in terms of the *body mass index* (BMI), which is weight in kilograms divided by height in meters squared. A BMI of 18.5 to 24.9 is considered normal, with <18.5 being underweight, 25 to 29.9 being overweight, and >30 being obese. A BMI over 40 is morbid obesity. However, the calculation of BMI does not consider the distribution of fat within the body, yet this is recognized as a major determinant of health risk. Abdominal fat (mainly around the viscera) is more metabolically active, more highly vascularized and innervated, and more likely to be a site of inflammation in the body than subcutaneous fat; abdominal fat (typified by the "potbelly" or "apple" stereotype) therefore carries a much higher health risk than subcutaneous fat (characterized as a "pear" shape). Because of this, assessment of the circumference of the waist (abdomen) at the top of the iliac crest is thought to be a better predictor of health risk than the BMI. By this determination, obesity is defined as a waist circumference of >102 cm in men and >88 cm in women.

The incidence of obesity is increasing throughout the world and creating a major public health problem, in part because it increases the risk for developing cardiovascular disorders, several cancers, type-2 diabetes mellitus, and other metabolic problems, and increases mortality. Obese individuals have both leptin resistance and insulin resistance; that

BOX 36.3 (*cont'd*)

is, although they secrete large amounts of both leptin and insulin in proportion to their adiposity, those signals are relatively ineffective at controlling metabolic parameters. Consequently, considerably more insulin is required to maintain plasma glucose within normal limits, and the brain is insensitive to the catabolic action of both leptin and insulin. The latter is thought to be due to a combination of reduced passage of these hormones through the blood–brain barrier as well as fewer leptin and insulin receptors within the brain itself.

Hypotheses as to why the incidence of obesity has been increasing so substantially in recent years abound, and often presume some combination of increased availability of energy-dense palatable foods and/or decreased average energy expenditure. It is axiomatic to state that obesity can be prevented or cured by reversing the trend—that is, by eating less and exercising more. Unfortunately, many humans in modern society cannot realistically modify these behaviors for long intervals, and they have consequently turned to other methods to aid in weight loss. Historically, several different neuropharmacologic approaches have been used, most of them targeting brain neurotransmitter systems thought to be important in appetite control. Specifically, pharmaceuticals developed to treat obesity have targeted the serotonin, catecholamine, or endocannabinoid systems, either with ligands for their respective receptors or else with chemical agents that influence their secretion, degradation, or reuptake. However, because each of these transmitter systems influences multiple brain circuits, and because none of the compounds available to date have been appetite-specific and often have undesirable side effects on mood and other behaviors, none are currently approved by the FDA in the United States to treat obesity. Further, actual weight loss achieved any by these pharmacological approaches was rarely greater than 10%.

During the last decade, bariatric surgery has become the treatment of choice, especially for morbidly obese individuals, and these surgeries often result in far greater weight loss than that achieved pharmacologically (i.e., up to 70% of excess fat or more). In the conceptually simplest procedure, a band is placed around the stomach near the esophagus. The result of this gastric banding procedure is that food is swallowed into a very small gastric pouch, severely limiting the amount of food that can be consumed at once due to gastric restriction. Distension of the remaining gastric pouch is thought to result in smaller meals. Even greater loss of weight may occur with more invasive procedures that involve rearrangement of the normal routing of ingested food through the gastrointestinal system. In a roux-en-Y gastric bypass (RYGB), swallowed food enters a small gastric segment and then is immediately shunted into the distal small intestine, effectively bypassing half or more of the small intestine and theoretically reducing the absorptive area for food. In a vertical sleeve gastrectomy (VSG), most of the stomach is surgically removed and consequently swallowed food enters a small cylinder of remaining stomach leading directly into the small intestine, thereby eliminating most of the stomach's normal ability to store ingested food. These commonly performed procedures result in rapid, substantial, and comparable weight loss; for example, many patients have their diabetes greatly improved, often within days after the surgery.

The mechanisms for the weight loss and reduction of diabetic symptoms after RYGB or VSG are not well understood. Although increased gastric stretch may be a factor in some procedures, it is not common to all, and malabsorption seems to have a minimal effect at best. Instead, a major contributing factor may be an alteration of the normal neural and endocrine signaling between the GI tract and the brain. For example, one feature common to the successful procedures is greatly increased meal-induced secretion of peptides such as GLP-1 and PYY from enteroendocrine cells, perhaps thereby creating a greater satiation signal as well as a greater stimulation of insulin secretion during meals. In this regard, many diabetic patients lose substantial amounts of body weight when their pharmacotherapy includes GLP-1 agonists.

Summary

Three effects of eating limit the size of an ongoing meal: gastric distension (potentiated by CCK), postgastric detection of calories (via satiation signals such as CCK and GLP-1, perhaps potentiated in the liver by insulin), and increased plasma osmolality. These signals reach the brain through visceral afferent fibers (especially those traveling in the vagus nerve) and the circulatory system. Meal size invariably increases after the inhibitory effects are experimentally removed by blocking the detection of gastric stretch or of satiating peptides, diluting the food with noncaloric material, or rehydrating the animal. Inhibition appears to be integrated so that as one effect diminishes (e.g., the signal associated with gastric distension), another increases (e.g., the signal associated with the postabsorptive delivery of calories and insulin to the liver), thereby maintaining satiety and prolonging the interval between meals. When the satiety signals disappear, hunger emerges and stimulates initiation of another meal.

Food intake is also normally linked closely with body weight. In experimental animals, periods of starvation or forced feeding are followed by self-regulated compensatory changes in eating patterns until prior body size is regained. Links between body weight and food intake can be mediated indirectly by altered gastrointestinal motility as well as by the blood-borne, centrally active hormones leptin and insulin.

CENTRAL CONTROL OF FOOD INTAKE

Early theories of the control of food intake focused on signals derived from stomach and blood. Peripheral factors, such as the concentration of glucose in the blood, were plausibly associated with food intake and were accessible to experimentation. Theories involving the brain emerged after development of a stereotaxic instrument that enabled discrete lesions of the cerebrum to be made in laboratory animals, permitting evaluation of ideas about brain function (Fig. 36.4). The first findings from such experiments were striking: Bilateral electrolytic lesions of the ventromedial hypothalamus (VMH) caused marked hyperphagia and obesity in rats. This observation was interpreted to mean that the animals had become less sensitive to incoming signals of satiation and that they therefore overate and became fat. Bilateral lesions in the adjacent *ventrolateral hypothalamus* (VLH) were later found to cause *aphagia* (absence of eating), which led to death by starvation. This finding was interpreted to mean that these rats no longer detected hunger signals, and thus they starved to death while unaware of their internal state. Collectively, these results provided the foundation of a dual-center hypothesis, in which a satiety center in the VMH was thought to suppress activity in a hunger center in the VLH. Both the syndrome of hyperphagia and obesity and the syndrome of aphagia and weight loss that result from focal hypothalamic lesions have been reproduced in multiple laboratories and in multiple species. However, additional observations have caused reinterpretation of these familiar and reliable findings, and they now have a very different meaning.

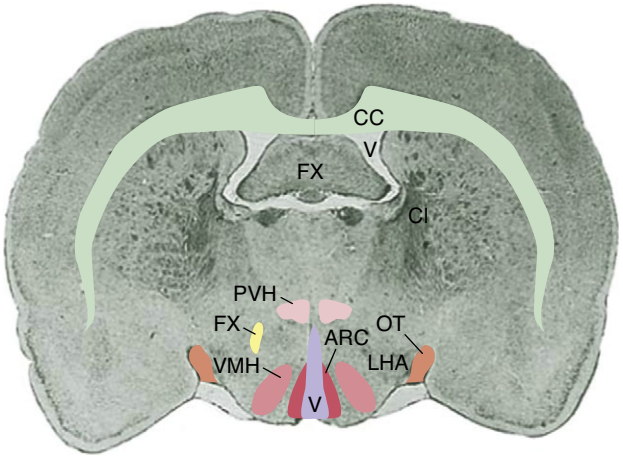

FIGURE 36.4 Coronal section through an adult rat brain at the level where the optic tract enters the two hemispheres. The lateral ventricle and third cerebral ventricle (V) are shaded, and selected fiber tracts are outlined for reference (OT, optic tract; CC, corpus callosum; FX, fornix). Key hypothalamic sites important in caloric homeostasis, present in each hemisphere, are paraventricular nuclei (PVN), ventromedial nuclei (VMN), arcuate nuclei (ARC), and the lateral hypothalamic area (LHA).

Food Intake is Not Controlled by Hypothalamic Hunger and Satiety Centers

The strength of the traditional dual-center model, in which one center mediates hunger and the other satiety, was that it provided a simple answer to the question of how the brain controls intake of food. The principal limitation of the model, however, was that it could not answer the next level of questions: What signals control individual meals? How are these signals integrated with physiological aspects of caloric homeostasis, including long-term maintenance of body weight? What is the influence of other neural sites and systems in the brain on the control of food intake? How are excitatory and inhibitory influences on eating integrated? Investigators are addressing these and related questions, but they now usually take a perspective that does not presume the existence of brain centers mediating hunger and satiety.

In addition to causing hyperphagia, VMH lesions profoundly reduce sympathetic tone and increase parasympathetic tone and vagal reflexes. For example, the high concentration of insulin in animals with VMH lesions is not simply a secondary consequence of hyperphagia but occurs even when food intake is limited. Because of the change in autonomic tone, caloric equilibrium in adipose tissue shifts away from lipolysis and toward lipogenesis, thereby allowing more rapid storage of ingested calories after a meal. Increased parasympathetic activity also allows faster gastric emptying. Importantly, VMH lesions do not cause loss of satiety. Meal sizes continue to correlate well with postmeal intervals, but the interval after a meal of any size is shorter in animals with VMH lesions than in control animals. Because the duration of their postprandial satiation signals is shorter than normal, rats with VMH lesions eat more frequent meals. They remain hyperphagic until the equilibrium between lipogenesis and lipolysis is reestablished in adipocytes. For this to happen, triglyceride stores must accumulate in the cells to levels sufficient to create insulin resistance, whereupon lipogenesis subsides, gastrointestinal motility diminishes, meals are eaten less frequently, and daily food intake is

reduced. The animal maintains its obese state as if it had a new "set point" for body weight. Thus, after obese rats with VMH lesions have been deprived of food and forced to lose weight, hyperphagia reoccurs until the prior level of high adiposity is reattained. Similarly, when neurologically normal rats are overfed and become obese prior to receiving a lesion of the VMH, they are not hyperphagic after the lesion but rather eat to maintain their elevated weight.

In sum, rats gain body fat after VMH lesions, and as they are becoming obese (indeed, in part because they are becoming obese), the duration of satiety after meals is relatively low. However, as fat accumulates the duration of satiety after meals increases back toward normal. This explanation contrasts with early hypotheses that body weight increased after VMH lesions because animals became obligatorily hyperphagic. The primary phenomenon is now recognized as a change in autonomic tone to promote vagal reflexes and fat storage. Because that change is observed even when increased food intake is prevented, hyperphagia cannot be the primary phenomenon. The key element appears to be the chronic, neurally stimulated increase in insulin secretion. When the increased insulin secretion is prevented by denervating the pancreas, obesity does not develop and hyperphagia is greatly attenuated.

In contrast to VMH lesions, rats with large VLH lesions do not eat and may starve to death. However, they also do not drink water when dehydrated and they do not move about in their cages or respond to diverse stimulation. In other words, the most prominent abnormalities in these rats are akinesia and sensory neglect. In this respect, rats with VLH lesions resemble human patients with Parkinson's disease, a neurological disorder that has been attributed to the degeneration of dopamine-containing neurons of the nigrostriatal bundle (see Chapters 30 and 31). Dopaminergic fibers course through the internal capsule just lateral to the VLH as they ascend from the ventral mesencephalon to the striatum along the medial forebrain bundle (Chapter 43). Large electrolytic lesions of the VLH area interrupt these dopaminergic fibers. More selective damage to the dopaminergic neurons near the VLH by intracerebral administration of the neurotoxin 6-hydroxydopamine also produces akinesia and sensory neglect in association with loss of food intake, and it does so without disturbing parasympathetic reflexes. Thus, the aphagia induced by large VLH lesions does not result from damage to a putative hunger center in the brain but instead reflects a more general disruption of movement and sensorimotor integration (Ungerstedt, 1971), at least in part (see later).

Summary

The ability of brain circuitry to control food intake initially was based on the consequences of stereotaxic lesions of ventromedial and ventrolateral hypothalamic nuclei leading to hyperphagia or aphagia, respectively. Subsequent studies revealed that each lesion also induces changes in autonomic function, in gastrointestinal activity, and in the equilibrium between lipolysis and lipogenesis in adipocytes. In addition, these lesions affected eating behavior through influences on spontaneous mobility and sensory responsivity to food-derived stimuli.

NEUROPEPTIDES AND THE CONTROL OF FOOD INTAKE

Although the details of the central control of food intake are incompletely understood, many neuropeptides have been implicated. To simplify the discussion, we focus on two broad categories of neuropeptides: those that are mainly anabolic and those that are mainly catabolic. Both of these subgroups in turn are modified by multiple influences, including satiation signals, adiposity signals, experience, habit, emotional state, the social situation, and so on. Anabolic peptides cause increased eating, decreased energy expenditure, and, when chronically elevated, increased body fat accumulation. Catabolic peptides reduce food intake, increase energy expenditure, and lead to loss of body fat. Figure 36.5 presents a simplified model of some of the better-known components of this control system. An interesting feature of the model is that major efferent outputs from the hypothalamus to autonomic nuclei and to motor nuclei controlling ingestion *per se* emanate from the VMH and VLH, the central neural sites that were the main focus of attention over a half-century ago.

The Hypothalamic Arcuate Nucleus (ARC) Mediates the Effect of Adiposity on Food Intake and Body Weight

The amount of body fat is signaled to the brain by leptin and insulin. Receptors for both peptides are located (among other sites) in the ARC on two distinct groups of neurons. The first group of ARC neurons synthesizes the neuropeptides, *α-melanocyte-stimulating hormone* (α-MSH) and *cocaine–amphetamine-related transcript* (CART); these neurons are activated by leptin and insulin. α-MSH and CART are potent catabolic peptides, and when either is administered locally into the third cerebral ventricle animals eat less food, have increased energy expenditure, and lose weight (Cone, 1999). α-MSH is in the *melanocortin* family of peptides, a group that also includes *adrenocorticotrophic hormone* (ACTH). These peptides act on melanocortin (MC) receptors, and two of these receptors, termed MC3 and MC4, are expressed in several nuclei of the hypothalamus, including the *paraventricular nucleus*

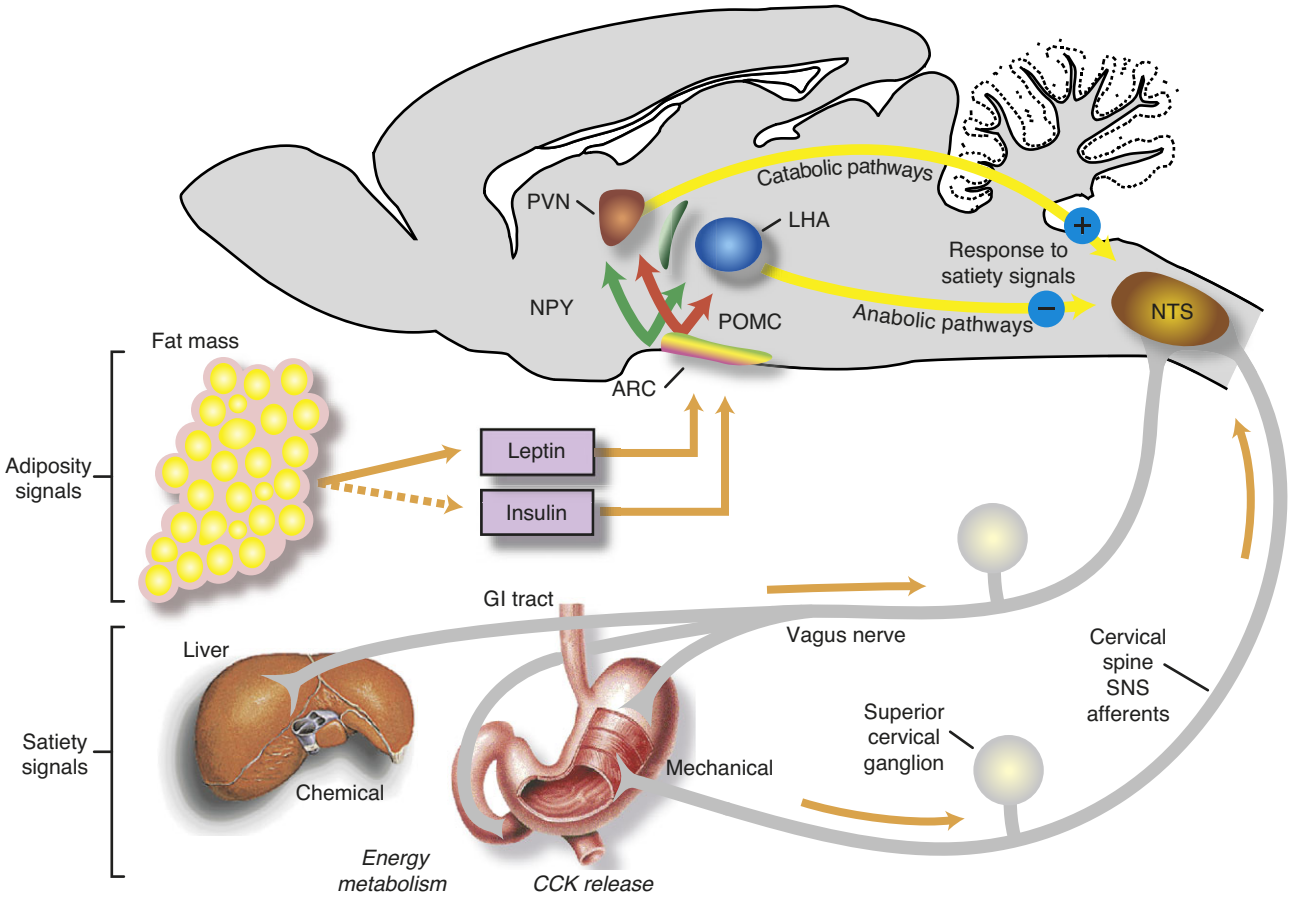

FIGURE 36.5 Schematic diagram of the signals that control caloric homeostasis. Satiety signals arising in the periphery such as gastric distension and CCK are relayed to the nucleus of the solitary tract (NTS) in the brainstem. Leptin and insulin, the two circulating adiposity signals, enter the brain and interact with receptors in the arcuate nucleus (ARC) and other brain areas. These adiposity signals inhibit ARC neurons that synthesize NPY and AgRP (NPY cells in the diagram) and stimulate neurons that synthesize proopiomelanocortin (POMC), the precursor of α-MSH, and CART. These ARC neurons in turn project to other hypothalamic areas, including paraventricular nuclei (PVN) and the lateral hypothalamic area (LHA). Catabolic signals from the PVN and anabolic signals from the LHA are thought to interact with the satiety signals in the brainstem to determine when meals will end. *From Schwartz, Woods, Porte, Seeley, and Baskin (2000).*

(PVN), VMH, and VLH, where α-MSH-containing axons project from the ARC and where α-MSH acts as an agonist. Animals that lack either MC3 or MC4 receptors become obese; animals with no MC3 receptors gain weight gradually over their lifetime without overeating, whereas animals without MC4 receptors are hyperphagic and become much fatter. The administration of selective MC4 antagonists causes neurologically intact animals to overeat and, if prolonged, to become obese. Hence, hypothalamic melanocortins, exemplified by α-MSH, exert a tonic catabolic effect to keep body weight from increasing (Cone, 1999). Importantly, the ability of exogenous leptin to reduce food intake and body weight is completely attenuated in the presence of an antagonist to MC3 and MC4 receptors, suggesting that the "downstream" pathway by which adiposity influences caloric homeostasis is via melanocortin signaling (Seeley et al., 1997).

The other type of ARC neuron influenced by adiposity signals synthesizes the neuropeptides *neuropeptide Y* (NPY) and *agouti-related protein* (AgRP). Both peptides are potent anabolic compounds in that the administration of either into the third ventricle results in hyperphagia, reduced energy expenditure, and weight gain. Although NPY is synthesized in many areas of the brain including the dorsomedial nucleus of the hypothalamus (DMN), AgRP synthesis is limited to the ARC. Neurons containing NPY and AgRP express receptors for both leptin and insulin, and the local administration of either insulin or leptin near the ARC reduces the synthesis of both NPY and AgRP. Hence, adiposity signals exert net catabolic effects through the joint mechanisms of stimulating α-MSH/CART neurons and simultaneously inhibiting NPY/AgRP neurons. For all these reasons, the ARC can be considered to be the brain's sense organ that detects body adiposity by monitoring

the levels of leptin and insulin. In turn, axons from these two groups of ARC neurons innervate many other hypothalamic nuclei as they modulate aspects of caloric homeostasis.

Two important tracts convey NPY-containing axons to the PVN, one from the ARC that co-expresses AgRP and one from the DMN that has no AgRP. The PVN expresses receptors for NPY, and careful mapping studies have identified the PVN as the most sensitive site to the orexigenic effect of exogenously administered NPY. Consistent with this finding, when antisense oligonucleotides to NPY receptors are given locally within the PVN, rats that have been deprived of food eat less than they usually would. Among the numerous sites that synthesize NPY within the brain, only those in the arcuate nucleus are sensitive to changes of food intake as signaled by leptin and insulin (Schwartz et al., 2000). NPY mRNA is increased in the ARC and DMN when animals are fasted and returns to baseline upon refeeding. Fasting also increases the levels of NPY in axon terminals in the PVN and increases secretion of NPY within the PVN. Hence, the fasted animal is primed to eat more food due in part to the action of elevated NPY in the area of the PVN. Circulating insulin and leptin are decreased during fasting, and local administration of either into the brain of a fasted rat lowers the elevation of NPY mRNA in the ARC and lowers the amount of food eaten by food-deprived rats (Schwartz et al., 2000). Hence, the metabolic state, as reflected by leptin and insulin, has a marked influence on arcuate NPY-containing neurons and consequently on neural pathways that influence energy intake and expenditure. Endogenous levels of NPY in the ARC–PVN system normally peak when daylight ends and nocturnal activity begins (Leibowitz, 1990), which also is the time when rats typically eat their largest meal of the day. Hence, NPY activity in the PVN appears to be a key mediator of anabolic activity.

The other neuropeptide synthesized in NPY neurons in the arcuate nucleus, AgRP, is an endogenous antagonist of MC3 and MC4 receptors (Cone, 1999). AgRP therefore promotes food intake by acting at MC receptors in the PVN and other areas to block the action of α-MSH. When exogenous AgRP is administered into the third cerebral ventricle, the resultant hyperphagia lasts for up to six days (Hagan et al., 2000). In contrast, the hyperphagia elicited by NPY lasts only a few hours. Hence, activation of the arcuate NPY/AgRP neurons results in an acute but robust increase of food intake caused by the actions of NPY and a steady and more prolonged increase caused by the actions of AgRP. Furthermore, the two peptides act in different ways. NPY acts through its receptors to stimulate anabolic pathways directly, whereas AgRP acts through a different receptor by antagonizing tonically active catabolic peptides. It is not known whether NPY and AgRP from ARC neurons act on the same or different target cells in the PVN, VLH, and elsewhere. An important distinction is that whereas NPY originating in both the ARC and the DMN project to the PVN and VLH, only DMN NPY neurons project to areas of the brainstem where satiation signals are relayed from the vagus (Moran, 2010).

In sum, the ARC appears to be a chemosensor in the brain that detects body adiposity by means of insulin and leptin receptors. One type of ARC neuron synthesizes peptide transmitters (α-MSH and CART) having a net catabolic effect, whereas another type synthesizes peptide transmitters (NPY and AgRP) with a net anabolic effect. Both types of neuron project to other hypothalamic areas where they influence specific aspects of caloric homeostasis.

Other Hypothalamic Peptides also Influence Food Intake

Several other neuropeptides important in the control of caloric homeostasis are synthesized in the VLH, including the *orexins* and *melanin-concentrating hormone* (MCH) (Shimada, Tritos, Lowell, Flier, & Maratos-Flier, 1998). Administration of either of these peptides into the brain stimulates food intake, whereas mice that lack the gene for MCH are lean and obesity resistant. Administering orexins into the brain also elicits wakefulness, and as orexin levels decline after a meal, wakefulness wanes and drowsiness takes over. It appears likely that the aphagia exhibited by animals with VLH lesions is due in part to reduced levels of these peptides and that the hyperphagia caused by electrical stimulation of the VLH is due in part to release of orexins and MCH.

Oxytocin is a peptide synthesized in the PVN and supraoptic nuclei of the hypothalamus and is secreted from the posterior lobe of the pituitary. In the systemic circulation of female mammals, this hormone is well known for stimulating uterine contractions for parturition and stimulating milk letdown in mammary glands during lactation. However, the hypothalamus and pituitary of males contain as much oxytocin as those of females; therefore, the peptide has long been suspected of being secreted in other circumstances and having additional functions. In fact, research has revealed that gastric distension, CCK administration, and plasma hyperosmolality, treatments that decrease food intake in rats, each elicit pituitary oxytocin secretion in male and female rats. In addition, increases in plasma concentrations of oxytocin correlate highly with observed decreases in food intake.

Although observations were consistent with oxytocin being an appetite suppressant, later experiments showed

that this was not the case: Systemic administration of oxytocin does not affect food intake. Instead, the reduced food intake seen after treatment with CCK or hypertonic saline appears to be mediated by oxytocin secreted from neurons whose cell bodies are located in the hypothalamic PVN but whose axons project within the central nervous system rather than to the pituitary gland. Consistent with this hypothesis, central injection of oxytocin into the cerebral ventricles (icv) decreases food intake in rats, an effect that is blocked by icv pretreatment of the animals with an oxytocin receptor antagonist. More to the point, the effects of exogenous CCK and hypertonic saline on food intake are blunted by icv pretreatment with an oxytocin receptor antagonist. A summary of some of the hypothalamic peptides that modulate food intake is depicted in Figure 36.6.

Stress is also well known to decrease food intake in animals, and various stressors activate the hypothalamic–pituitary–adrenal (HPA) axis. A key mediator of this effect is *corticotropin-releasing hormone* (CRH), which is synthesized and secreted from the PVN. CRH stimulates the secretion of ACTH from the anterior pituitary, and ACTH in turn elicits steroid hormone secretion from the adrenal cortex (see Chapter 40). In rats, icv injection of CRH decreases food intake in the absence of stress and in association with oxytocin secretion from the posterior pituitary. In addition, icv pretreatment with an oxytocin receptor antagonist eliminates CRH-induced inhibition of food intake. These findings are consistent with central oxytocinergic neurons mediating the inhibition of food intake that occurs during stress. Such inhibitory effects on eating would complement the known inhibitory effects of central oxytocin on gastric motility and emptying. CRH neurons also stimulate activity of the sympathetic nervous system, and the PVN is considered to be the major integrative site where stressors activate both the HPA axis and the sympathetic nervous system. Some individuals when stressed increase their consumption of "comfort foods," which are generally palatable and calorically dense. Recent evidence suggests that consumption of these foods is a buffer against the magnitude of the physiological responses to both physical and psychological stressors (Ulrich-Lai et al., 2010).

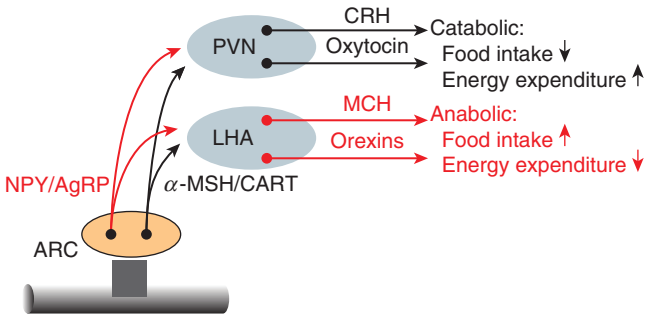

FIGURE 36.6 Hypothalamic neuropeptides that influence caloric homeostasis. The adiposity hormones, leptin and insulin, are transported through the blood–brain barrier and influence neurons in the arcuate nucleus (ARC). ARC neurons that synthesize and release NPY and AgRP are inhibited by adiposity signals, whereas ARC neurons that synthesize and release α-MSH and CART are stimulated by adiposity signals. NPY/AgRP neurons are inhibitory to the PVN and stimulatory to the LHA, whereas α-MSH/CART neurons are stimulatory of the PVN and inhibitory of the LHA. The PVN in turn has a net catabolic action, whereas the LHA has a net anabolic action.

The Brainstem Plays an Important Role in the Control of Food Intake

The NST and the adjacent area postrema in the brainstem receive sensory fibers from gustatory receptors in the mouth and throat (see Chapter 24), as well as afferent information from the stomach, small intestine, pancreas, and liver. In the central control of food intake, these linked brainstem sites likely are where sensory input from the viscera is first integrated with input from taste buds. This sensory information is relayed along prominent neural projections from the brainstem to the hypothalamus, amygdala, and other portions of the limbic system, as well as to the thalamus and gustatory cortex. Reciprocal neural connections to the brainstem from these rostral sites allow emotion and cognitive function to influence the control of eating. Complementary and linked efferent elements participate in the central control of the gastrointestinal tract and liver, and of autonomic function generally.

Evidence of the brainstem's control over food intake comes from investigations of the chronic decerebrate rat in which all axonal connections between the caudal brainstem and the forebrain are severed at the midcollicular level of the midbrain (Grigson, Kaplan, Roitman, Norgen, & Grill, 1997). This animal does not seek food or initiate spontaneous meals, but, like an intact animal, it will reflexively swallow liquid food put directly into its mouth via an oral fistula. The decerebrate rat will swallow a sucrose solution when its stomach is empty, such as after a period of food deprivation; however, it will not swallow water or saline when food deprived, nor will it swallow sucrose solution when its stomach is full or when it has received a systemic injection of CCK or hypertonic saline (but instead lets the administered fluid passively drip from its mouth). These experiments suggest that considerable control of food intake exists entirely within the caudal brainstem, which receives signals that arise when ingested food contacts peripheral sensory organs (i.e., taste buds, gastric stretch receptors, intestinal CCK-secreting cells). Nonetheless, decerebrate animals are incapable of receiving input from forebrain

sites that could modify intake based on learning or other experience, on body adiposity, or on time of day.

Other observations provide additional support for an important role of the brainstem in the control of meal size. When the area postrema is ablated, rats eat larger meals than normal, although total daily food intake is normal; that is, they compensate for their large meals by eating less frequently, indicating that long-term controls of food intake are not impaired. A similar effect is seen in rats pretreated with capsaicin, a neurotoxin that destroys most gastric afferent vagal axons, eliminating the food intake-reducing effects of CCK and presumably damaging the signal of gastric distension.

Summary

We began this chapter with a description of the physiology of caloric homeostasis in order to provide a biological context within which to consider the purpose of eating and the fate of ingested food. Two principles were emphasized. First, meal size is determined by the integrated effects of several acute stimuli. Delivery of calories to the stomach and small intestine upon food consumption and postabsorptive delivery of nutrients to the liver elicit sensory neural signals from the stomach and the liver, respectively, to the brainstem. Second, food intake is also influenced by chronic signals associated with body adiposity. Adiposity indirectly affects gastric and hepatic signals of satiety. In addition, humoral signals proportional to adiposity enter the brain and affect food intake. One signal, leptin, emanates from adipose tissue itself, and the other, insulin, comes from the pancreas. These two peptides appear to be important in the central control of food intake; they modulate the response of the brain to the acute neural signals that affect food intake.

These neural and humoral signals are related to caloric homeostasis and are inhibitory in nature. During meals, they combine to stop ongoing ingestion; later, when these signals disappear in the postabsorptive state, new meals begin. Other inhibitory signals are unrelated to caloric homeostasis yet can have a pronounced effect on the cessation of eating. These signals include gastric distension, toxins (in the food and consumed inadvertently, or else injected systemically), and dehydration.

The central nervous system exerts control over eating at many levels. The spinal cord and brainstem influence all aspects of caloric homeostasis via the autonomic nervous system. The hypothalamus and limbic forebrain receive signals about ingested food and body adiposity and integrate them with information about the taste of the food, the memory of that food, the experience of previous meals, the competition of other desires, and aspects of the environment. Thus, the central control of eating involves many areas of the central nervous system in the collective maintenance of caloric homeostasis.

CHAPTER

37

Water and Salt Intake and Body Fluid Homeostasis

Body fluids are the watery matrix in which the biochemical reactions of cellular metabolism occur. The concentration of substrates in cellular fluid is a key factor in determining the rate at which those reactions take place. All tissues depend on circulating blood to deliver the nutrients needed to support cellular metabolism and to carry away unwanted metabolites for excretion. Thus, the maintenance of solute concentrations or osmolalities—*osmotic homeostasis*—and the regulation of plasma volume—*volume homeostasis*—are essential functions in the physiology of animals.

When normal body fluid osmolality or plasma volume is threatened, various physiological and behavioral responses are stimulated to maintain or restore the basal state adaptively. For example, during water deprivation, animals decrease water lost in urine to prevent dehydration from worsening and they consume water to replace the fluid they have lost. Similarly, hemorrhage stimulates the urinary conservation of water and sodium as well as the ingestion of water and NaCl. Water retention and sodium retention are accomplished through actions of the antidiuretic hormone *arginine vasopressin* (AVP) and the antinatriuretic hormone *aldosterone*, whereas water ingestion and NaCl ingestion are motivated by *thirst* and *salt appetite*. These complementary responses are mediated and coordinated by the brain.

This chapter describes the various mechanisms by which the signals for fluid homeostasis are detected and integrated by the central nervous system. However, we first present a brief overview of body fluid physiology to provide a context in which to consider the regulated functions.

BODY FLUID PHYSIOLOGY

Water is the largest constituent of the body. It contributes 55 to 65% of the body weight of animals, including humans, varying mostly in relation to the amount of body fat. Total body water is distributed between *intracellular fluid* (ICF) and *extracellular fluid* (ECF) *compartments*, with approximately two-thirds in the former and one-third in the latter. The ECF can be further subdivided into the *interstitial fluid* surrounding the cells and the intravascular fluid within blood vessels. The *intravascular fluid*, the plasma (or serum) of blood, averages 7 to 8% of total body water, or 20 to 25% of the ECF.

Fluid compartments differ not only in their volumes but also in the solutes they contain. Specifically, membrane-bound Na^+-K^+ pumps move Na^+ outside the cells and K^+ inside. Despite the differences in solute composition, the *osmotic pressure*, which reflects the concentrations of all solutes in a fluid compartment, is equivalent between ECF and ICF compartments. This equilibrium occurs because water is driven across cell membranes by osmosis from a relatively dilute compartment into one with a higher solute concentration until the osmotic pressures are equivalent on both sides of the cell membrane.

Multiple Mechanisms Help Maintain Blood Volume and Pressure

The distribution of fluid between intravascular and interstitial fluid compartments is determined by a balance between the *hydrostatic pressure* of the blood, which

© 2013 Elsevier Inc. All rights reserved.

is maintained by cardiac output and arteriolar vasoconstriction, and the opposing osmotic pressure contributed by plasma proteins. Although those proteins contribute only 1 to 2% to overall plasma osmolality, the permeability of capillary membranes to such large molecules is low; therefore, proteins exert a pressure differential (of approximately 15–20 mm Hg), called the *colloid osmotic (oncotic) pressure*, that tends to pull interstitial fluid into the circulation. Figure 37.1 summarizes the forces governing transcapillary fluid transfer between the two extracellular compartments, a phenomenon first described by the English physiologist Starling (1896). Note that according to this arrangement, interstitial fluid acts as a reservoir for plasma. The Starling equilibrium is such that when blood pressure falls, as after hemorrhage, interstitial fluid moves into the circulation, thereby helping restore plasma volume. The reverse occurs when saline is added to the blood because plasma proteins are then diluted and the oncotic pressure they provide diminishes, allowing fluid to flow into the interstitial space.

Blood pressure also is maintained by two other mechanisms intrinsic to the cardiovascular system. First, although the arteries that receive the cardiac output of blood have thick walls to preserve blood pressure, the veins are thin-walled, distensible vessels. After a moderate hemorrhage, veins collapse, redistributing blood to arteries that cannot collapse and thus remain full. Consequently, arterial blood pressure is not compromised and the blood deficit occurs primarily on the venous side of the circulation. Conversely, fluid accumulates in the veins when blood volume is expanded, again without much effect on arterial blood pressure. This property is called the *capacitance* or *compliance* of the vascular system. Second, the filtration of blood in the glomeruli of the kidneys is determined in large part by blood pressure in the renal arteries. A drop in blood pressure reduces the *glomerular filtration rate* (GFR) and decreases urine formation, whereas a rise in blood pressure elevates GFR and promotes urinary fluid loss. This normal function of the kidneys is so efficient that the development of hypertension always implicates renal dysfunction as a contributing factor because the kidneys failed to adjust to the elevated blood pressure by increasing fluid excretion in urine.

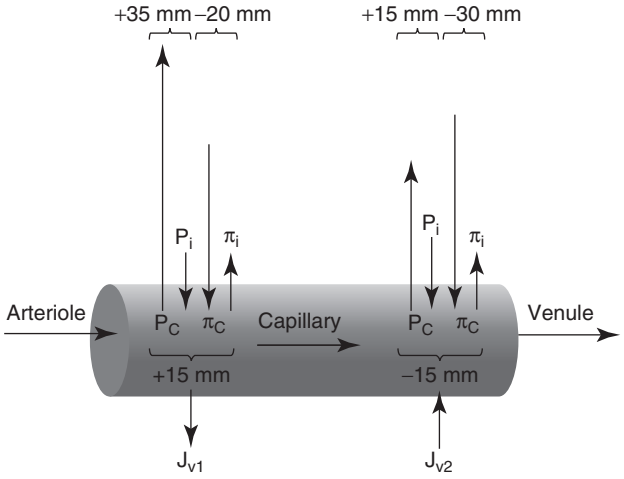

FIGURE 37.1 Starling forces governing transcapillary fluid transfer. At the arteriolar end of the capillary, the difference between the intravascular hydrostatic pressure (P_c) and the interstitial hydrostatic pressure (P_i) exceeds the oppositely oriented difference between the intravascular oncotic pressure (π_c) and the interstitial oncotic pressure (π_i); the resultant pressure gradient drives capillary fluid into the interstitial space (J_{v1}). As fluid leaves the capillary, P_c decreases due to fluid loss and π_c increases due to hemoconcentration. Consequently, at the venous end of the capillary, interstitial fluid is pulled back into the vascular space (J_{V2}). Numerical values indicate approximate net pressure differences (in mm Hg) between intravascular and interstitial spaces. Relative sizes of P and π are indicated by arrow length. Note that fluid accumulating in the interstitial space ultimately returns to the blood via the lymphatic system (not shown).

Summary

Body fluid homeostasis is directed at achieving stability in the osmolality of body fluids and the volume of plasma. Such homeostatic regulation is promoted by several mechanisms intrinsic to the physiology of body fluids and the cardiovascular system. Nevertheless, changes in body fluid osmolality and plasma volume may be so large that additional mechanisms must be recruited to maintain homeostasis. These other responses involve the central control of water and sodium excretion in urine through the actions of specific hormones, and the central control of water and NaCl consumption motivated by thirst and salt appetite.

OSMOTIC HOMEOSTASIS

Osmolality is an expression of concentration—that is, a ratio of the total amount of solute dissolved in a given weight of water:

$$\frac{\text{solute (osmoles)}}{\text{water (kilograms)}}.$$

Dehydration and the consequent need for water occur whenever this ratio is elevated, whether by a decrease in its denominator or by an increase in its numerator. In fact, both changes occur naturally and often: Body water decreases as a result of water deprivation or the loss of dilute fluids to accomplish evaporative cooling (e.g., sweating), and it increases as a result of solute load (e.g., the consumption of NaCl in foods).

The water loss associated with dehydration is borne by the ECF and the ICF in proportion to their sizes because the osmolality of fluid in the two compartments remains in equilibrium. In contrast, the increase in plasma osmolality that results from a solute load results only in cellular dehydration because the water leaving cells by osmosis expands ECF volume. Thus, a solute load is a more abrupt, less complex treatment than water deprivation for stimulating AVP secretion and thirst, the two main osmoregulatory responses of the brain.

Arginine Vasopressin Is the Antidiuretic Hormone

AVP is a nine amino acid peptide that is synthesized in the magnocellular neurons in the supraoptic nucleus (SON) and the paraventricular nucleus (PVN) of the hypothalamus. The peptide is cleaved enzymatically from its prohormone and transported along axons projecting from the hypothalamus to the nearby posterior lobe of the pituitary gland (*neurohypophysis*). There, AVP is stored within neurosecretory granules until specific stimuli, such as an increase in the effective osmolality of body fluids, activate its secretion into the bloodstream. The importance of AVP in maintaining water balance is underscored by the fact that its stores in the pituitary contain sufficient hormone to enable maximal antidiuresis when dehydration is sustained for more than a week.

The circulating hormone acts on a subset of AVP receptors (the V2 subtype) in the kidney to increase water permeability of the collecting ducts of nephrons through insertion of water channels, called aquaporins, into the apical membranes of tubular epithelial cells. Antidiuresis occurs when water moves out of the distal convoluted tubule and collecting duct by osmosis. As secondary responses to the increased net water reabsorption, urine flow decreases and urine osmolality increases. See Box 37.1 for more on renal water channels.

With refinement of radioimmunoassays for AVP, the unique sensitivity of the hormone to small changes in osmolality has become apparent, as has the remarkable sensitivity of the kidney to small changes in plasma AVP levels. Circulating AVP is linearly related to plasma osmolality above a threshold of 1 to 2% (Fig. 37.2). Urine osmolality, in turn, is related linearly to AVP levels from 0.5 to 5–6 $pgml^{-1}$, in association with increases in plasma osmolality to only 4% above the threshold for AVP secretion (Fig. 37.3). However, because urine volume is related inversely to urine osmolality, small increases in plasma AVP concentration (e.g., from 0.5 to 2 $pgml^{-1}$) have the effect of decreasing urine flow much more than subsequent larger increases (e.g., from 2 to 5 $pgml^{-1}$; Fig. 37.3). This relationship emphasizes the marked physiological effects of small initial changes in plasma AVP levels. The net result of these relations among plasma osmolality, AVP secretion, urine volume, and urine osmolality is a finely tuned regulatory system that adjusts the rate of free water excretion according to plasma osmolality via changes in pituitary hormone secretion.

Thirst Is Another Effective Osmoregulatory Response to Dehydration

Accompanying the excretion of concentrated urine is reabsorption of conserved water, which can considerably dilute remaining body fluids. Thirst, and the water intake it provokes, is a much more rapid and less limited response to dehydration than antidiuresis. Thirst may be defined as a strong motivation to seek, to obtain, and to consume water in response to deficits in body fluids. Like AVP secretion, thirst can be stimulated by cellular dehydration caused by increases in the effective osmolality of ECF (Gilman, 1937). Studies in animals consistently indicate that drinking behavior is elicited by 1 to 3% increases in plasma osmolality above basal levels, and analogous research has revealed that similar thresholds must be reached to produce thirst in humans (Robertson, 1986). This arrangement, in which the threshold for drinking is slightly higher than that for secretion of AVP (Fig. 37.3), ensures that ongoing behavior is not disrupted by thirst unless the buffering effects of osmosis and antidiuresis are insufficient to maintain osmoregulation. It also ensures that dehydration does not become severe before thirst is stimulated. See Box 37.2 for more on how the neurohypophysis controls the volume of water in the body.

Also like AVP secretion, water intake increases linearly in proportion to increases in the effective osmolality of ECF. The dilution of body fluids by ingested water complements the retention of water that occurs during antidiuresis, and both responses occur when drinking water is available. However, there may be marked individual differences in whether dehydrated subjects respond to their need for water promptly by drinking or more slowly by increasing renal water conservation (Kanter, 1953). AVP secretion and urine osmolality are more elevated when an induced increase in plasma osmolality is not compensated for by water intake (e.g., because drinking water is not available). Conversely, water intake in response to a solute load increases in animals after their kidneys are removed or their capability to secrete AVP is compromised, thereby precluding rapid excretion of the load in concentrated urine.

BOX 37.1

WATER CHANNELS

Water conservation by the kidney is dependent on its ability to concentrate the urine. Urine is concentrated through the combined actions of the loop of Henle and the collecting duct of the kidney. The loop of Henle generates a high osmolality in the renal medulla via a mechanism known as the countercurrent multiplier system. AVP acts in the collecting duct to increase water permeability, thereby allowing osmotic equilibration between the urine and the hypertonic interstitium of the renal medulla. The net effect of this process is to extract water from the urine into the medullary interstitial blood vessels, resulting in increased urine concentration and decreased urine volume.

AVP produces antidiuresis by virtue of its effects on the epithelial principal cells of the collecting duct in the kidney, which are endowed with AVP receptors of the V2 type. It has long been known that binding of AVP to G protein-coupled V2 receptors causes cAMP generation via activation of adenylate cyclase. However, the intracellular mechanisms responsible for the subsequent increased water reabsorption across the collecting duct cells were elucidated only after the discovery of *aquaporins*, which are a widely expressed family of water channels that facilitate rapid water transport across cell membranes.

Many different aquaporin water channels are expressed in various body tissues, including the brain. Several of these channels have been localized in the kidney. Aquaporin-1 is expressed constitutively in the proximal tubule and thin descending limb of the loop of Henle and is believed to be responsible for reabsorption of a large fraction of the water filtered by the glomerulus. The other three water channels, aquaporin-2, -3, and -4, are expressed in collecting duct principal cells, target cells for the action of AVP to regulate collecting duct water permeability. Aquaporin-2 is the only water channel known to be expressed in the apical membrane (i.e., the side bordering the tubular lumen, through which urine flows) of collecting duct principal cells and is also abundant in intracellular vesicles located below the apical membrane. Aquaporin-2 is the major AVP-regulated water channel and mediates water transport across the apical plasma membrane of the principal cells of the collecting ducts. In contrast, aquaporins-3 and -4 are expressed at high levels in the basolateral plasma membranes (i.e., the side bordering the blood) of principal cells and are responsible for the constitutively high water permeability of the basolateral plasma membrane.

There are at least two ways by which AVP regulates osmotic water permeability in the collecting duct: short-term and long-term regulation (Knepper, 1997). Short-term regulation is associated with increases in water permeability within a few minutes of AVP exposure, an effect that is rapidly reversible. AVP triggers this response by binding to the V2 receptor and increasing intracellular cyclic AMP levels by activating adenylate cyclase. The increase in collecting duct water permeability is a consequence of fusion of aquaporin-2-containing intracytoplasmic vesicles with the apical plasma membranes of the principal cells, a process that increases apical water permeability by markedly increasing the number of water-conducting pores in the apical plasma membrane. Dissociation of AVP from the V2 receptor allows intracellular cAMP levels to decrease, and the water channels are reinternalized into the intracytoplasmic vesicles, thereby terminating the increased water permeability. By virtue of the subapical membrane localization of the aquaporin-containing vesicles, they can be quickly shuttled into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism therefore allows minute-to-minute regulation of renal water excretion through changes in ambient plasma AVP levels. Long-term regulation of collecting duct water permeability represents a sustained increase in collecting duct water permeability in response to prolonged high levels of circulating AVP. This response requires at least 24 h to elicit and is not as rapidly reversible. This conditioning effect is due largely to the ability of AVP to induce large increases in the abundance of aquaporin-2 and -3 water channels in the collecting duct principal cells. Greater total expression of the number of aquaporin-2 and -3 water channels, when combined with the short-term effect of AVP to shift aquaporin-2 into the apical plasma membrane, allows the collecting ducts to achieve extremely high water permeabilities during conditions of prolonged dehydration, thereby further enhancing the urine concentrating capacity in response to elevated levels of circulating AVP.

Rapid Inhibitory Feedback Control of Drinking

When dehydrated, many animals drink water very quickly, stopping long before the ingested water actually rehydrates them. This anticipatory satiety appears to be mediated by a neural message communicated from the oropharynx to the brain in association with the act of swallowing. The main experiments were done in dogs with implanted gastric fistulas (Thrasher, Nistal-Herrera, Keil, & Ramsay, 1981). When the fistula was

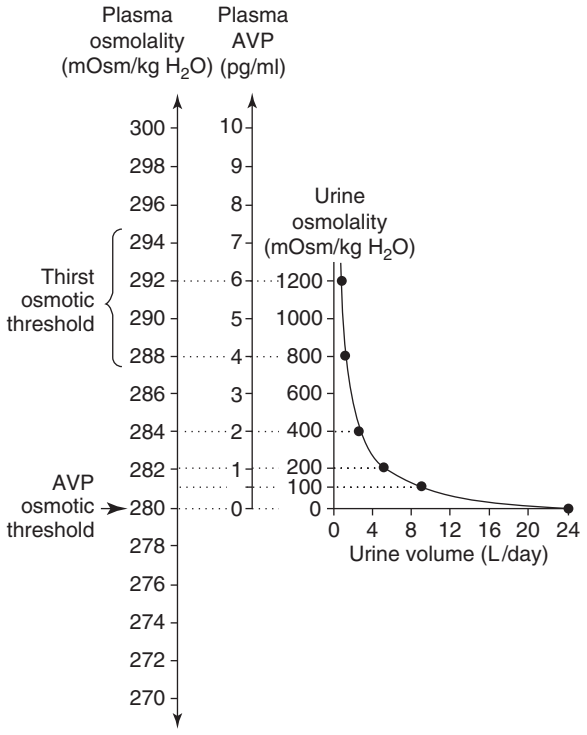

FIGURE 37.3 Relationship of plasma osmolality, plasma AVP concentrations, urine osmolality, and urine volume in humans. Note that small changes in plasma AVP concentrations have larger effects on urine volume at low plasma AVP concentrations than at high plasma AVP concentrations. *Modified with permission from Robinson (1985).*

closed, ingested water flowed normally from the stomach into the small intestine and was absorbed; water-deprived dogs drank rapidly, stopped 15 min before their plasma osmolalities began to decrease, and did not resume drinking as their stomach emptied because plasma osmolalities had returned to normal. In contrast, when the fistula was left open, ingested water drained out from the stomach, never entering the intestine and thus never being absorbed; the dogs drank normal amounts, stopped drinking, and after 10 to 20 min resumed drinking. In another study, when the dogs were not allowed to drink but water was introduced into the stomach through the fistula, thus bypassing the oropharynx, the gastric load did not affect water intake until it had been absorbed.

These seminal observations are consistent with a temporary satiety being produced by the act of water consumption, with a more long-lasting satiety occurring only after absorption of the ingested water and rehydration of the dog. AVP secretion is affected in parallel, showing that physiological and behavioral components of osmoregulation are influenced similarly. Ingestion of a concentrated NaCl solution instead of water produced the same temporary satiety and inhibition of AVP secretion, but after the saline was absorbed, the increase in plasma osmolality stimulated more drinking and AVP secretion than occurred at first. In similar experiments, people responded the same way but rats appear to have a different mechanism of rapid feedback, perhaps involving peripheral osmoreceptors.

Osmoreceptor Cells Stimulate AVP Secretion and Thirst

All body cells lose water by osmosis when the effective osmolality of ECF is increased. Thus, cells that provoke AVP secretion and thirst do not have unique osmosensitive properties (unlike retinal photoreceptor cells, for example, which are uniquely responsive to light). Instead, the exceptional feature of osmoreceptor cells is thought to be their neural circuitry, which activates the central systems for AVP secretion and thirst when the cells are dehydrated.

Destruction of osmoreceptor neurons should eliminate detection of increased plasma osmolality and thus the AVP secretion and thirst responses that are elicited by dehydration. In fact, ample research has confirmed that certain brain lesions eliminate AVP secretion and thirst responses. Such studies also have revealed that osmoreceptor cells (Johnson & Buggy, 1978; Thrasher, Keil, & Ramsay, 1982) appear to be located in the vascular organ of the lamina terminalis (OVLT) and areas of the adjacent anterior hypothalamus, near the anterior wall of the third cerebral ventricle (Fig. 37.4). Surgical destruction of that

BOX 37.2

DIABETES INSIPIDUS

The disease *diabetes insipidus* (DI), in which the secretion of AVP is impaired or absent, illustrates the crucial role of AVP in controlling the volume of water in the body. An eighteenth century Scottish physician, William Cullen, named the disease diabetes insipidus, or insipid urine, to distinguish it from *diabetes mellitus*, or sweet urine, in which abnormally high concentrations of glucose in the blood result in glucose appearing in the urine.

AVP is the only known antidiuretic substance in the body. In its absence, the kidney is unable to concentrate urine maximally to conserve water. The result is a continued excretion of copious amounts of very dilute urine. Patients with severe cases of DI, in whom the ability to excrete AVP is completely lost, can excrete up to 25 liters of urine each day. Such patients urinate almost hourly, which renders the completion of even simple tasks and activities of daily living, including sleeping, exceedingly difficult.

Patients with DI can quickly become dehydrated if their urinary fluid losses are not replaced by drinking water. Fortunately, thirst remains intact in most patients with DI because lesions that destroy the magnocellular neurons in the SON and PVN that synthesize AVP generally leave intact the osmoreceptors in the anterior hypothalamus as well as the higher brain centers that control thirst. Consequently, extreme thirst is one of the hallmarks of this disease, leading to the characteristic symptoms of *polydipsia* (excessive drinking) and *polyuria* (excessive urination). If drinking water is unavailable, or if a person with DI is unable to drink, then the unreplaced urinary water loss leads to dehydration and death in the absence of medical intervention.

DI can be caused when tumors and infiltrative diseases of the hypothalamus destroy the magnocellular neurons that produce AVP. Because four nuclei contain magnocellular neurons, and 10 to 20% of AVP-producing neurons are sufficient for normal urine concentration, brain lesions that cause DI are generally large. Less commonly, DI is idiopathic (of unknown cause), most likely from an autoimmune basis. DI can also be genetic, transmitted as an autosomal-dominant trait. Some patients with DI do not have any defect in AVP secretion but rather have defects in the V2 AVP receptors in the kidney that respond to circulating AVP. These cases are called *nephrogenic* (of kidney origin) DI.

The treatment for DI of hypothalamic origin, like that of other endocrine deficiency disorders, is replacement of the deficient hormone, in this case AVP. The short half-life of AVP in the circulation allows mammals to have minute-to-minute control of their urine output. However, longer-acting synthetic analogs of AVP are more convenient for treatment because they need not be taken as frequently as short-acting drugs (Robinson, 1985). These agents can restore urinary concentration and allow a person with DI to lead a more normal life.

area of the brain in animals abolishes the AVP secretion and thirst responses to hyperosmolality but not their responses to other stimuli. The same conclusion was drawn after a study of people who were unable to osmoregulate when water deprived or when given an NaCl load; these patients were found to have focal brain tumors that destroyed the region around the OVLT.

The location of osmoreceptor cells in the OVLT is consistent with the results of pioneering investigations in which hyperosmotic solutions injected into blood vessels perfusing the anterior hypothalamus stimulated AVP secretion in dogs (Verney, 1947). The OVLT and surrounding areas of the anterior hypothalamus were subsequently implicated by studies in rats. After systemic injections of hypertonic NaCl solution, modern immunocytochemical techniques were used to detect early gene products in cells associated with the production of new protein. Dense staining in the OVLT (and in AVP-secreting cells in the hypothalamus) indicated that it had been strongly stimulated by the experimentally induced dehydration and closely paralleled pituitary AVP secretion (Hoffman, Smith, & Verbalis, 1993).

The neural pathways connecting the OVLT with magnocellular AVP-secreting cells in the hypothalamic SON and PVN have been identified, whereas the neural circuits in the forebrain that control thirst are less well known. Early reports identified the lateral hypothalamus as a "thirst center" because its destruction in rats eliminated the drinking response, but not the associated AVP secretion, to increased osmolality of body fluids. However, later investigations showed that the critical damage was not to hypothalamic cells but to dopamine-containing fibers that coursed through the area. The induced disruption of behavior was not specific to drinking but instead reflected a general inability of the brain-damaged animals to initiate movement (Stricker, 1976). Indeed, the syndrome of behavioral dysfunctions seen in these animals generally resembled that of Parkinson's disease, which has also been attributed to the loss of dopaminergic fibers in the brain. (See Chapter 36 for the same reinterpretation

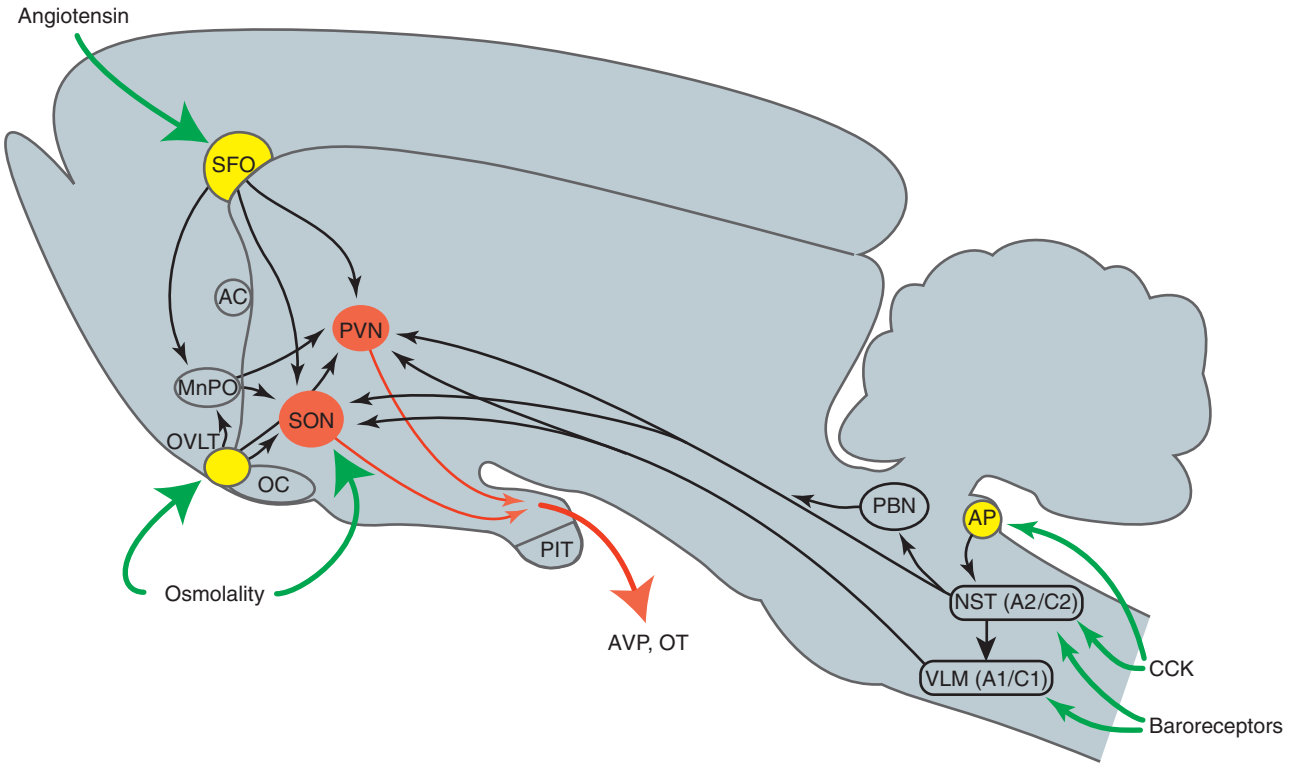

FIGURE 37.4 Summary of the main anterior hypothalamic pathways that mediate secretion of arginine vasopressin (AVP) and oxytocin (OT). The vascular organ of the lamina terminalis (OVLT) is especially sensitive to hyperosmolality. Hyperosmolality also activates other neurons in the anterior hypothalamus, such as those in the subfornical organ (SFO) and median preoptic nucleus (MnPO), and magnocellular neurons, which are intrinsically osmosensitive. Circulating angiotensin II (AII) activates neurons of the SFO, an essential site of AII action, as well as cells throughout the lamina terminalis and MnPO. In response to hyperosmolality or AII, projections from the SFO and OVLT to the MnPO activate excitatory and inhibitory interneurons that project to the supraoptic nucleus (SON) and paraventricular nucleus (PVN) to modulate direct inputs to these areas from the circumventricular organs. Cholecystokinin (CCK) acts primarily on gastric vagal afferents that terminate in the nucleus of the solitary tract (NST), but at higher doses it can also act at the area postrema (AP). Although neurons apparently are activated in the ventrolateral medulla (VLM) and NST, most oxytocin secretion appears to be stimulated by monosynaptic projections from A2/C2 cells, and possibly also noncatecholaminergic somatostatin/inhibin b cells, of the NST. Baroreceptor-mediated stimuli, such as hypovolemia and hypotension, are more complex. The major projection to magnocellular AVP neurons appears to arise from A1 cells of the VLM that are activated by excitatory interneurons from the NST. Other areas, such as the parabrachial nucleus (PBN), may contribute multisynaptic projections. Cranial nerves IX and X, which terminate in the NST, also contribute input to magnocellular AVP neurons. It is unclear whether baroreceptor-mediated secretion of oxytocin results from projections from VLM neurons or from NST neurons. AC, anterior commissure; OC, optic chiasm; PIT, anterior pituitary.

of the inability of rats to eat normally after dopamine-depleting lesions of the lateral hypothalamus.) More recent studies using functional magnetic resonance imaging of the brain have implicated the anterior cingulate cortex as a likely area involved in thirst perception (Egan et al., 2003).

Natriuresis and Inhibition of Solute Intake Also Promote Osmotic Homeostasis during Dehydration

When body fluid is hyperosmolar, adaptive behavior includes not only drinking and conserving water (thereby increasing the denominator in the ratio that represents body fluid osmolality) but also excreting NaCl and avoiding the consumption of additional osmolytes (thereby decreasing the numerator of that ratio). Endogenous natriuretic agents promote urinary sodium loss after an administered NaCl load or a period of imposed water deprivation. One such agent is the hormone *atrial natriuretic peptide* (ANP), which is synthesized in the atria of the heart and released when increased intravascular volume distends the atria. Another is the hormone *oxytocin*. Like AVP, oxytocin is synthesized in magnocellular neurons in the PVN and SON and secreted from the posterior pituitary in proportion to induced hyperosmolality (Stricker & Verbalis, 1986). In rats, oxytocin is as potent in stimulating natriuresis as AVP is in stimulating antidiuresis (Verbalis, Mangione, & Stricker, 1991), by acting directly in the kidneys and indirectly by eliciting secretion of ANP.

Salt loads are also known to decrease the intake of osmolytes, whether in the form of NaCl solution or

food, complementing the stimulation of thirst and the secretion of AVP and oxytocin. However, because destruction of the OVLT eliminates the two latter effects but not the dehydration-induced reduction in NaCl intake, osmo- or Na^+ receptors located outside the basal forebrain must mediate the inhibition of NaCl and food intake. Possible sites for such cells include the *hepatic portal vein* and the *area postrema*, both of which have been suspected of having Na^+ receptor functions. In addition, cells in the hepatic portal vein are well situated to detect the sodium content of ingested food and to modulate its intake accordingly.

Diuresis and Inhibition of Water Intake Promote Osmotic Homeostasis during Overhydration

Osmoregulation is required not only under conditions of dehydration but also during periods of acute overhydration and hypoosmolality, as may result when beverages are consumed in excess of water needs or when AVP levels are non-osmotically elevated. Such consumption may occur not because of thirst but, for example, because of the palatability of or chemical substances in the beverages (e.g., caffeine, alcohol). (See Box 37.3 on water intoxication.) Unlike excess food, which is stored as triglycerides in adipose tissue, excess water is not stored for later use but instead is excreted in urine. When plasma osmolality is below normal, circulating levels of AVP are reduced and, in consequence, the kidneys excrete dilute urine and thereby raise plasma osmolality. The major behavioral contribution of osmotic dilution to osmoregulation is inhibition of free water intake; the ingestion of osmolytes in food and NaCl is not stimulated by osmotic dilution.

Summary

Osmoregulation during dehydration in animals and humans is accomplished by a combination of physiological responses, resulting in antidiuresis and natriuresis, and the behavioral response of increased water intake. Osmoreceptor cells critical for mediating these functions have been identified in the basal forebrain. These neurons respond to very small increases in plasma osmolality, and the effector systems they control correct any increase in plasma osmolality. In addition, an early stimulus must exist, generated by peripheral osmo- or Na^+ receptor cells, which signals the brain in anticipation of subsequent rehydration. Other osmo- or Na^+ receptor cells appear to mediate the inhibition of NaCl and food intake, which also contributes to osmoregulation during dehydration. Conversely, diuresis and inhibition of water intake promote osmoregulation during overhydration, whereas excitation of NaCl or food intake does not.

VOLUME HOMEOSTASIS

Like osmotic dehydration, loss of blood volume (hypovolemia) stimulates several adaptive compensatory responses appropriate for restoring circulatory volume. The physiological contributions to volume regulation have been studied extensively in laboratory animals subjected to a controlled loss of blood. Because behavior is compromised by the anemia and hypotension that result from extensive hemorrhage, researchers studying thirst in rats often instead produce hypovolemia by subcutaneous injection of a colloidal solution. Such treatment disrupts the Starling equilibrium in capillaries near the injection site because the extravascular colloid opposes the oncotic effect of plasma proteins. Consequently, fluid leaches out of capillaries and remains in the interstitial space. Ingested fluid is also drawn into the interstitial space by the colloid so the total fluid volume required to correct the plasma volume deficit may be substantial. Water does not move from the cells by osmosis, however, because the osmolality of the injected colloidal solutions actually is similar to that of cells.

After colloid injections, rats conserve water and Na^+ in urine and increase their consumption of water and saline solution (Stricker, 1981). When given an isotonic NaCl solution to drink, these rats ingest volumes appropriate to their needs. When given separate bottles of water and concentrated NaCl solution, remarkably the rats drink appropriate amounts of each to create an isotonic fluid mixture. These observations raise several questions: How do the hypovolemic rats detect their plasma volume depletion? How are their thirst and salt appetite coordinated so that they consume the desired isotonic mixture of fluid? How are these two behavioral responses integrated with the complementary physiological responses of water and Na^+ conservation in urine? Research has provided answers to these and related questions, which are discussed in the following sections.

Neural and Endocrine Signals of Hypovolemia Stimulate AVP Secretion

An appropriate physiological response to volume depletion should include water conservation and urine concentration. In fact, like plasma hyperosmolality, hypovolemia is an effective stimulus for AVP secretion (Robertson, 1986; Stricker & Verbalis, 1986). However, AVP secretion does not occur until blood loss exceeds 10% of total blood volume, meaning AVP secretion is much less sensitive to hypovolemia than to increases in ECF osmolality (Fig. 37.2). The effects of hypovolemia and osmotic dehydration are additive; that is, a given increase in osmolality causes greater secretion of AVP when animals are hypovolemic than when they are euvolemic (Fig. 37.5).

BOX 37.3

WATER INTOXICATION

Overhydration that leads to retention of excess water is commonly called water intoxication. This can be caused by two mechanisms: excessive ingestion of fluids in volumes greater than the ability of the kidneys to excrete water or impaired kidney water excretion. In many cases, both mechanisms contribute to the water retention. Ingestion of dilute fluids normally causes slight decreases in plasma osmolality, which are sufficient to reduce circulating AVP concentrations to levels that allow the kidneys to excrete the ingested water in dilute urine, thereby maintaining osmotic homeostasis. The capacity of mammalian kidneys to excrete excess fluid is very large, in humans ranging from 800 to 1,000 ml/h, or 19 to 24 L/d. Humans rarely ingest fluids at these large volumes; however, this does occur in patients with schizophrenia, who drink compulsively for reasons not related to thirst, or during periods of forced water consumption as has occurred during fraternity hazing or freshwater drowning. More commonly, water retention occurs when the water excreting capacity of the kidney is limited by increased plasma AVP levels. This can occur because of physiological nonosmotic stimuli that cause AVP secretion, such as hypovolemia, or because of pathological AVP secretion caused by a variety of disease processes, including tumors that synthesize and secrete AVP or central nervous system disorders that interfere with normal regulation of AVP secretion, which is called the *syndrome of inappropriate antidiuretic hormone secretion* (SIADH) (Verbalis, 2007).

The metabolic consequence of excess water retention is a dilution of the osmolality of body fluids, or *hypoosmolality*, and a commensurate dilution of the extracellular fluid (ECF) sodium concentration to low levels, or *hyponatremia*. The physiological consequence of lowered ECF osmolality is an imbalance of osmolality across the intracellular fluid (ICF) and ECF compartments. In response, water will move across cell membranes from the ECF to the ICF until osmotic equilibrium is again achieved. This water movement results in swelling of all cells throughout the body. In most organs this is well tolerated, but the brain is enclosed in a rigid bony skull that limits the degree of brain swelling, or *cerebral edema*, to approximately 8%, which is the space occupied by cerebrospinal fluid within the skull. Once this limit is reached, the brain herniates through the openings at the base of the brain, which compresses the brainstem respiratory regulatory center leading to cessation of breathing and death. This pathological process is the cause of death in cases of water intoxication that develops rapidly, as in individuals engaging in endurance exercise events such as marathon races, who ingest too much fluid relative to their reduced urine excretory capacity as a result of exercise-induced stimulation of AVP secretion (Noakes et al., 2005). Individuals with lesser degrees of cerebral edema nonetheless can develop neurological manifestations ranging from disorientation to seizures, obtundation, and coma, a syndrome called *hyponatremic encephalopathy* (Fraser & Arieff, 1997).

However, such dire consequences do not develop in most patients with hypoosmolality and hyponatremia because the brain is able to adapt to hypoosmolality via a process called *brain volume regulation* (Verbalis, 2010). In response to hypoosmolality-induced cell swelling, the brain loses electrolytes and small molecules culled from the ICF and ECF spaces, thereby decreasing brain water content back toward normal levels. This process generally requires 24–48 hours in both experimental animals and humans. The marked variability in the presenting neurological symptoms of hyponatremic patients can be understood in the context provided by this process of brain volume regulation. Most of the severe neurological symptoms associated with hyponatremia are thought to reflect the cerebral edema that occurs as a consequence of osmotic water movement into the brain. However, once the brain has volume adapted through solute losses, thereby reducing the cerebral edema, neurological symptoms are not as prominent and in some cases may even be totally absent. On the other hand, even patients with chronic hyponatremia appear to be at risk from deleterious complications as a result of the cellular solute losses that allow survival during hypoosmolar conditions. These include altered neurocognition, gait instability, increased falls and bone loss leading to bone fractures, and a debilitating demyelinating disorder called central pontine myelinolysis if the hyponatremia is corrected too rapidly.

Loss of blood volume is first detected by stretch receptors in the great veins entering the right atrium of the heart. These stretch receptors provide an afferent vagal signal to the *nucleus of the solitary tract* (NST) in the brainstem (Chapter 36). Still larger decreases in blood volume may also lower arterial blood pressure and reduce the stretch of receptors in the walls of the carotid sinus and aortic arch. That information is integrated in the NST with neural messages from the low-pressure, venous side of the circulation. Note that these sensory neurons are not actually baroreceptors (literally, pressure receptors); although commonly they

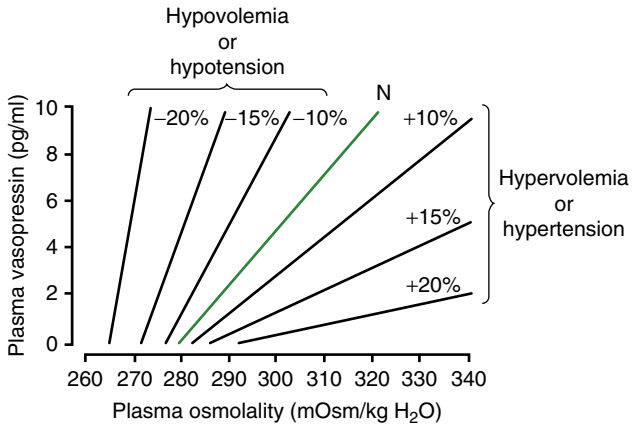

FIGURE 37.5 The relationship between the osmolality of plasma and the concentration of vasopressin (AVP) in plasma depends on blood volume and pressure. The line labeled N shows plasma vasopressin concentration across a range of plasma osmolality in an adult with normal intravascular volume (euvolemic) and normal blood pressure (normotensive). Lines to the left of N show the relationship between plasma vasopressin concentration and plasma osmolality in adults whose low intravascular volume (hypovolemia) or blood pressure (hypotension) is 10, 15, and 20% below normal. Lines to the right of N are for volumes and blood pressures 10, 15, and 20% above normal. *Modified with permission from Robertson (1986).*

are referred to as such, they are more accurately described as stretch receptors.

The ascending pathway between the NST in the brainstem and the SON and PVN in the hypothalamus includes noradrenergic fibers arising from A1 cells in the ventrolateral medulla. Volume depletion stimulates AVP secretion via other pathways as well. In addition, the kidneys secrete renin during hypovolemia, a response mediated in part by sympathetic neural input to β-adrenergic receptors on cells that secrete renin. Renin is an enzyme that initiates a cascade of biochemical steps that result in the formation of *angiotensin II* (AII) (Fig. 37.6), an extremely potent vasoconstrictor. AII stimulates AVP secretion by acting in the brain at the *subfornical organ* (SFO) (Ferguson & Renaud, 1986), which is located in the dorsal portion of the third cerebral ventricle. Because this circumventricular organ lacks a blood–brain barrier, its AII receptors can detect very small increases in the blood levels of AII. Neural pathways from the SFO to the SON and PVN in the hypothalamus mediate AVP secretion and may use AII as a neurotransmitter. Another pathway from the SFO goes to the OVLT, perhaps providing an opportunity for the integration of information about volume states and osmotic concentration.

Neural and Endocrine Signals of Hypovolemia Also Stimulate Thirst

In addition to the antidiuresis and vasoconstriction produced by the secretion of AVP and activation of the renin–angiotensin system, colloid treatment increases water intake in rats (Fitzsimons, 1961). Once 5 to 10% of the normal plasma volume has been lost, the water intake elicited by hypovolemia increases linearly in relation to further deficits in plasma volume. This stimulus for water intake and the effect of an NaCl load on thirst are additive. The stimulus of thirst during hypovolemia appears to be the same as the signal for AVP secretion—that is, a combination of neural afferents from cardiovascular baroreceptors and endocrine stimulation by AII (Fitzsimons, 1969). Each signal can stimulate water intake in the absence of the other. For example, water intake by hypovolemic rats is not diminished by destruction of the NST and loss of neural input from baroreceptors, nor is it eliminated by the loss of AII resulting from bilateral removal of the kidneys (Fitzsimons, 1961). Presumably, colloid treatment would not elicit thirst in rats subjected concurrently to bilateral nephrectomy and NST lesions.

Intravenous infusion of AII strongly stimulates thirst in rats and most other animals studied in the laboratory (including humans). AII adds to the thirst stimulated by an osmotic load when the two treatments are combined. There had been considerable controversy about whether AII functions as a normal physiological stimulus of thirst because the doses of AII required to stimulate significant water intake produce blood levels of AII well above the physiological range. However, such doses also increase arterial blood pressure, and it has been shown that this acute hypertension inhibits thirst and limits the induced water intake. For example, drinking was enhanced considerably when the hypertensive effects of AII were blunted by simultaneous administration of vasodilating agents (Robinson & Evered, 1987).

Osmotic Dilution Inhibits Thirst and AVP Secretion during Hypovolemia

Hypovolemic rats need isotonic saline, not water alone, to repair their plasma volume deficits. When the rats drink only water, about two-thirds of the ingested volume moves into cells by osmosis and much of what remains extracellular is captured by the colloid. Thus, most of the water that is consumed does not remain in the vascular compartment, and the volume deficit within the vascular compartment persists. This situation may be contrasted with the negative feedback control of osmoregulatory thirst in which the dehydration of osmoreceptor cells causes thirst and ingested water repairs dehydration, eliminating the stimulus for thirst.

Rather than repairing the volume deficit, the water consumed by hypovolemic rats causes a second serious challenge to body fluid homeostasis: osmotic dilution. The animals cannot readily eliminate this self-administered water load because hypovolemia reduces GFR and

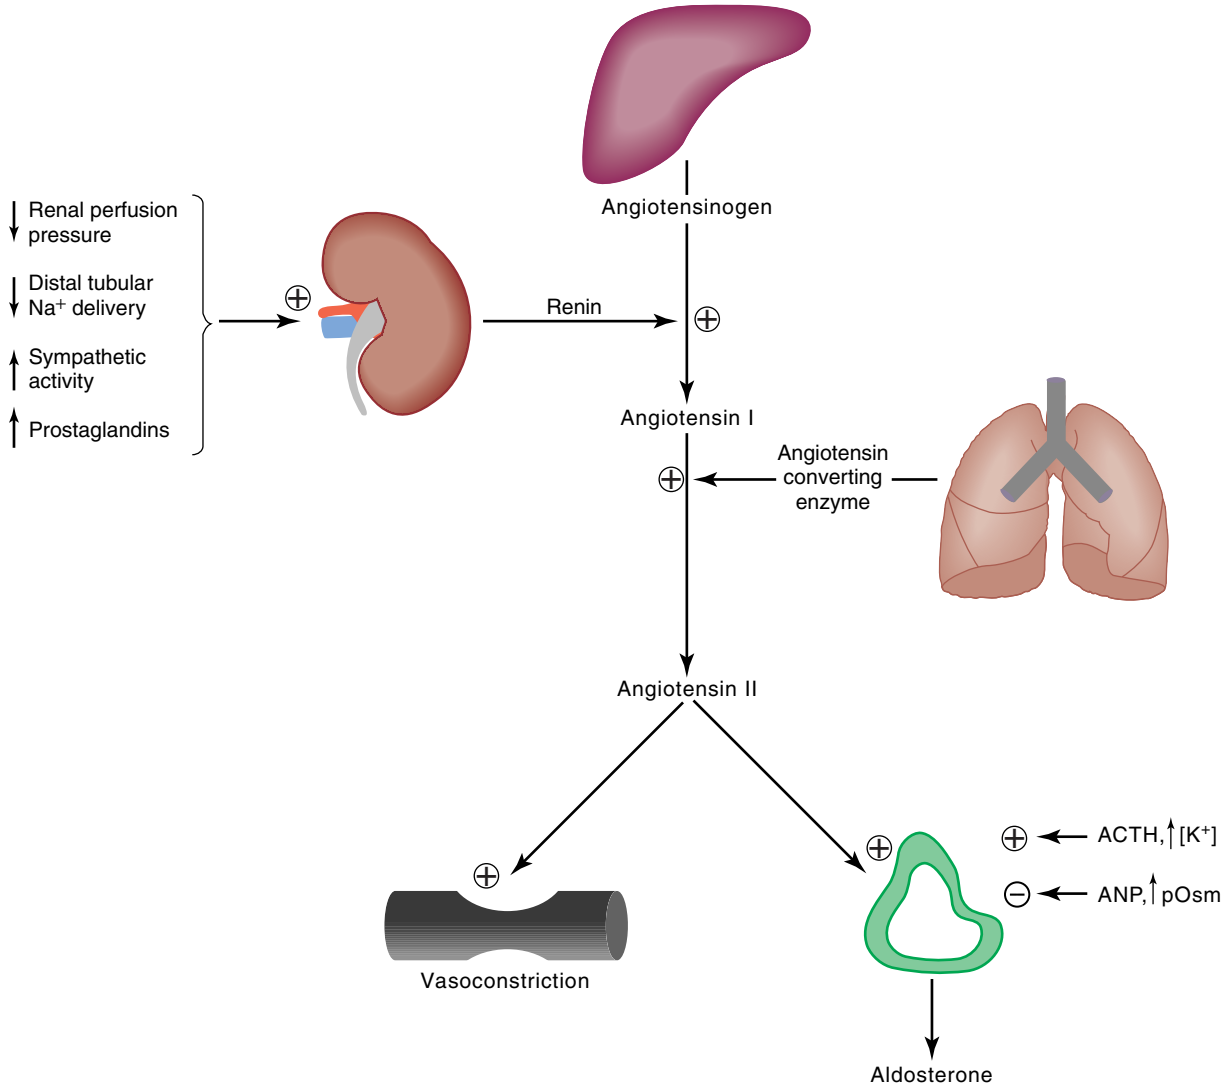

FIGURE 37.6 The renin–angiotensin cascade. Baroreceptors in the aortic arch, carotid sinus, and renal afferent arterioles sense hypovolemia and then cause the kidneys to secrete the enzyme renin. Renin cleaves angiotensinogen, which is synthesized by the liver, to produce angiotensin I. The angiotensin-converting enzyme, primarily in the lungs, cleaves angiotensin I to produce angiotensin II (AII), a peptide made of eight amino acid residues. AII is a potent vasoconstrictor and one of several stimulants of aldosterone secretion. Stimulation of aldosterone secretion from the adrenal cortex, along with possible direct intrarenal effects of AII, promotes renal conservation of sodium ions, complementing the pressor effect of AII in stabilizing arterial pressure and volume. ACTH, adrenocorticotropic hormone; ANP, atrial natriuretic peptide; pOsm, plasma osmolality.

thereby diminishes urinary excretion independent of AVP. Therefore, when water is the only drinking fluid available, an appropriate response of colloid-treated rats would be to stop drinking and thereby limit the secondary problem of osmotic dilution. In experiments, colloid-treated rats actually do stop drinking water despite persistent hypovolemia, and the stimulus for the inhibition of thirst has been found to be osmotic dilution of body fluids (Stricker, 1969). A 4 to 7% decrease in osmolality is sufficient to stop drinking that has been motivated by a 30 to 40% loss of plasma volume. Thus, the osmoregulatory system appears dominant in the control of thirst. Comparable data demonstrate the same to be true of AVP secretion in colloid-treated rats: osmotic dilution inhibits AVP secretion even in severely hypovolemic rats (Stricker & Verbalis, 1986).

Hypovolemia Also Stimulates Aldosterone Secretion and Salt Appetite

As mentioned earlier, hypovolemic animals need to consume and retain water and NaCl, not just water. Appropriately, colloid-treated rats drink NaCl solution

and conserve Na^+ in urine. Renal Na^+ retention is mediated largely by aldosterone secreted from the adrenal cortex, although Na^+ conservation also occurs in association with the decrease in GFR. The central nervous system does not innervate the adrenal cortex, as it does the adrenal medulla. However, a neural influence on aldosterone secretion is provided indirectly because AII is a very potent stimulus of aldosterone secretion, and renin secretion from the kidneys during hypovolemia is stimulated in part by the sympathetic nervous system (Fig. 37.6). The secretion of aldosterone is also stimulated by another peptide hormone, *adrenocorticotrophic hormone* (ACTH), which is secreted from the anterior lobe of the pituitary gland in response to *corticotropin-releasing hormone* (CRH). The release of CRH from the PVN is triggered by various stressors, including activated cardiovascular baroreceptors. Yet another stimulus of aldosterone secretion is increased plasma levels of K^+, which can develop as a consequence of reduced GFR and an associated decrease in urinary K^+ excretion. The effects of these three independent stimuli of aldosterone secretion are additive. Aldosterone has also been found to stimulate salt appetite in animals, which therefore complements its renal effects to cause sodium conservation. (See Box 37.4 on salt appetite after adrenocortical dysfunction.)

The onset of salt appetite induced in rats by colloid treatment is curiously delayed relative to the appearance of thirst. That is, water intake increases within 1 to 2 h after colloid treatment whereas the intake of NaCl solution does not increase until at least 5 h later (Stricker, 1981). Investigations showed that the delay is caused both by the gradual appearance of an excitatory stimulus of salt appetite (i.e., AII) and by the gradual disappearance of an inhibitory stimulus for NaCl intake (i.e., central secretion of oxytocin). When rats are maintained on Na^+-deficient diet for a few days instead of standard Na^+-rich laboratory chow, NaCl intake appears very rapidly after colloid treatment—even before thirst. Those results have been attributed in part to the suppression of central oxytocin secretion and in part to the increased blood levels of AII and aldosterone observed then; indeed, the latter two hormones are known to act synergistically in the stimulation of salt appetite.

Aldosterone and other mineralocorticoids appear to act directly on neurons in the NTS with mineralocorticoid receptors, which have the important additional property of containing an enzyme 11β-hydroxysteroid dehydrogenase type 2 (HSD2) that inactivates glucocorticoids (which also bind to those receptors) and thereby allows the receptors specificity to mineralocorticoids. These HSD2-containing cells are activated by all treatments that elicit salt appetite in rats but are quickly inactivated once saline has been consumed (Geerling, Engeland, Kawata, & Loewy, 2006). In addition, it seems relevant that rats with discrete lesions of the area postrema, which sends inhibitory neural input to those cells in the NTS, consumed prodigious amounts of concentrated NaCl solution whereas rats with area postrema lesions that invaded the NTS had much smaller saline intakes.

Analogous to the control of thirst, presystemic signals appear to inhibit salt appetite in association with

BOX 37.4

SALT APPETITE AFTER ADRENOCORTICAL DYSFUNCTION

Fifty years ago, a 4-year-old boy was brought to the Johns Hopkins University Hospital in Baltimore with the peculiar behavior of eating large amounts of table salt. The child heavily salted all his food, even juice, and often consumed salt directly from its container. His parents tried unsuccessfully to keep him from ingesting salt and brought him to the hospital in the hope that his strange behavior could be understood and stopped. The physicians were able to prevent the boy from having access to NaCl, but they were shocked when he died a few days later. An autopsy revealed that the child had bilateral tumors in his adrenal glands. In retrospect, it seems clear that he could not secrete aldosterone and therefore lost Na^+ in urine uncontrollably. Like patients with diabetes insipidus, who excrete a copious amount of dilute urine and drink comparable volumes of water in compensation (see Box 37.2 on diabetes insipidus), this boy evidently was consuming salt as an adaptive compensation to his recurrent need for sodium (Wilkins & Richter, 1940). He died when that response was prevented.

Rats increase their consumption of NaCl after surgical removal of their adrenal glands, by amounts proportional to the sodium loss in urine (Richter, 1936). The stimulus for this salt appetite appears to be a combination of elevated circulating levels of AII and reduced activity in a central oxytocinergic inhibitory system. In humans, however, a comparable salt appetite is not as common in patients with Addison disease, whose adrenocortical dysfunction causes them to lose Na^+ in urine excessively. Nor is salt appetite usually stimulated in people who lose excessive amounts of Na^+ in perspiration. No explanation is available for why an adaptive salt appetite appears readily in laboratory animals but not in humans, but this difference may be related, in part, to factors associated with herbivorous versus carnivorous eating behaviors.

gastrointestinal distension and increased plasma osmolality. The visceral signals appear to project through the vagus to the NTS and area postrema and then to the parabrachial nucleus (PBN), and, in this regard, lesions of peripheral sensory fibers or of the viscerosensory input to the PBN led to remarkably large intakes of NaCl solution by rats. In contrast, the inhibition of salt appetite associated with increased plasma osmolality has been attributed to central secretion of oxytocin.

Central Oxytocin Inhibits Salt Appetite

Recall that hypovolemic rats ordinarily drink water before they consume saline and, in doing so, thereby cause an osmotic dilution of body fluids. That dilution inhibits secretion of pituitary AVP and oxytocin, either of which effects might have removed an inhibitory stimulus for salt appetite. In other studies, rats showed a strong inverse relationship between intake of NaCl and plasma levels of oxytocin (but not AVP), suggesting that circulating oxytocin was an inhibitory stimulus of salt appetite. However, in tests of this hypothesis, an intravenous infusion of physiological doses of oxytocin did not decrease NaCl intake in hypovolemic rats, nor did infusion of an oxytocin receptor blocker increase NaCl intake. These findings were clarified by the observation that, coincident with the secretion of oxytocin from magnocellular neurons, oxytocin was released from parvicellular neurons projecting centrally from the PVN. Thus, plasma oxytocin may have been a peripheral marker of the centrally acting oxytocin that mediated the inhibition of salt appetite in rats (Blackburn, Verbalis, & Stricker, 1992). This hypothesis has been strongly supported by the results of a series of investigations. For example, salt appetite in hypovolemic rats was eliminated by a systemic injection of naloxone, an opioid receptor antagonist that disinhibits oxytocin secretion, and this effect was blocked by the prior injection of an oxytocin receptor antagonist directly into the cerebrospinal fluid. Conversely, NaCl ingestion in response to hypovolemia or AII was potentiated by diverse treatments that inhibit the secretion of oxytocin. In addition to osmotic dilution, these treatments included systemic injection of ethanol, maintenance on a sodium-deficient diet (instead of the standard laboratory diet rich in Na^+), and peripheral administration of mineralocorticoid hormones such as aldosterone. Thus, excitatory and inhibitory components together regulate NaCl intake in a dual-control system in the brain. See Box 37.5 on the control of thirst and salt appetite during hypovolemia in rats.

Central oxytocinergic neurons can inhibit salt intake and food intake (Chapter 36). Thus, when osmotic dehydration activates oxytocinergic neurons, the intake of food and salt is inhibited and hyperosmolality is thereby prevented. From this perspective, food is a source of osmolytes (not just of calories) and NaCl solution provides osmolytes without calories. Inhibition of intake of osmolytes complements the natriuretic effect of pituitary oxytocin in supporting osmoregulation.

Salt Appetite Is Also Inhibited by Atrial Natriuretic Peptide

The role of oxytocin in osmoregulation has become apparent only during the last decade or so, and the identification of other peptide hormones as important factors in the homeostasis of body fluids may be anticipated. One likely candidate is atrial natriuretic peptide. Like oxytocin, ANP is secreted by neurons within the brain, and when administered directly into the cerebrospinal fluid it inhibits an experimentally induced salt appetite in rats, perhaps by opposing the actions of AII. Moreover, destruction of ANP receptors in the brain eliminates the inhibition of salt appetite caused by an NaCl load (Blackburn, Samson, Fulton, Stricker, & Verbalis, 1995). Further work will be needed to understand the role of ANP-containing neurons in the central control of salt intake and the relationship of the neurons with other systems that participate in the regulation of water and NaCl intake.

Summary

Regulation of blood volume, like osmoregulation, is accomplished by a combination of physiological responses to hypovolemia, resulting in antidiuresis and antinatriuresis, and the complementary behavioral responses of increased water and NaCl intake. Cardiovascular baroreceptor cells detect hypovolemia and send neural signals to the brainstem, which communicates to the hypothalamus and forebrain structures mediating neurohypophyseal AVP and oxytocin secretion, as well as thirst. AII also appears to stimulate these responses while additionally stimulating salt appetite and supporting blood pressure as a potent vasoconstrictor. However, AII and hypovolemia both increase central oxytocin secretion, which mediates inhibition of NaCl intake, so for salt appetite to emerge this effect must be inhibited (as by osmotic dilution of body fluids, resulting from the renal retention of ingested water). The integration of these stimuli ensures that behavioral and physiological responses occur simultaneously, and their redundancy allows these vital regulatory processes to occur even when one stimulus is lost due to injury or disease. More generally, studies of water and NaCl ingestion provide insights into how the brain controls motivation, and how peptide and steroid hormones interact with neural signals in the control of behavior.

BOX 37.5

THIRST AND SALT APPETITE DURING HYPOVOLEMIA IN RATS

Hypovolemia elicits two endocrine effects in the excitation of salt appetite in rats—acute stimulation by a peptide hormone (AII) and more gradual stimulation by a steroid hormone (aldosterone). However, hypovolemia and AII each provide conflicting stimuli for salt appetite, since each signal also stimulates central oxytocin secretion, which mediates inhibition of salt appetite. The coordination of thirst and salt appetite stimulated by hypovolemia-induced colloid treatment in rats can be conceptualized as follows (Fig. 37.7). The combination of hypovolemia and AII stimulates thirst but provides a mixed stimulus of salt appetite. Thus, the animals at first drink water; however, by doing so, they dilute their body fluids, and the osmotic dilution eventually becomes large enough to inhibit thirst. Osmotic dilution has the additional effect of reducing central oxytocin secretion, which in turn disinhibits salt appetite, and the rats begin to drink concentrated NaCl solution. The ingested solute raises plasma osmolality and thereby removes the dilution-induced inhibition of thirst and oxytocin secretion. Consequently, the rats stop drinking saline and resume drinking water. Osmotic dilution again develops, thirst is again inhibited, and salt appetite is again disinhibited. And thus the hypovolemic animals, stimulated by neural and endocrine signals of hypovolemia, alternate their intakes of the two fluids while maintaining the concentration of body fluids near isotonic. Water and Na^+ are conserved in urine until the deficit in plasma volume is repaired, at which point the stimuli for adaptive physiological and behavioral responses disappear, and normal body fluid volume and tonicity are restored. Because the same neural and endocrine signals of hypovolemia stimulate thirst, salt appetite, and AVP and oxytocin secretion, these responses are integrated.

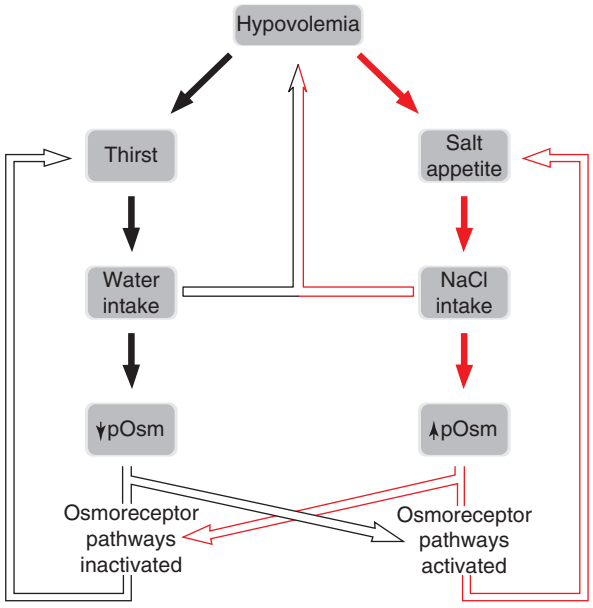

FIGURE 37.7 Schematic diagram of the mechanisms controlling thirst and salt appetite in hypovolemic rats. Solid arrows indicate stimulation and unfilled arrows indicate inhibition. The combination of the effects of blood-borne AII on the brain and neural baroreceptor signals to the brainstem stimulates hypovolemic animals to drink water and concentrated saline solution. The rats alternately drink the two fluids in amounts that ultimately add up to a volume of isotonic saline sufficient to repair the volume deficit. When the animals have access to only one fluid, the water and salt intakes are limited by activation of the appropriate inhibitory osmoregulatory pathways. When rats drink isotonic saline instead of water and concentrated saline, neither inhibitory pathway is activated and consequently intake is continuous.

In addition, presystemic signals may participate in the control of water and saline consumption. For example, distension of the stomach and small intestine by ingested fluid may inhibit further drinking despite continued deficits of plasma volume. Similarly, osmotic dilution detected by visceral osmoreceptors may inhibit intake of water, whereas osmotic concentration may inhibit intake of hypertonic NaCl solution. Thus, both systemic and presystemic signals, providing information about the concentration and volume of body fluid and of ingested fluid, respectively, appear to be available to the hypovolemic animal. The integration of these signals by the brain is critical in the control of water and saline intakes and determines the volume of each fluid that is consumed.

Neuroendocrine Systems

THE HYPOTHALAMUS IS THE CENTRAL NEUROENDOCRINE ORGAN

The hypothalamus, located at the most rostral region of the brainstem in the diencephalon, is a key center regulating numerous and diverse physiological functions, including growth, metabolism, stress responses, reproduction, osmoregulation, and circadian rhythms. All these functions are critically involved in maintaining the homeostasis of the organism and in coordinating the occurrence and timing of physiological functions with the appropriate environmental conditions. In order to accomplish this, the hypothalamus acts as an integrator, receiving converging inputs from the sensory and autonomic systems related to the internal and external environment of the organism. The hypothalamus responds rapidly to this convergent information by changing its output of neurotransmitters and neuropeptides, which in turn effect change at its targets within the central nervous system (CNS), the pituitary gland, and the bloodstream.

The hypothalamus contains several populations of cells that are defined as neuroendocrine, meaning that they have both neuronal and endocrine features. The neuroendocrine cells express neural markers and release a peptide or neurotransmitter in response to a depolarizing stimulus, similar to other neurons in the brain. Unlike other "traditional" neurons, neuroendocrine cells release their neurotransmitter directly into a blood system. Considering that endocrine glands are defined by the release of a chemical into the bloodstream, neuroendocrine cells are part of the endocrine system. Although the chemicals released by most neuroendocrine cells are peptides and neurotransmitters, they are also appropriately referred to as hormones, or neurohormones, because of this endocrine property.

The primary target of hypothalamic neuroendocrine cells is the pituitary gland, comprising the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). Some species also possess an intermediate pituitary lobe. The hypothalamic cells that regulate the anterior pituitary are referred to as hypothalamic releasing or inhibiting cells, and are the major focus of this chapter. These neurons have their cell somata in the hypothalamus, and they have an axonal process that extends to and terminates in the median eminence at the base of the hypothalamus (Yin & Gore, 2010). The median eminence is highly vascularized by a blood system called the portal capillary plexus. Hypothalamic releasing/inhibiting hormones are released into the portal capillary vasculature, which then transports these neurohormones to the anterior pituitary gland (Fig. 38.1). There, each hypothalamic hormone has at least one corresponding pituitary hormone whose release is regulated by patterns and levels of hypothalamic input.

The posterior pituitary gland also is regulated by hypothalamic cells, but the anatomical connectivity between the hypothalamus and the neurohypophysis differs from the hypothalamic-adenohypophysial system (Fig. 38.1). Hypothalamic cells that regulate the neurohypophysis have their cell bodies in the hypothalamus, but their nerve terminals project directly into the posterior pituitary gland. From there, the neurohypophyseal hormones are released into the general circulatory system and are transported to reach their targets elsewhere in the body. This chapter begins with a detailed description of hypothalamic-anterior pituitary control, followed by a section on hypothalamic-posterior pituitary control (Box 38.1).

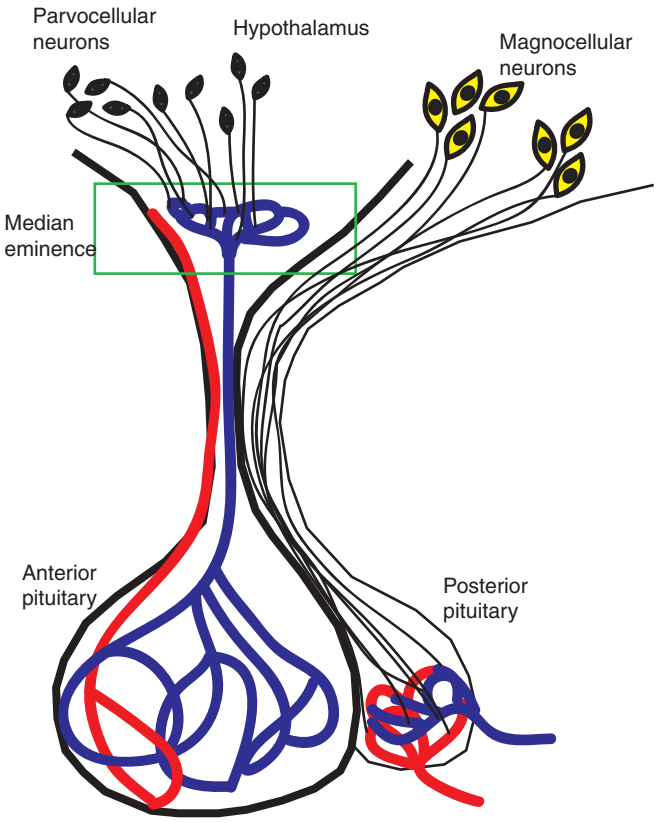

FIGURE 38.1 Overview of the central neuroendocrine systems. Several populations of hypothalamic cells regulate anterior pituitary function through release of releasing or inhibiting factors into the portal capillary vasculature. Cell bodies of these hypothalamic-adenohypophysial are small in size (parvocellular), and terminate in the median eminence at the base of the hypothalamus. Other populations of hypothalamic neurons are much larger (magnocellular), existing in the paraventricular and supraoptic nuclei, and project into the posterior pituitary (hypophysis) to release their hormones into general circulation.

HYPOTHALAMIC CONTROL OF ANTERIOR PITUITARY HORMONES AND THEIR REGULATED FUNCTIONS

The hypothalamic regulation of anterior pituitary hormonal synthesis and release is integral to the regulation of stress, reproduction, metabolism, growth, and lactation (Table 38.1). Each of these systems has a similar anatomical and hierarchical organization (Fig. 38.1). At the top of the hierarchy are the hypothalamic neurons that release their neurohormone from neuroterminals in the median eminence. With the exception of the prolactin-inhibiting hormone (dopamine), all of the hypothalamic releasing/inhibiting hormones are peptides that are cleaved from larger prohormones. The processed hypothalamic hormones are released from secretory vesicles in the axon terminals and diffuse through the extracellular fluid into the portal capillary vasculature, by a mechanism similar to volume transmission. Once in the portal capillaries, the hormones are transported to the pituitary gland where they exert an effect on synthesis and secretion of one or more pituitary hormones through binding to a specific receptor on a subset of pituitary cells. The pituitary hormones are all large peptides or small proteins. Pituitary hormone release into the general circulation is stimulated by hypothalamic releasing hormones, and each pituitary hormone targets a tertiary organ to cause hormone release or a functional outcome. In the case of hypothalamic inhibiting hormones, pituitary hormone synthesis/secretion is inhibited.

The hypothalamic–pituitary target organ axes are not an independent series of parallel regulatory systems. These axes have considerable crosstalk with one another

BOX 38.1

HISTORICAL PERSPECTIVE ON HYPOTHALAMIC HORMONES

The concept of a link between the hypothalamus and the pituitary gland was suggested and later demonstrated by Geoffrey Harris (1971), who proved the existence of a tiny series of blood vessels leading from the median eminence at the base of the hypothalamus to the anterior pituitary gland. Harris proposed that the hypothalamus controls the release of anterior pituitary hormones via this vascular connection. Subsequent studies have shown that the hypothalamic–anterior pituitary connection is critical for maintaining numerous physiological functions involved in metabolism, growth, reproduction, stress responses, and lactation. The isolation and purification of the hypothalamic releasing hormones in the late 1960s by the laboratories of Roger Guillemin, Andrew Schally, and others led to an enormous increase in knowledge of these molecules. Guillemin and Schally were awarded the Nobel Prize in Physiology and Medicine in 1977 for these fundamental discoveries in neuroendocrinology. They shared it with Rosalyn Yalow, who invented the radioimmunoassay, a tool for carefully and accurately measuring hormone levels in the body.

Andrea C. Gore

TABLE 38.1 Summary of the Five Neuroendocrine Hypothalamic Systems Regulating Anterior Pituitary Function

Function	Hypothalamic Hormone(s)	Receptor Characteristic & Localization	Anterior Pituitary Hormone(s)	Receptor Characteristic & Localization	Target Hormone(s)	Receptor Characteristic & Localization
Stress	Corticotropin-releasing hormone (CRH): 41 amino acid peptide, cleaved from precursor	CRH receptor: GPCR; on corticotrope (also CNS, adrenal, placenta, ovary, immune tissues)	Adrenocorticotropic hormone (ACTH), 39 amino acid peptide, cleaved from precursor and encoded by POMC gene	ACTH receptor: melanocortin receptor family of GPCRs; in adrenal cortex	Cortisol (humans) or corticosterone (rats, mice); steroid hormone family	Glucocorticoid receptor; steroid receptor family member; in brain & numerous body tissues
Basal metabolism (thyroid)	Thyrotropin-releasing hormone (TRH): 3 amino acid peptide, multiple copies cleaved from precursor	TRH receptor: GPCR; on thyrotrope	Thyroid-stimulating hormone (TSH), composed of α and β subunits of ~100 amino acids each	TSH receptor: GPCR, mainly in thyroid gland	Thyroid hormones (T3 and T4); lipophilic hormones synthesized from tyrosine and iodide	Thyroid hormone receptor; nuclear receptor superfamily member; in CNS and most tissues
Growth	Growth-hormone releasing hormone (GHRH): 44 amino acid peptide, cleaved from precursor Growth-hormone inhibiting hormone (GHIH, also called somatostatin): 14 or 28 amino acid peptide, cleaved from precursor	GHRH receptor: GPCR; on somatotrope Somatostatin receptor: 5 known GPCRs; on somatotrope & other tissues	Growth hormone (GH, also called somatotropin), 191 amino acid protein	GH receptor: cytokine receptor family member, on liver, muscle, bone, & other tissues	Insulin-like growth factor-1 (IGF-1): 70 amino acid peptide, cleaved from precursor	IGF-1 receptor: receptor tyrosine kinase family member; located on muscle, bone, brain, & other tissues
Reproduction	Gonadotropin-releasing hormone (GnRH)*: 10 amino acid peptide, cleaved from precursor	GnRH receptor: GPCR; on gonadotropes, brain, gonads, other tissues	Luteinizing hormone (LH), Follicle-stimulating hormone (FSH): they have a common α and a unique β subunit of ~100 amino acids each	LH receptor, FSH receptor: GPCRs, on gonads	Gonadal steroids (estrogens, progestins, androgens)	Gonadal steroid receptors (ER, PR, AR): member of steroid receptor family; in reproductive tissues, brain, pituitary, & body tissues
Lactation	Dopamine (prolactin-inhibiting hormone)	Dopamine D2 receptor: GPCR, on lactotropes & CNS	Prolactin (PRL): 198 amino acid protein	PRL receptor: GH receptor cytokine receptor family member; on mammary gland (also liver, kidney, GI tract, brain, adrenal, gonad)	NA (milk is not a hormone within the lactating woman)	NA

*A gonadotropin-inhibiting hormone (GnIH) has recently been identified (Kriegsfeld et al., 2006), but it appears to act as a traditional neuropeptide rather than a neuroendocrine substance in mammals.

Abbreviations: AR, androgen receptor; CNS, central nervous system; ER, estrogen receptor; GPCR, G-protein coupled receptor; GI: gastrointestinal; NA: not applicable; POMC, proopiomelanocortin; PR, progesterone receptor.

and can interact at multiple levels. For example, reproductive and stress axes regulate each other at specific hypothalamic neurons, both through direct actions at the CNS, as well as through feedback from the target steroid hormones. During stressful situations, elevated adrenal glucocorticoids will feed back to the brain and have actions not only at the CRH neurons, but at the GnRH neurons as well, thereby suppressing reproduction at a time when it is not optimal. Therefore, these hypothalamic neurons serve as integrators of multiple, complex pieces of information about the homeostasis and environment of the organism.

The Hypothalamus is Regulated by Neural, Glial, and Hormonal Inputs

As already stated, hypothalamic neuroendocrine cells are at the top of the hierarchy in the control of homeostatic function. Nevertheless, it is important to remember that the hypothalamus is an integrated part of the central nervous system. Thus, the hypothalamus has neural afferents/efferents between hypothalamic nuclei, as well as with brain nuclei outside of the hypothalamus. For example, each hypothalamic-releasing or -inhibiting hormone neuron receives afferent inputs from neurons and is in close communication with glia. The importance of such neural/glia communication within and between hypothalamic populations, and between hypothalamic and other CNS regions, is made clear when considering the regulation of homeostasis. In order for the organism to respond to its environment, both internal and external, it must receive input from the environment and be able to integrate that input in a coordinated manner. This is certainly the case with hypothalamic neuroendocrine cells, which are responsive to scores of neurotransmitters and neurotrophic factors arising from numerous neural/glial sources.

Hypothalamic neuroendocrine cells are also regulated by feedback from the hormones released by peripheral target organs (Table 38.1). This may occur directly at the respective hypothalamic cells via the target hormone receptor. For example, stress-regulating CRH neurons express the glucocorticoid receptor, which can sense circulating adrenal cortisol levels. In addition or alternatively, some hypothalamic neurons may be regulated by indirect feedback from peripheral hormones, mediated by other interneurons. This appears to be the case for reproduction-regulating GnRH neurons, which do not express the major estrogen, progestin, or androgen receptors. For most neuroendocrine systems, feedback regulation is a combination of direct and indirect. In addition, feedback is generally negative, meaning that high levels of a peripheral target hormone downregulate the hypothalamic cells at the top of the hierarchy. When peripheral hormone levels are low, negative feedback is relieved or reduced, enabling the hypothalamic hormone to increase its output and stimulate that neuroendocrine axis to replenish/increase peripheral hormone concentrations. In the case of reproduction, there is also positive feedback of peripheral hormones in females during ovarian cycles, something that will be discussed in the hypothalamic-pituitary-gonadal section following.

Characteristics of Neurohormone Release: Ultradian and Circadian/Diurnal Patterns

In considering the release of a hypothalamic hormone and its resulting effect on downstream targets, it is important to note the rhythmicity of this release. Hypothalamic hormones are released in a pulsatile manner, characterized by brief bursts of release, usually at intervals of 1–2 h (Krsmanovic, Hu, Leung, Feng, & Catt, 2009). This rhythmic pattern also is referred to as ultradian (i.e., shorter than daily rhythms) or circhoral (approximately hourly intervals of release). The corresponding anterior pituitary cells respond to each pulse of a hypothalamic hormone with a corresponding pulse of its pituitary hormone shortly thereafter (Fig. 38.2). It has been speculated that the pulsatile release of hypothalamic hormones is necessary to prevent the desensitization of their receptors in the anterior pituitary gland.

Along with these ultradian pulses of hypothalamic pulses are the circadian or diurnal rhythms of hormonal

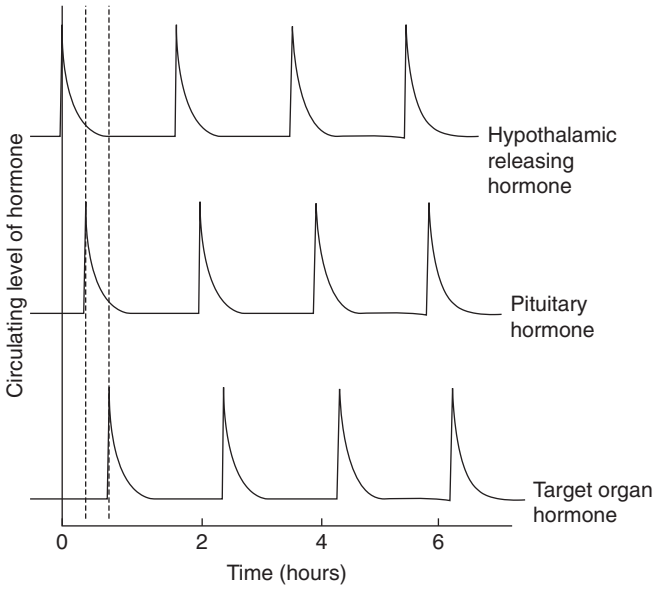

FIGURE 38.2 Representation of pulsatile hormone release in a neuroendocrine system. A representative hypothalamic-releasing hormone is released in discrete pulses at 1- to 2-h intervals. This causes pulses of the corresponding anterior pituitary hormone to occur shortly thereafter. The release of the pituitary hormone stimulates the target organ to release its hormones.

release that are characteristic of the neuroendocrine system. These 24-h rhythms of hormone release, which can occur independently of the light/dark cycle (circadian) or are entrained to the light/dark cycle (diurnal), are characteristic of neuroendocrine systems (Gore, 1998). Circadian rhythms are driven by a part of the hypothalamus called the suprachiasmatic nucleus (SCN), and the SCN makes projections within the hypothalamus to regulate neuroendocrine release in a 24-h cycle.

Cycles of hormonal release longer than 24 h can be observed for the reproductive axis. Female vertebrates often exhibit reproductive cycles, such as the four-day estrous cycles of rats or the 28-day menstrual cycles of many primates, including humans. Reproductive hormones undergo substantial fluctuations across these cycles. Even longer cycles are observed in the cases of seasonal breeders, as discussed following in the section on the hypothalamic control of reproduction.

Hypothalamic Control of Stress

Overview, Characteristics and Physiological Functions of the Hypothalamic-Pituitary-Adrenal Axis

In order to survive, an animal must be able to respond to stressors, an internal or external cue that disrupts the homeostatic status of the animal (Aguilera, 2011). The stress response enables the "fight-or-flight" reaction and is highly adaptive in the short term, although it may become maladaptive in the long term.

The neuroendocrine system involved in mediating the stress response is the hypothalamic–pituitary–adrenal (HPA) axis. As summarized in Table 38.1, the hypothalamic releasing hormone controlling this axis is corticotropin-releasing hormone (CRH), produced in highest levels in the medial parvocellular part of the paraventricular nucleus (PVN; Fig. 38.3). CRH nerve terminals release this 41–amino acid peptide into the portal vasculature, where CRH targets the corticotropes of the anterior pituitary gland. Additionally, arginine vasopressin (AVP), another hypothalamic hormone produced in the magnocellular elements of the PVN, acts at pituitary corticotropes to exert synergistic effects. The corticotropes have receptors for and respond to both CRH and AVP with the synthesis and release of adrenocorticotropic hormone (ACTH). ACTH is released from the pituitary gland into the general circulation, where it acts at receptors on the adrenal cortex to stimulate the production and release of glucocorticoids. The feedback of glucocorticoids onto the brain and pituitary negatively regulates the synthesis of CRH and ACTH: therefore, this neuroendocrine system is a classical negative feedback loop.

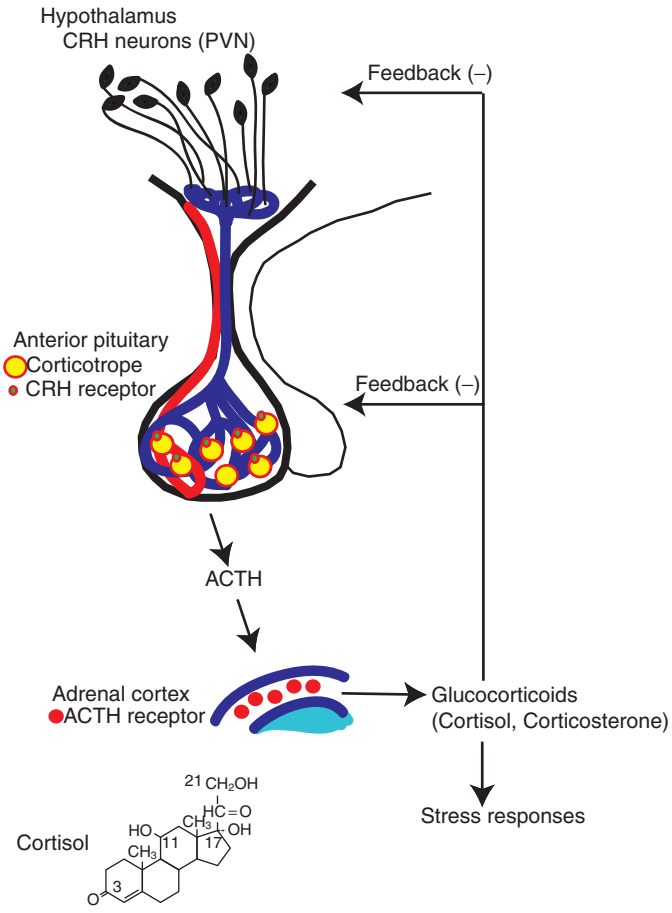

FIGURE 38.3 The hypothalamic–pituitary–adrenal (HPA) stress axis is shown. Hypothalamic CRH neurons in the paraventricular nucleus project their neuroterminals to the external zone of the median eminence. CRH travels through the portal vasculature to cause the synthesis and release of ACTH from corticotropes. This molecule acts at the adrenal cortex to cause the biosynthesis and release of glucocorticoids. These are released into general circulation to mediate the stress response, and they feed back in a negative manner at the corticotropes of the pituitary and the CRH neurons of the PVN (indicated by long arrows). The structure of cortisol, the major glucocorticoid released by the adrenal cortex in humans, is shown (bottom). Abbreviations: CRH: corticotropic-releasing hormone; ACTH: adrenocorticotropic hormone; PVN: paraventricular nucleus.

PHYSIOLOGY

Corticosteroids are necessary for normal fetal development. Enzymes in the liver, gastrointestinal system, lungs, and adrenal medulla are stimulated by glucocorticoids. There, glucocorticoids play important roles in the regulation of glycogen utilization and storage, with glucocorticoids promoting the production of glycogen synthase. The stress axis is subject to developmental and age-related regulation due to changes in afferent connections to the hypothalamus, glucocorticoid and mineralocorticoid receptor-binding changes, and alterations in the negative feedback of glucocorticoids on CRH neurons.

Glucocorticoids exert effects on the cardiovascular system, causing elevations in heart rate and blood pressure and alterations in blood flow. They act in close coordination with the autonomic nervous system to exert their effects. In general, their role is to mobilize energy stores and to improve cardiovascular tone. Glucocorticoids may also modulate immune responses and inhibit cytokine production, thereby playing a role in the inhibition of the inflammatory response. Glucocorticoids can interact with hormones produced by other neuroendocrine axes, such as those involved in thyroid function, reproductive function, and growth (O'Connor, O'Halloran, & Shanahan, 2000).

RELEASE

Stress hormones exhibit both pulsatile and circadian cycles. When the hypothalamic nucleus responsible for circadian rhythms, the SCN, is lesioned, the 24-h pattern of CRH release is obliterated. During the 24-h day, glucocorticoid levels peak during the early morning (~0700 h) and reach a nadir during the afternoon in humans.

Glucocorticoids and their Receptors

Glucocorticoids are members of the steroid hormone family. As is the case for sex steroid hormones (discussed later), they derive from a cholesterol precursor. Following a series of enzymatic reactions, the major corticosteroids, such as cortisol (in humans) or corticosterone (in rats and mice), are synthesized.

The glucocorticoid receptor (GR) is widely distributed in the central nervous system, including the hypothalamus and, more specifically, the CRH cells of the PVN, where cortisol negative feedback can be exerted. GRs are also abundant in the hippocampus, in pyramidal and dentate granule cells. The hippocampus appears to play a role in mediating the stress response, and there are multiple redundant pathways between the hippocampus and the PVN. GRs are found in many other brain regions such as the olfactory cortex, cerebral cortex, amygdala, septum, thalamus, midbrain raphe nuclei, cerebellum, and brainstem (Morimoto, Morita, Ozawa, Yokoyama, & Kawata, 1996). The widespread distribution of this receptor suggests important and diverse effects of glucocorticoids in the central nervous system.

Glucocorticoids can also bind to the mineralocorticoid receptor (MR), the primary ligand of which is aldosterone. Moreover, the brain MR has a higher (~10-fold higher) affinity for glucocorticoids than the GR. Both of these receptors are members of the steroid hormone superfamily. They are thought to reside in the cytoplasm of target cells in the unliganded state. When bound to their ligands, GRs or MRs translocate into the nucleus, where they bind to specific sites on the promoter of the responsive gene. Thus, GR and MR are transcription factors. Their efficacy in stimulating or inhibiting gene transcription is modulated by their binding to other molecules, such as heat shock proteins, which can alter the translocation of the receptor–ligand complex to the nucleus, or transcriptional coactivators, which modulate the complexes associated with the gene.

Glucocorticoids are involved in numerous neural processes, both normal and pathological. Chronic high glucocorticoid exposure may lead to neurodegeneration and eventually cell death. A lack of glucocorticoids can also be detrimental. In the dentate gyrus, maintenance of the dentate granule cell number appears to require glucocorticoids, and adrenalectomy results in the loss of granule cells. Moreover, neurogenesis in the adult dentate gyrus also appears to be glucocorticoid dependent. There are functional correlates to the effects of glucocorticoids on the hippocampus, with these hormones playing roles in learning and memory. Acute stress can interfere with the ability of an organism to learn, and chronic stress is correlated with deficits in spatial learning.

Disruptions in the Stress Axis

The negative feedback loop of CRH–ACTH–glucocorticoids is kept in a delicate balance. In response to stress, there is a large increase in the activity of the stress axis, but the system is downregulated rapidly by negative feedback from the glucocorticoids to the brain and pituitary gland, causing it to return the output of the stress axis to basal low levels.

Overactivity of the stress axis can increase susceptibility to infection and tumors and reduce inflammatory and autoimmune disease (O'Connor et al., 2000). For example, Cushing's disease is characterized by hypercortisolemia and abnormal secretion and/or bioactivity of ACTH. The high levels of cortisol suppress CRH release and cause alterations in immune function. People with Cushing's disease have an increase in appetite and can experience changes in fat distribution.

Underactivity of the stress axis can cause the opposite effects of hyperactivity—namely resistance to infection and tumors but increased susceptibility to inflammatory and autoimmune disease. In the case of adrenocortical insufficiency, there is generally a failure of the adrenal cortex to respond to ACTH. Addison's disease is characterized by an insufficient release of glucocorticoid secretion, and its symptoms include muscle weakness and fatigue, psychological symptoms, gastrointestinal symptoms, and changes in skin pigmentation. Fortunately, glucocorticoid and mineralocorticoid replacement can help mitigate these symptoms.

Hypothalamic Control of Basal Metabolism

Overview, Characteristics, and Physiological Functions of the Hypothalamic-Pituitary-Thyroid Axis

The proper regulation of metabolism is critical for the development and survival of the organism. The

hypothalamic–pituitary–thyroid (HPT) axis plays a critical role in the control of metabolic activity, stimulating an increase in metabolic processes in target cells. The hypothalamic hormone involved in this function is thyrotropin-releasing hormone (TRH; Nillni, 2010), produced by a group of cells in a specific nucleus in the hypothalamus, the paraventricular nucleus, parvocellular compartment (Fig. 38.4). TRH targets receptors on thyrotropes, a subset of cells in the anterior pituitary gland that, when stimulated, produce the thyroid-stimulating hormone (TSH). TSH acts at receptors in the thyroid gland, located in the neck. These cells then produce the thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), the latter being the more potent thyroid hormone, which are released into the general circulation.

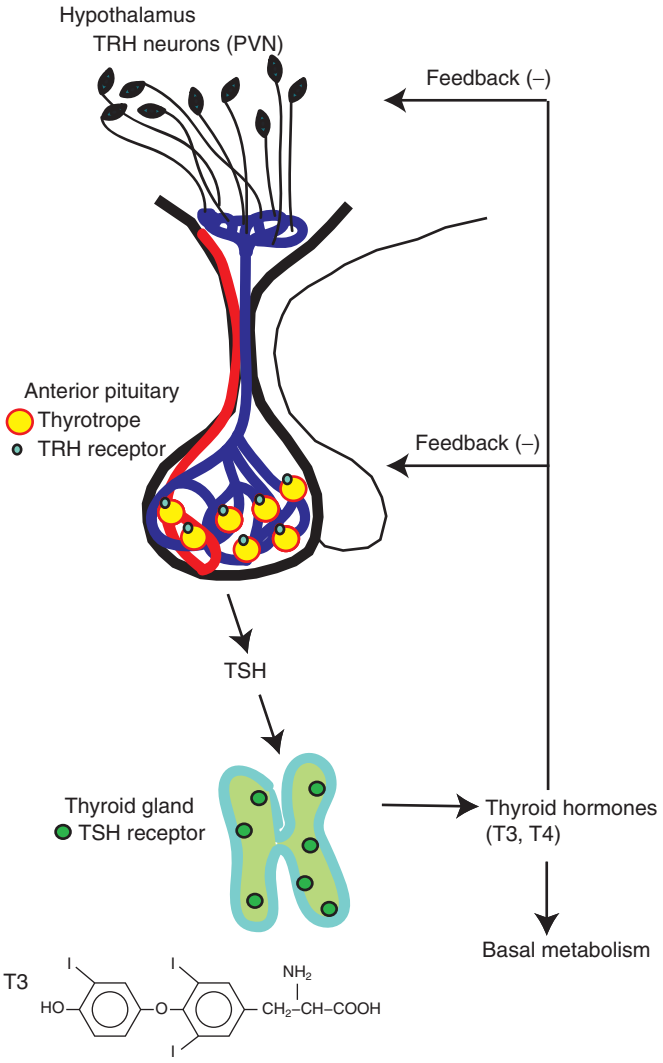

FIGURE 38.4 The hypothalamic–pituitary–thyroid (HPT) axis controlling basal metabolic functions is shown. TRH neurons in the paraventricular nucleus of the hypothalamus project their neuroterminals to the external zone of the median eminence. TRH travels through the portal vasculature to cause the synthesis and release of TSH from thyrotropes. This molecule acts at the thyroid gland to cause the biosynthesis and release of the thyroid hormones, T_3 and T_4. These are released into the general circulation to affect metabolism. Negative feedback of T_3 and T_4 at the thyrotropes of the pituitary and at the TRH neurons of the PVN is indicated by the long arrows. The structure of T_3 is shown (bottom). Abbreviations: TRH: thyrotropin-releasing hormone; TSH: thyroid-stimulating hormone; T_3: triiodothyronine; T_4: tetraiodothyronine or thyroxine; PVN: paraventricular nucleus.

PHYSIOLOGY

Thyroid hormones act at target organs throughout the body to regulate cellular metabolism. T_3 and T_4 also feed back at the brain and anterior pituitary gland to regulate levels of TRH and TSH, respectively. The thyroid hormone axis is a classical negative feedback loop, as thyroid hormone feedback inhibits the secretion of these hypothalamic and pituitary hormones, thereby maintaining appropriate levels of free thyroid hormone in the bloodstream. Such precise regulation of thyroid hormone levels is critically important because elevated or depressed levels of this hormone can have substantial adverse consequences on the body, particularly during sensitive periods of development.

The brain–pituitary–thyroid axis is involved in metabolism, protein synthesis, and development of the brain. Thyroid hormone receptors are located throughout the brain, and they are also found in peripheral and autonomic nervous systems, pituitary gland, bone, muscle, liver, heart, testis, lung, placenta, and other tissues. The major function of the thyroid hormone is the regulation of basal metabolic rate and calorigenic responses. In the target cells, thyroid hormones regulate ATP levels produced by mitochondria and alter protein synthesis. The maintenance of thyroid hormone levels is extremely important for adult metabolic activity, and thyroid hormone abnormalities in the developing organism can have catastrophic consequences. Thyroid hormone deprivation in the fetus causes permanent nervous system abnormalities and substantial adverse effects on growth and bone development that may be reversed or mitigated only if the thyroid hormone is replaced.

Along with its regulation by TSH, the thyroid gland also receives direct neuronal inputs from the autonomic nervous system. Fibers from the sympathetic and parasympathetic nervous systems penetrate the thyroid gland and terminate around arterioles, capillaries, and, less frequently, venules near follicular cells, providing additional mechanisms for regulation of thyroid hormone output.

RELEASE

The pituitary hormone TSH, and presumably the hypothalamic hormone TRH, is released in a pulsatile manner, with pulses occurring at approximately 90- to 180-min intervals in humans (Gore, 1998). Studies on the pulsatile release of TSH in humans demonstrate that its levels also change across the 24-h period, peaking from the evening through 0400 h, decreasing through

noon, and remaining low until the beginning of the next cycle in the evening. The increase in TSH release during the evening is referred to as the nocturnal TSH surge. This appears to be a true circadian rhythm, and it is driven by the suprachiasmatic nucleus of the hypothalamus (see Chapter 39).

It is important to note the terminology of *free* versus *bound* hormone. When the thyroid hormones are released into the circulation from the thyroid gland, a large portion bind to binding globulins. The free (or not protein-bound) thyroid hormone constitutes only <1% of all thyroid hormone circulating in the bloodstream. It is the free thyroid hormone that is responsible for the negative feedback regulation of TRH neurons and thyrotropes, as well as for actions at target tissues. Bound hormone is not immediately bioavailable but may provide a reservoir for thyroid hormones when they are needed.

Thyroid Hormones and Their Receptors

The two major thyroid hormones are T_4 and T_3, which have four or three iodide molecules, respectively (Fig. 38.4). T_3 has greater biological activity. Thyroid hormones contain two phenolic rings, which make these molecules lipophilic, facilitating their transport through the lipophilic membranes of target cells. Some plasma membrane transport molecules assist with this process because the thyroid hormones possess a polar alanine side-chain that appears to impede the process of passive diffusion. Thyroid hormones bind to the thyroid hormone receptors in target tissues. They also mediate negative feedback effects on TRH cells in the hypothalamus and pituitary. Although T_4 is released from the thyroid gland in greater quantities than T_3, most T_4 is converted to T_3, as catalyzed by two enzymes, type I and type II deiodinase. Type I deiodinase is found mostly in peripheral tissues and the pituitary gland, and type II deiodinase is found in the brain, pituitary gland, and brown fat. Because an important component in the synthesis of thyroid hormones is iodine, an iodine-deficient diet results in the impairment of thyroid hormone metabolism, leading to developmental abnormalities or adult dysfunctions.

With respect to the negative feedback regulation by thyroid hormone (Fig. 38.4), thyroid hormone receptors have been localized within TRH neurons in the paraventricular nucleus (Segerson et al., 1987). Thus, these actions can be mediated directly on TRH neurons in the brain. In addition, the expression of the thyroid hormone receptor is abundant in the anterior pituitary gland, particularly thyrotrope cells, indicating direct feedback action of the thyroid hormone on this organ as well.

The thyroid hormone receptor is a member of the nuclear hormone superfamily, with isoforms (α and β) and splice variants, most commonly α1 and β2 in the hypothalamus (Lechan, Qi, Jackson, & Mahdavi, 1994). These are nuclear transcription factors that bind to a regulatory element on the DNA to activate or inhibit gene transcription. Binding of the thyroid hormone to its receptor causes the heterodimerization of the receptors with another member of the nuclear receptor superfamily, RXR, and facilitates the binding of the dimerized receptor-ligand complex to the promoter of the target gene, thereby modulating gene transcription.

Disruptions in the Thyrotropic Axis

Thyroid hormone excess or insufficiency can have profound effects on the central nervous system, particularly during development. Thus, a normal ("euthyroid") tone is necessary for the health and survival of the organism. Excessive thyroid hormone, or hyperthyroidism, can result in symptoms such as tremor, nervousness, tremulousness, insomnia and sleep disorders, and impairments in memory and concentration. More profound effects include neuropsychiatric syndromes, seizure, chorea, and even coma. Deficiencies of the thyroid hormone, called hypothyroidism, can cause problems such as sleep apnea, hypothermia, hypoventilation, neuropsychiatric syndromes, peripheral neuropathy, cerebellar ataxia, and coma. During chronic thyroid hormone deficiency, fluids can accumulate and result in puffiness of the hands, feet, face, and tongue and cause speech impairment. This is called myxedema. Hypothyroidism generally is treated by thyroid hormone replacement.

When an organism is exposed to insufficient thyroid hormone during fetal or early neonatal development, it can develop cretinism, characterized by severe deficits in mental, neurological, and physical development. Most of these deficiencies can be mitigated or even reversed by newborn infant screening and thyroid hormone replacement.

Hypothalamic Control of Growth

Overview, Characteristics, and Physiological Functions of the Hypothalamic-Somatotropic Axis

The somatotropic axis controlling body growth has three levels: the primary hypothalamic hormones, of which there are two, growth hormone-releasing hormone (GHRH) and a growth hormone-inhibiting hormone, called somatostatin; the secondary pituitary hormone, called growth hormone (GH) or somatotropin; and the tertiary target organ—in this case the liver—which produces insulin-like growth factor I (IGF-I) in response to the GH stimulus (Fig. 38.5). A special characteristic of the somatotropic axis is that both its pituitary hormone, GH, as well as GH's target hormone, IGF-I, can exert growth-promoting effects alone or in combination. In fact, GH and IGF-I act synergistically with each other to affect somatic growth. However, both of these hormones play important roles, as mutations

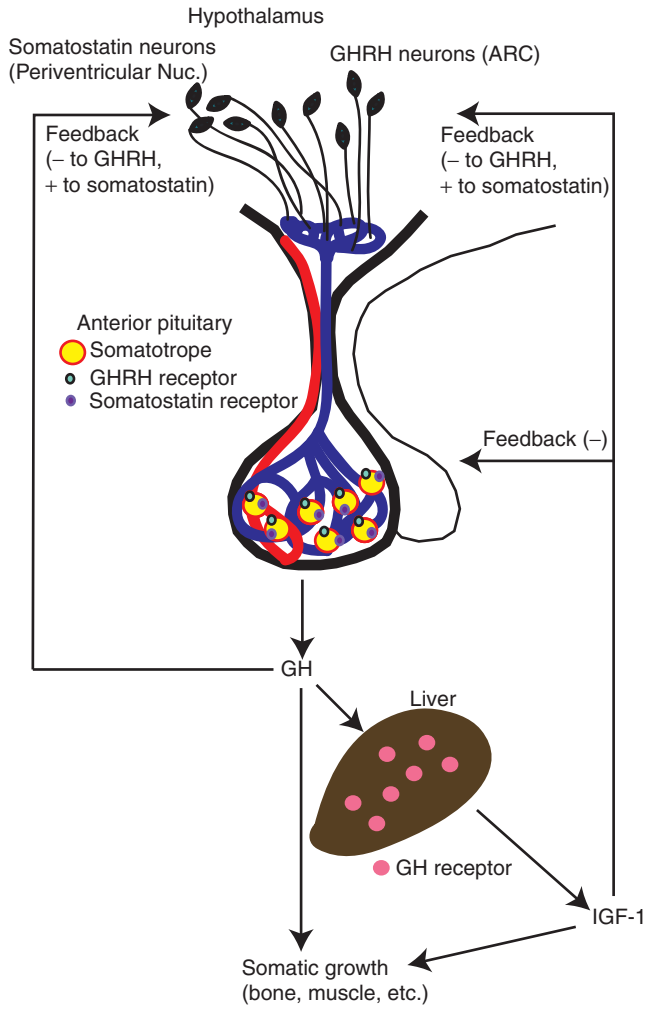

FIGURE 38.5 The hypothalamic control of somatic growth is shown. GHRH neurons in the arcuate nucleus, and somatostatin neurons in the periventricular region of the anterior hypothalamus, provide the stimulatory and inhibitory inputs to pituitary somatotropes, respectively (via the portal capillary vasculature). The synthesis and release of GH is stimulated (GHRH) or inhibited (somatostatin) at the somatotropes. This molecule acts at the liver to cause the biosynthesis and release of IGF-I. Both GH and IGF-I are released into the general circulation to affect somatic growth, and they both feed back negatively at the somatotropes of the pituitary and the GHRH neurons of the arcuate nucleus. IGF-I and growth hormone also feed back to stimulate somatostatin. Abbreviations: ARC, arcuate nucleus; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor I.

resulting in the absence of GH, IGF-I, or their receptors result in dwarfism.

Unlike most other neuroendocrine systems, the somatotropic axis has two known hypothalamic hormones that play important but opposing roles (Fig. 38.5). One hormone, GHRH, is stimulatory to the release of the pituitary GH. GHRH somata are localized in the arcuate nucleus of the hypothalamus. The other hypothalamic hormone, somatostatin, inhibits GH release. Perikarya of the somatostatin neurons involved in the regulation of growth hormone release are found primarily in the periventricular region of the anterior hypothalamus. Although arising from different sources, these hormones are both released into the portal capillary vasculature to affect the synthesis and release of GH, from specialized cells in the anterior pituitary gland called somatotropes, constituting approximately 30% of pituitary cells. The GH binds to its receptors in the liver to stimulate the release of the tertiary hormone, IGF-I. Both GH and IGF-I have somatotropic actions on target organs and tissues undergoing growth, regeneration, or metabolic homeostasis, such as bone and muscle.

PHYSIOLOGY

GH plays its major role in neonatal and postnatal growth and is particularly important in the pubertal growth spurt. Its anabolic activities are critical for metabolic homeostasis. The growth hormone stimulates protein synthesis, influences carbohydrate metabolism, enhances glucose uptake and utilization, and has lipolytic effects. At the systems level, it stimulates the growth of organs, such as the heart and kidney, and plays a role in hormone production, skeletal growth and maturation, and immune function. Many of its effects are sexually dimorphic, as are the distribution of its receptors and other proteins involved in this axis.

Growth hormone and IGF-I are both involved in the feedback regulation of the somatotropic axis (Fig. 38.5). In the case of GHRH, GH acts as a classical negative feedback molecule, downregulating the synthesis and secretion of GHRH. By contrast, GH *stimulates* gene expression of the inhibitory hypothalamic hormone somatostatin. In the absence of GH, somatostatin mRNA levels are downregulated. IGF-I also acts as a feedback regulator of the somatotropic axis, negatively regulating GHRH levels and stimulating somatostatin gene expression.

RELEASE

Patterns of somatotropic hormones are similar to those for other neuroendocrine systems. Both GHRH and somatostatin are released from hypothalamic nerve terminals into the portal circulation in a pulsatile manner, similar to other neurohormones. Importantly, the growth hormone is released in a strongly diurnal pattern and its release is associated with sleep, with highest levels occurring shortly after the onset of slow-wave sleep, and most GH secretion occurring at night in humans.

Growth Hormone, IGF-I, Binding Proteins, and Receptors

GROWTH HORMONE

Growth hormone, or somatotropin, is a 191–amino acid protein that contains two disulfide bonds that give it a

three-dimensional conformation that is necessary for its biological activity. Release of the growth hormone is triggered by GHRH and is inhibited by somatostatin. The growth hormone plays a negative feedback role in the somatotropic axis, feeding back at the level of the GHRH neuron in the hypothalamus to inhibit GHRH mRNA levels and synthesis and stimulating somatostatin gene expression and release. Not only does the regulation of growth hormone involve the balance between GHRH and somatostatin, but it also involves other neurotransmitters and neuroactive substances, such as dopamine, vasoactive intestinal peptide, pituitary adenylate cyclase-activating peptide, TRH, galanin, neuropeptide Y, motilin, and interleukins. In addition, other hormones, such as the thyroid hormone, glucocorticoids, sex steroid hormones, and metabolic fuels, can influence the release of growth hormone, highlighting the interwoven nature of the different neuroendocrine systems.

The growth hormone is released into the general circulation, where approximately 50% of this molecule is transported in association with a growth hormone–binding protein that is structurally similar to the extracellular domain of the growth hormone receptor. This molecule and the growth hormone receptor (GH-R) are alternative splice products of the same precursor RNA: one encoding the growth hormone–binding protein and the other the GH-R.

IGF-I

A major target for the growth hormone is the IGF-I system. IGF-I is a growth factor that exerts effects on neurite outgrowth and nervous system development. In addition, it is an important mediator of the somatotropic axis and, in fact, was originally referred to as somatomedin. Both GH and IGF-I individually have similar effects on somatic growth and development; however, the two hormones act much more efficiently in combination. In addition, it appears that the growth-promoting effects of IGF-I are particularly important in the central nervous system. This is consistent with the observation that along with its production by the liver, IGF-I is also produced in the brain, and it is probably this central IGF-I that is responsible for many of its neurotrophic effects.

Like the growth hormone, IGF-I plays a feedback role in the inhibition of GHRH biosynthesis (Fig. 38.5). This may involve central and not peripheral IGF-I, as most animal studies have demonstrated that only centrally but not peripherally administered IGF-I has this effect. At the level of the pituitary, IGF-I appears to be the major regulator of negative feedback of growth hormone synthesis and release. Somatotropes contain IGF-I receptors, and IGF-I inhibits growth hormone gene expression and release under basal and GHRH-stimulated conditions. IGF-I can also act as a negative feedback regulator of GHRH neurons, as it can cross the blood–brain barrier to a limited extent. Moreover, IGF-I is synthesized in the central nervous system, including the hypothalamus, and therefore local IGF-I can exert an influence on GHRH neurons. It also has been shown that IGF-I can stimulate somatostatin release, albeit at higher doses than those necessary to inhibit GHRH release, suggesting that IGF-I may be more involved in the suppression of GHRH than the enhancement of somatostatin levels.

IGF-I in the circulation binds to several binding proteins, the major one being IGF-I binding protein 3 (IGFBP-3). Free IGF-I is more biologically active than bound IGF-I, and therefore IGFBP-3 levels are an important regulator of the actions of IGF-I.

Disruptions of the Somatotropic Axis

Somatic growth and development are affected by disruptions of the somatotropic axis, and the consequences are dependent on when during development the system is affected. In early development, growth hormone deficiency can result in an extremely short stature, with adults sometimes reaching a maximal height of less than 1 m. Growth hormone deficiency is generally treated with growth hormone replacement using recombinant growth hormone. In some cases, GHRH, rather than growth hormone, is replaced in a pulsatile manner. Dwarfism is sometimes caused by mutations in the IGF-I system, or in the GH receptor. Laron dwarfism, characterized by mutations in the GH receptor gene, results in very low IGF-I levels, but GH levels are high, probably due to reduced negative feedback from the low IGF-I concentrations.

If GH is oversecreted or dysregulated during development, the consequence can be gigantism, resulting in an extremely large stature. When abnormal GH stimulation occurs after adulthood, this results in acromegaly. In adulthood, only certain tissues remain responsive to growth hormone stimulation, including the jaws, nose, orbital ridges, fingers, elbows, and knees, and these tissues are stimulated to grow, while other tissues are not, causing deformations in proportions and appearance.

Hypothalamic Control of Reproduction

Overview, Characteristics, and Physiological Function of the Hypothalamic-Pituitary-Gonadal Axis

Reproduction is critical to the survival of the species. In vertebrate organisms, the hypothalamic-pituitary-gonadal (HPG) axis hierarchical organization includes (1) the gonadotropin-releasing hormone (GnRH) neurons of the hypothalamus and preoptic area; (2) the gonadotropes of the anterior pituitary gland; and (3) the gonads (ovary in females and testis in males) (Fig. 38.6). The GnRH peptide, cell bodies of which are localized in the preoptic area and mediobasal hypothalamus, is released

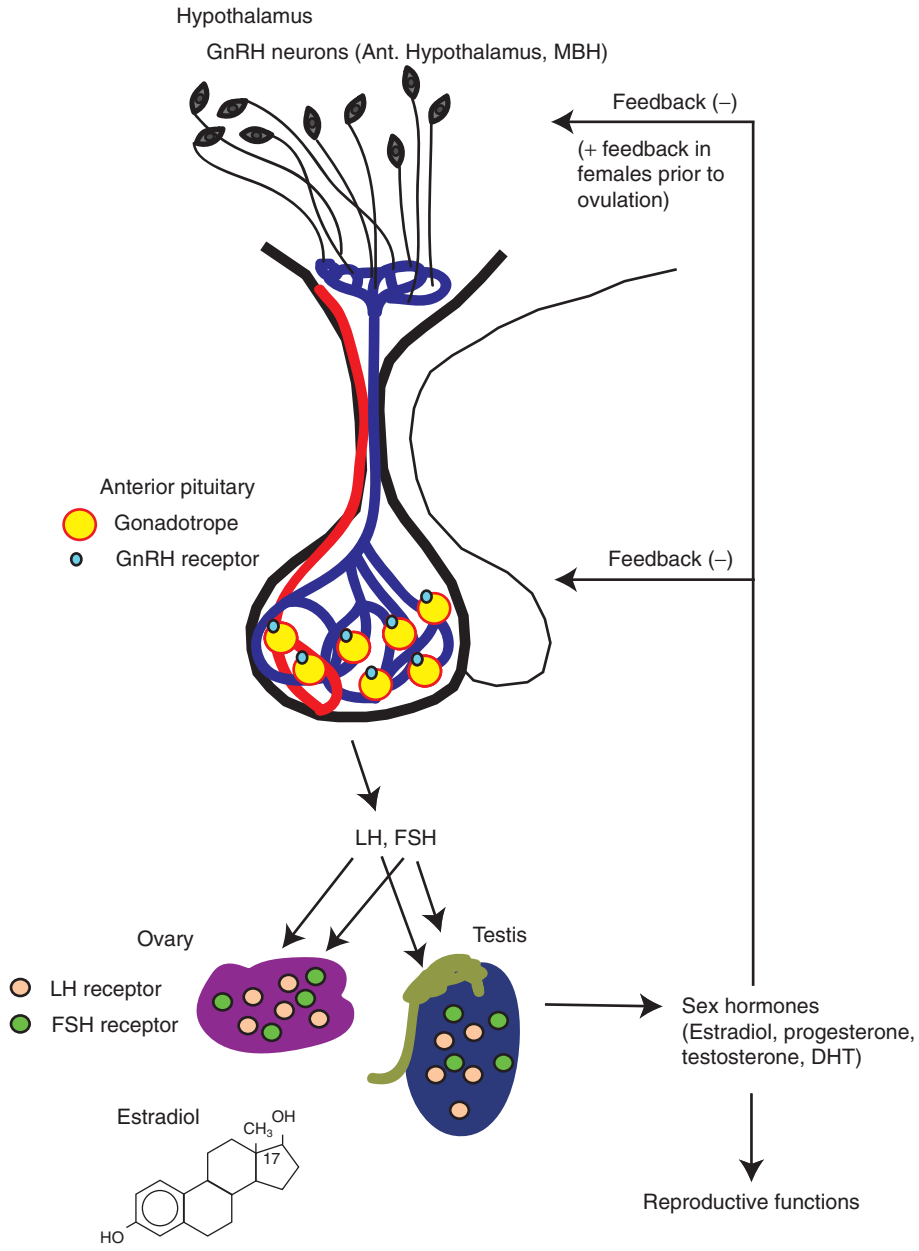

FIGURE 38.6 The hypothalamic–pituitary–gonadal axis controlling reproduction is shown. GnRH neurons in the preoptic area/anterior hypothalamus (rodents) or basal hypothalamus (primates) project their neuroterminals to the external zone of the median eminence. GnRH travels through the portal vasculature to cause the synthesis and release of the gonadotropins, LH and FSH, from gonadotropes of the anterior pituitary. These molecules act at the gonads (ovary and testis) to cause the biosynthesis and release of sex steroid hormones. These are released into general circulation to affect secondary sex characteristics and act at other somatic tissues. Sex steroid hormones feed back negatively at the brain and pituitary to regulate biosynthesis of GnRH and the gonadotropins in males and females. In addition, prior to ovulation, these steroids exert positive feedback in females. The structure of estradiol is shown (bottom). Abbreviations: FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; MBH, medial basal hypothalamus.

from neuroterminals in the median eminence in a pulsatile manner, acting upon the pituitary gonadotropes to cause pulsatile release of the pituitary gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These hormones in turn bind to receptors on specialized cells in the ovaries or testes to stimulate steroidogenesis, spermatogenesis in males, and oogenesis in females. The gonads of both sexes respond to this activation by synthesizing and secreting the sex steroid hormones, estrogens, progestins, and androgens. Although the dominant steroid hormones produced by the ovaries are estrogens and progestins, ovaries also produce appreciable amounts of androgens. The testes produce androgens at higher levels than females, but they also secrete estrogens and progestins. Thus, there is no such thing as a "male" or "female" sex steroid hormone. Rather, what differs between the sexes are the concentrations of these hormones.

Unlike other neuroendocrine cells, GnRH neurons of most vertebrates have an unusual embryonic origin, deriving from cells that are first detected in the olfactory placode (Wray, 2001). During embryonic development, GnRH neurons migrate into the brain, reaching their final destinations in the preoptic area and hypothalamic regions during mid- to late embryogenesis. Also, unlike most other neuroendocrine peptide systems, GnRH neurons are relatively scattered through these regions and are not tightly concentrated in a single discrete nucleus.

GnRH neurons are functionally regulated by numerous neurotransmitters and neurotrophic factors, and this is probably related to the integrative nature of the GnRH neuron (Gore, 2002). In order for reproduction to be successful, the organism must be able to assess the conditions of internal and external environment to determine that conditions are optimal. The numerous inputs to GnRH neurons from other sensory and neuroendocrine cells enables these key reproductive neurons to evaluate the organism's health and fitness and the external conditions (e.g., season, food availability, the presence of predators or a conspecific mate) and to coordinate the timing of reproduction, which is quite costly, with the optimal external and internal circumstances. Thus, GnRH cells are regulated by inputs from neurotransmitters such as glutamate, GABA, catecholamines and monoamines, neuropeptides such as kisspeptin, CRH, β-endorphin, vasopressin, neurotensin, neurotrophic factors, and many other substances. In this way, GnRH neurons receive cues regarding nutritional status, thermogenesis and exercise, stress, and social cues and can integrate these inputs to coordinate the timing of reproduction with the appropriate stimuli.

PHYSIOLOGY

The sex steroid hormones, once released into the circulatory system, act at receptors that are located throughout the body to exert their classical effects on secondary sex characteristic development and on adult reproductive function. In addition, sex steroid hormones act on receptors in the brain, including the hypothalamus, to exert diverse effects on the CNS. One of the major effects of sex steroid hormones is as a feedback modulator of the hypothalamic GnRH neurons. However, along with the traditional negative feedback exerted in neuroendocrine systems, in females, ovulation is controlled by *positive* feedback from sex steroid hormones. This concept of negative/positive feedback regulation is discussed later, and is unique to the reproductive neuroendocrine system of females.

Not surprisingly, functions of the reproductive axis change during the life cycle of the organism, as reproductive function varies with developmental stage (Plant, 1988). During the late embryonic/early postnatal period, as the GnRH system finishes its neuroanatomical development, there is increased activity of the brain–pituitary–testicular axis in males and, to a lesser extent, the brain–pituitary–ovarian axis in females. Shortly after birth, the reproductive system becomes quiescent, possibly due to the development of inhibitory inputs to GnRH neurons or the lack of stimulatory inputs to this system. This quiescent period, sometimes called the "prepubertal hiatus," is characterized by low GnRH, gonadotropin, and steroid hormone release.

At the onset of puberty, the GnRH system becomes activated, probably due to the removal of inhibitory afferents to GnRH neurons and the increasing dominance of excitatory inputs. Although the neural circuits controlling GnRH are complex, pharmacological studies suggest that the major inhibitory neurotransmitters putting the brake on GnRH prior to puberty are GABA and, to a lesser extent, endogenous opioid peptides and melatonin. As this inhibitory influence wanes, inputs from excitatory neurotransmitters begin to dominate, resulting in increased GnRH release. To date, numerous substances have been implicated in the activation of GnRH neurons at the onset of puberty, including glutamate (through both NMDA and non-NMDA glutamatergic receptors), kisspeptin, norepinephrine, and growth factors such as transforming growth factor-α and IGF-I. Once mature reproductive function has been attained (ovulation in females, viable sperm in ejaculates of males), the pulsatile release of GnRH and its regulation of the reproductive axis continues for much of the life cycle. In many species, females exhibit reproductive cycles (estrous cycles, menstrual cycles) of varying lengths, such as the 4-day estrous cycles of small rodents and the 28-day menstrual cycles of humans and many nonhuman primates.

Many species are sexually active during certain periods of the year, and as infrequently as once per year or even less. This seasonality enables organisms to coordinate the energetically demanding process of pregnancy, lactation, and rearing of the offspring with the appropriate environmental conditions. Seasonal breeding animals such as sheep have an almost completely inactive reproductive axis during the nonbreeding season, with very low GnRH release, low basal and GnRH-stimulated gonadotropin release, and a lack of ovulation. In many of these species, day length is what drives the seasonal breeding cycles, although this varies among the species. For hamsters, short nights stimulate the reproductive system, whereas short nights inhibit the reproductive axes of sheep. Males of some species undergo a process of testicular regression and recrudescence in coordination with the season. The pineal hormone melatonin appears to be critical to the coordination of reproduction with the season (Revel, Masson-Pevet, Pevet, Mikkelsen, & Simonneaux, 2009). It has been proposed that a "photoneuroendocrine" system exists whereby melatonin conveys signals about day length to the HPG axis, a process that involves input from the SCN (see Chapter 39) and convergence onto neurons that regulate GnRH release (Revel et al., 2009).

In human females but not most other species, menopause, the cessation of menstrual cycles and lack of ovulation, signals the end of the reproductive life cycle. The most obvious characteristic of menopause is a loss of ovarian follicles, called follicular atresia. Although many other mammals undergo reproductive senescence,

characterized by a lack of spontaneous reproductive cycles, this is not always due to follicular atresia. Instead, in these species, such as rodents, reproductive senescence is probably due to the loss of drive from hypothalamic GnRH neurons and/or changes in pituitary gonadotropin responses to GnRH rather than overt ovarian changes. In humans, it is quite possible that there are also hypothalamic and pituitary changes that may play a role in the menopausal process that are only just beginning to be understood.

RELEASE

A pulsatile manner of GnRH release is necessary for the maintenance of pituitary gonadotropin function. The pulsatile release of GnRH is more or less constant in males, with pulses occurring approximately every 1–2 h. However, in females, the nature of GnRH pulses varies across the reproductive cycle. In primates that have a 28-day menstrual cycle, LH pulses (measured as proxy for GnRH pulses) occur approximately once per hour during the early follicular phase, but slow to a frequency of once every 90 min later in the follicular phase as estrogen negative feedback increases. Just prior to ovulation, a large increase in GnRH release can be measured, although it is still controversial whether discrete pulses continue to be superimposed on this "GnRH surge." Nevertheless, it is likely that there is a change in the mode of GnRH release during the preovulatory period.

The pulsatile release pattern of GnRH, LH, and FSH is superimposed upon a diurnal pattern of the release of these hormones (Gore, 1998). Thus, the timing of the preovulatory LH surge in rodents is coordinated with the 24-h light/dark cycle (i.e., it is a diurnal but not a circadian rhythm). Although in women these diurnal rhythms are not as obvious as those in rats, it appears that the release of gonadotropins has a weak diurnal rhythm in humans. Men have also been reported to have nocturnal increases in reproductive hormone release.

Gonadal Steroid Hormones and Their Receptors

Sex steroid hormones are synthesized from the precursor cholesterol in a multistep process. Cholesterol first is converted to pregnenolone, which is converted to progesterone. This hormone is a major end point for biosynthesis in gonadal tissues and exerts potent effects on the body and brain. Progesterone serves as a precursor for the synthesis of testosterone following conversion first to 17α-hydroxyprogesterone and then androstenedione. Testosterone is the dominant steroid hormone in males, although it is also found in females. It serves as a precursor via the enzyme 5α-reductase for 5α-dihydrotestosterone, which is responsible for many of the masculinizing effects of steroids in males. Testosterone is also the direct precursor via the enzyme p450 aromatase for 17β-estradiol, which is the primary estrogen responsible for sexual behavior and physiology in females, and which also plays roles in masculine physiology and behavior. The sex steroid hormones bind to their receptors, members of the nuclear hormone superfamily. The binding of a steroid hormone to its receptor, and subsequent receptor dimerization, allows these transcription factors to bind to specific sites on the promoter of the target gene, called androgen-response elements (AREs), estrogen-response elements (EREs), and progesterone-response elements (PREs). This enables the receptor-ligand complexes to induce or repress gene transcription in their target tissues.

Sex steroid hormones are synthesized and secreted from the ovaries or testes to regulate the expression of secondary sex characteristics and to maintain adult reproductive function. In the Leydig cells of the testis, LH released from the pituitary gland is responsible for testosterone biosynthesis. Together with FSH, testosterone acts to coordinate and stimulate spermatogenesis in testicular seminiferous tubules. The testosterone that is released from the testis acts at secondary sex targets such as the internal and external genitalia (prostate, seminal vesicles, penis) to cause their development and maintain their functions. In addition, testosterone acts at muscle to increase muscle mass, causes the growth of facial and body hair, and enlarges the epiglottis, which is responsible for the deepening of the voice. In the ovary, FSH stimulates follicular development during each ovarian cycle, and LH is the primary stimulator of ovulation. Steroidogenesis in the ovary is also stimulated by FSH and LH. The resulting ovarian hormones, primarily 17β-estradiol and progesterone, are responsible for the development of female secondary sex characteristics such as the genitalia and mammary tissue.

Sex steroid hormone feedback in the male is accomplished by the usual neuroendocrine negative feedback mechanism (Fig. 38.6). Pulses of GnRH cause pulses of the gonadotropins, which in turn are responsible for pulses of testosterone. Feedback of testosterone onto the brain causes an inhibition of hypothalamic GnRH neurons, and testosterone also feeds back negatively onto the pituitary gonadotropes. At the pituitary gland, sex steroid hormones appear to act primarily to decrease the sensitivity of pituitary gonadotropes to GnRH, resulting in a decrease in LH pulse amplitude.

In the female, the ovarian steroid hormones estradiol and progesterone can act at the hypothalamus to provide negative feedback. During most of the reproductive cycle, these hormones feed back at the brain and the pituitary gland to suppress the release of GnRH and the gonadotropins, respectively. However, during the

mid- to late follicular stage in primates, or on the day of proestrus in rats with a four-to five-day estrous cycle, feedback effects of estrogens on GnRH release become positive. The stimulatory effects of estradiol on the hypothalamus result in the occurrence of the "preovulatory GnRH surge," which in turn triggers a preovulatory LH surge that triggers the final maturation of the ovum in the follicle and results in ovulation and the subsequent development of the corpus luteum. After ovulation, feedback of ovarian steroid hormones upon the hypothalamus and pituitary reverts to the negative mode until the next cycle.

Unlike the other neuroendocrine systems, the primary feedback site of gonadal steroid hormones does not appear to be the GnRH neurons. Although GnRH neurons express the ERβ, they do not express appreciable levels of ERα, androgen receptors (AR), or progesterone receptors (PR). Therefore, it is thought that other neural cells that make afferent inputs to GnRH neurons, and which express nuclear sex steroid receptors, may mediate effects of sex steroid feedback onto GnRH cells. The mediation of gonadal steroid feedback by intermediary cells in the CNS, primarily those expressing the ERα, may also help to explain the "switch" between negative and positive feedback onto the GnRH neurons in females (Wintermantel et al., 2006). For example, some afferent inputs to GnRH neurons that inhibit GnRH release may exert a dominant tone during most of the reproductive cycle and be responsible for negative feedback. Other afferent inputs that stimulate GnRH release may be regulated by higher levels of estrogens and underlie the positive feedback response to ovarian steroids that results in the preovulatory GnRH surge.

Disruptions in the Reproductive Axis

Mutations to the GnRH or GnRH receptor genes result in failure to undergo reproductive development and to attain normal adult maturation. More recently, mutations in other hypothalamic neurons that converge upon GnRH neurons have been associated with partial or incomplete reproductive capacity. Of these, kisspeptin and its receptor (GPR54) are particularly important, and emerging evidence shows that the ligands and receptors involved in fibroblast growth factor, neurokinin B, prokineticin, and other parts of the neural circuitry controlling GnRH release are involved (Caronia et al., 2011).

Other defects of the reproductive system involve the timing of the onset of puberty. In idiopathic central precocious puberty, GnRH is released far earlier than is normal. This results in activation of the release of pituitary gonadotropins, stimulation of the gonads, and the early development of secondary sexual characteristics. Treatment with long-lasting GnRH agonists, which initially stimulate but rapidly downregulate pituitary GnRH receptors, cause a downregulation of the reproductive axis and can halt pubertal development until the normal timing of puberty occurs. In the case of delayed puberty, the normal pubertal release of GnRH does not occur, and exogenous GnRH can be infused in a pulsatile manner to cause the stimulation of puberty in these individuals.

Hypothalamic Control of Lactation

Overview, Characteristics, and Physiology of the Hypothalamic-Lactational Axis

The pituitary hormone prolactin is a major regulator of lactation in mammals (Grattan & Kokay, 2008). However, unlike the other pituitary hormones, a unique releasing neuropeptide hormone for prolactin has not been identified in the hypothalamus, although there is a prolactin-inhibiting factor, dopamine (Fig. 38.7). Prolactin is synthesized in pituitary cells called lactotropes. Its release

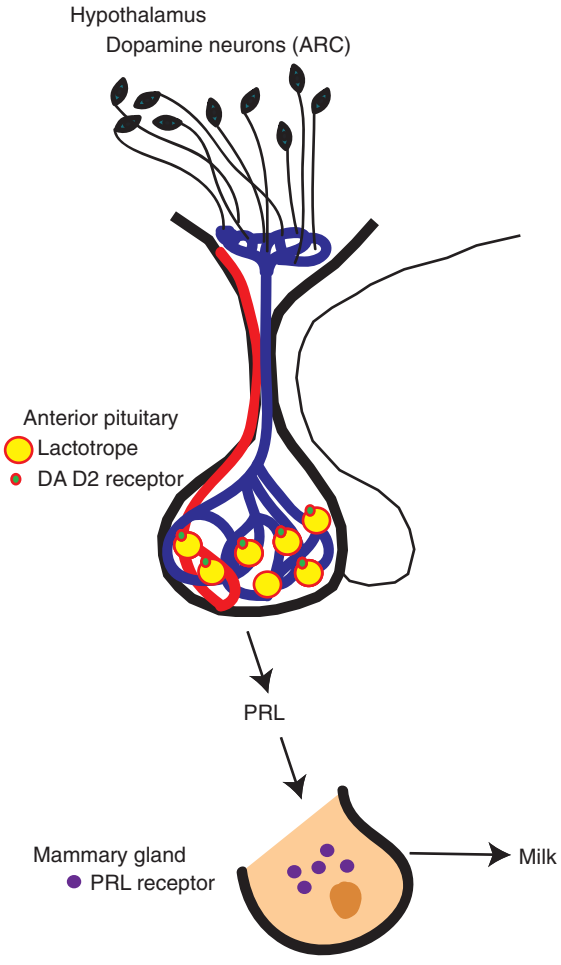

FIGURE 38.7 The hypothalamic control of lactation is depicted. Hypothalamic cells in the arcuate nucleus release dopamine into the portal capillary vasculature. The dopamine exerts negative regulation of prolactin release under most circumstances, via inhibitory D2 receptors. During lactation this inhibition is relieved and prolactin is released from the lactotropes of the anterior pituitary gland. Abbreviations: ARC, arcuate nucleus; DA, dopamine; PRL, prolactin.

into the circulatory system from the anterior pituitary gland causes milk synthesis and secretion into the alveoli of the mammary glands in response to the suckling stimulus. Prolactin, together with oxytocin, which is involved in milk ejection (see later), is responsible for the maintenance of lactation.

It is generally accepted that hypothalamic dopamine plays a major role in the inhibition of prolactin release, and dopamine is the major prolactin-inhibiting factor (Ben-Jonathan, Arbogast, & Hyde, 1989). Dopamine is abundant in the hypothalamus and is found in high concentrations in the median eminence, where it acts as an endocrine hormone to influence the function of the anterior pituitary gland via the portal capillary system. Dopamine receptors are present on pituitary lactotropes, and changes in dopamine concentrations in the portal capillary system correlate with changes in prolactin release under physiological conditions. The major hypothalamic population of dopamine neurons believed to regulate prolactin release is called the tuberoinfundibular dopaminergic system, also referred to as the A12 cell group. Their perikarya lie in the arcuate nucleus.

Regarding the stimulation of prolactin release by a hypothalamic factor(s), though many molecules have been proposed, none appears to be a unique prolactin-releasing hormone. TRH, vasoactive intestinal polypeptide, and oxytocin can stimulate prolactin release but they do not appear to have the one-to-one relationship between a true hypothalamic releasing factor and its adenohypophysial hormone. Thus, the search for a unique hypothalamic-releasing hormone for prolactin is ongoing.

PHYSIOLOGY

The release of prolactin varies by age, sex, and reproductive status. Levels of prolactin are higher in females than males, probably due to the higher estrogen levels in females, which stimulate prolactin release. During reproductive cycles in females, prolactin levels vary, with levels being higher during the luteal (postovulatory) than the follicular (preovulatory) phase in humans. In rats, prolactin levels peak shortly before the preovulatory LH surge that causes ovulation, a time when estrogen levels are high. Prolactin levels also increase during pregnancy, decrease just before birth, and increase again in response to suckling.

The role of prolactin in lactation is its best-studied and probably most important function. In all mammals, prolactin acts on the mammary gland to prepare and maintain its secretory activity. It causes the growth of ductal and lobuloalveolar tissues and causes increases in mRNA levels and translation of the milk protein, casein. Prolactin release is stimulated directly by suckling and results in the synthesis of milk. In addition, there is a relationship between suckling and the inhibition of reproductive function, as suckling can delay implantation of fetuses conceived during a postpartum estrus or cause long periods of anovulation. Prolactin may also play a role in maternal behavior, although this is not well understood.

Prolactin can influence the reproductive axis through its actions on the ovary. There, prolactin causes increases in LH receptors in the corpus luteum, progesterone synthesis by the corpus luteum, and high- and low-density lipoprotein binding in membranes of the corpus luteum. These functions may be related to uterine endometrial development and implantation of the blastocyst in rats, although it is not clear if this is the case in humans. Other functions of prolactin include osmoregulation, primarily in fish and amphibians.

RELEASE

Like the other pituitary hormones, prolactin is released from the anterior pituitary in a pulsatile manner. It has a diurnal rhythm, as it is driven by sleep cues rather than the circadian clock, similar to its related hormone, growth hormone (Gore, 1998).

Disruptions in the Prolactin System

Hyperprolactinemia is a pathological elevation in the secretion of prolactin. This is a common human pituitary disorder and can be a result of disrupted dopamine transmission, which normally would suppress prolactin release. Hyperprolactinemia can also result from pituitary adenomas that secrete prolactin. As a result of hyperprolactinemia, inappropriate lactation can occur, as can be the case with drugs that affect the dopamine system (neuroleptics, dopamine receptor blockers, antidepressants, antihypertensives, oral contraceptives). This syndrome can occur in both males and females.

HYPOTHALAMIC CONTROL OF POSTERIOR PITUITARY HORMONES AND THEIR REGULATED FUNCTIONS

Although the major focus of this chapter is the neuroendocrine regulation of anterior pituitary function, it is important to introduce the neuroendocrine control of neurohypophysial function. The posterior pituitary releases two major neurohormones, oxytocin and vasopressin (referred to here as arginine vasopressin or AVP; also called anti-diuretic hormone or ADH). The hypothalamic-neurohypophysial AVP and oxytocin neurons have large cell somata that are 20–40 μm in diameter, and are referred to as magnocellular neurons (as opposed to their parvocellular counterparts of 10–15 μm). These cells are localized in the supraoptic nucleus (SON), comprised entirely of magnocellular neurons; and the paraventricular nucleus (PVN), which has both magnocellular and parvocellular divisions (Burbach, van Schaick, de Bree, Lopes da Silva, & Adan, 1995). The hypothalamic-neurohypophysial somata

in the SON and PVN project axons that traverse the pituitary stalk and terminate in the posterior pituitary gland (Fig. 38.8). These axon terminals are abundant in secretory granules storing oxytocin or AVP, and in response to depolarization of their cell bodies, release these neuropeptides into general circulation.

PHYSIOLOGY

AVP and oxytocin have numerous functions in the brain and body, and a brief discussion of their diverse neuroendocrine-neurohypophysial functions is provided here (Burbach, Luckman, Murphy, & Gainer, 2001). One of AVP's critical roles is salt and water balance (Frank & Landgraf, 2008; see Chapter 37). In mammalian systems, changes in osmolality of extracellular fluids alter secretion of AVP, and to a lesser extent oxytocin, which can regulate salt and water intake through actions on kidney tubules and by exerting behavioral effects on drinking and salt appetite. AVP plays a further role as a vasoconstrictor in response to hemorrhage. As discussed earlier, AVP also is involved in the regulation of the stress response. Some of these effects may be mediated through transport of AVP to pituitary corticotropes via the portal capillary vasculature leading to the anterior pituitary gland. In addition, neurohypophysial actions of AVP on osmolality may indirectly modulate the brain–pituitary–adrenal axis.

Oxytocin is best known for its roles related to parturition and milk ejection in mammals (Russell, Leng, & Douglas, 2003). Oxytocin is important for uterine contraction during delivery. With regard to lactation, oxytocin responds to the suckling stimulus by stimulating contraction of the cells around the alveoli of the mammary gland to stimulate milk ejection. Oxytocin, together with AVP, plays key roles in social behaviors related to successful reproduction, such as maternal and paternal behaviors and pair bonding (Lim & Young, 2006).

RELEASE

An obvious difference between the neurophysial and adenohypophysial systems is that the former is a direct neural link between hypothalamus and pituitary, whereas the latter is mediated by the portal capillary vasculature. The neural innervation of posterior pituitary enables much more rapid regulation, triggered by changes in blood osmolarity (AVP) or the suckling stimulus (oxytocin), processes that require immediate responses.

GENES

The oxytocin and AVP are 9-amino acid neuropeptides synthesized from genes localized on the same chromosome, but they are in a "head to head" organization separated by a domain called the intergenic region. Therefore, these genes are transcribed in opposite directions (Fig. 38.8; Young & Gainer, 2003). The AVP

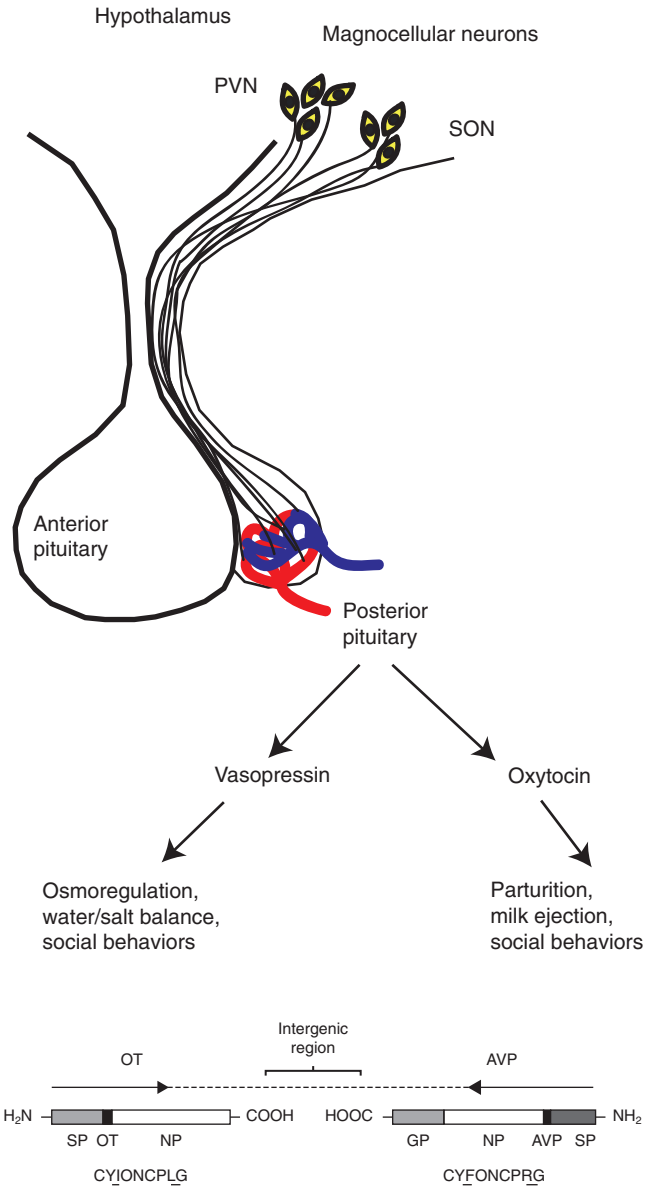

FIGURE 38.8 The hypothalamic-neurohypophysial control of vasopressin and oxytocin release is shown (top). Large cells (magnocellular) in the paraventricular and supraoptic nuclei synthesize vasopressin or oxytocin, which are transported by axonal transport into nerve terminals located in the posterior pituitary gland (neurohypophysis). When stimulated by depolarization, vasopressin and/or oxytocin are released from the posterior pituitary into general circulation. The structural organization of the vasopressin and oxytocin genes are shown (bottom). The RNA sequences are transcribed off of a single gene but in opposite directions, indicated by arrows. Each gene is made up of three exons that encode a signal peptide, the neurohormone (either vasopressin or oxytocin) and a neurophysin that may be involved in chaperoning the neuropeptides. Vasopressin also contains an additional sequence for a glycoprotein. The regions are separated by an intergenic sequence. The nonapeptide sequence of each neurohormone is shown below its respective genes, with differences indicated by underlines. Abbreviations: AVP, arginine vasopressin; GP, glycoprotein; NP, neurophysin; OT, oxytocin; PVN, paraventricular nucleus; SON, supraoptic nucleus; SP, signal peptide. For more information, see Young and Gainer (2003).

and oxytocin genes are structurally similar, comprising three exons that encode a signal peptide, the nonapeptide (either AVP or oxytocin), and a neurophysin whose function is not entirely known but may be involved in chaperoning the neuropeptides as they are processed in secretory vesicles (Fig. 38.8; Burbach et al., 2001).

HORMONES, THE BRAIN, AND BEHAVIOR

Central neuroendocrine control begins in the brain and ends with a target hormone or hormones exerting peripheral actions. At the same time, there is feedback to the CNS to enable adjustments in hypothalamic output. While the mechanisms for these regulatory loops differ from system to system, many of the neuroendocrine systems described above involve actions of steroid hormones on the nervous system. For example, HPG, HPA, and HPT hypothalamic hormones are regulated by gonadal, adrenal, and thyroid hormone feedback, respectively. This underscores the point that there are steroid hormone receptors in the brain mediating these actions of peripheral hormones. Furthermore, beyond the regulation of neuroendocrine physiology, peripheral hormones can also regulate and coordinate the behaviors connected to those physiological functions. The best example of this is the control of reproductive physiology and behavior by the gonadal steroids estrogens, progestins, and androgens. These hormones act upon estrogen receptors (ERs), androgen receptors (ARs), and progesterone receptors (PRs), beginning as early as fetal development (Roselli, Resko, & Stormshak, 2006). All of these receptors are abundant in the hypothalamus, and neuroscientists have begun to look beyond the hypothalamus as a CNS target for steroid hormones, in order to understand how these molecules may mediate or mitigate nonreproductive CNS functions including neuroprotection, synaptic plasticity, neurogenesis, cognition, and neurodegeneration.

Sexual Differentiation of the Brain

The brain is sexually differentiated, with morphological, anatomical, and functional differences between males and females (Schwarz & McCarthy, 2008). In most mammals and many other vertebrates, these differences appear to be established, or "organized," in late gestation and early postnatal life, due to early hormonal exposures. The developing fetus is exposed not only to its own gonadal hormones, but also to maternal and environmental factors, exposures to all of which have permanent effects on brain development, and ultimately, on adult neural and behavioral functions. Recent research suggests that the mechanisms by which hormones sculpt the developing nervous system involve epigenetic actions: nongenomic actions that affect gene regulation independent of changes in the DNA base pair sequence (McCarthy et al., 2009). Perinatal differences in sex steroid hormones act to alter the size of these brain regions such that they differ between males and females; in general, because the fetal testis is much more active than the ovary, testicular hormones are responsible for these neuroanatomical changes. Although it might be predicted that testosterone is responsible for these effects in males, depending upon the brain region, it is often testosterone's metabolite, 17β-estradiol, that is much more potent in many of these actions in mammalian species. Testosterone is a direct precursor to estradiol, metabolized by the P450 aromatase enzyme. This enzyme is found in the hypothalamus, as well as many other brain regions that are steroid sensitive. The perinatal *organizational* effects of testosterone and estradiol are crucial in order for normal sex-specific reproductive physiology and behavior to occur in adulthood. These behaviors also require further actions of gonadal steroid hormones, which are secreted in increasing amounts during the pubertal process. These so-called *activational* effects of steroids at puberty require that normal organization has occurred early in life. It is also becoming clear that the pubertal period is characterized by continued development of the brain, including neural plasticity that is modulated by steroid hormones. Thus, puberty may be considered as a second organizational period, as well as one during which activation of neonatally-organized circuits occurs (Sisk & Foster, 2004).

The issue of sexual dimorphism in the human brain has been quite controversial, but there is strong evidence for morphological and functional differences in specific brain nuclei in humans (Cahill, 2006). Sex differences in hypothalamic subnuclei, along with regions of the corpus callossum, hippocampus, amygdala, and neocortex have robust sex differences in size and neurochemistry, a difference speculated to be due to differential exposure to sex steroid hormones (Cahill, 2006).

Hormones and Sexual Behavior

There are clearly differences in the sexual behavior of males and females, effects that are dependent upon organizational and activational effects of gonadal steroid hormones. For example, copulatory behavior in male rodents comprises mounts of the female by the male, penile intromissions, and ejaculations. A receptive female rodent will respond to male copulatory behaviors with a lordosis response, characterized by a rigid stance and an arched back. These behaviors are driven in large part by the responses of hypothalamic nuclei to hormones, and the nature of the adult behavior is determined by the prenatal/neonatal exposure to hormones. Thus, the hypothalamus of adult males, which has been masculinized neonatally by testicular testosterone (or its aromatization product, estradiol), will respond to the testosterone produced by

the adult gonad (metabolized to DHT) by causing the typical male pattern of sexual behavior. In contrast, the female hypothalamus, which is not exposed neonatally to sufficient levels of ovarian hormones to cause masculinization of her brain, responds to estrogen produced by her adult ovary with the appropriate female receptive response.

The regions of the brain responsible for sex behavior differ between males and females. Sexual behavior in male rodents is largely driven by the preoptic area (POA) of the brain, just rostral to the hypothalamus, although other regions contribute to this process. Lesions of the POA in males cause the loss of sexual behavior, and testosterone implanted into the POA can induce sex behavior. In female rodents, the primary hypothalamic site regulating receptive sexual behavior is the ventromedial nucleus of the hypothalamus, although as in males, other regions also play contributing roles. Estradiol, followed by progesterone, facilitates the expression of the lordosis reflex and coordinates the timing of female receptivity with the preovulatory GnRH/LH surge that causes ovulation. Thus, the timing of mating behavior and ovulation is coordinated by the release of ovarian steroid hormones. Female reproductive cyclicity and the ability to ovulate in adulthood is also organized by sex-specific exposures to neonatal steroid hormones. This exemplifies the point that the timing of hormonal exposures has long-term consequences on both physiology and behavior in adulthood. Disruptions of endogenous hormones, or perturbations by exogenous hormonally-active substances (e.g., endocrine-disrupting chemicals) during critical developmental periods can have lifelong effects on reproductive behavior (Box 38.2).

Pheromones, the Vomeronasal Organ, and Sexual Behavior

Reproductive behavior in many species involves signals from pheromones, which are chemical signals used for communication between animals (Tirindelli, Dibattista, Pifferi, & Menini, 2009). Pheromones are chemical messengers that typically are produced by specialized glands, such as the sebaceous glands in the flanks of animals, or released in urine or vaginal fluid. They are released not into the body but rather into the external environment to convey information about the physiological status of the animal to other individuals.

The ability to detect pheromones in most mammals or other vertebrates involves the vomeronasal organ, an auxiliary olfactory organ found near the nasal cavity, and its projections to the accessory olfactory bulbs. Cells in these latter regions contact a number of brain regions, including the medial amygdala, cortical regions, and the bed nucleus of the stria terminalis, all of which are implicated in sex behavior. These regions in turn project to the hypothalamus and preoptic area. Thus, information from pheromones about mating status can be conveyed to parts of the brain coordinating reproductive physiology and behavior.

In most species, information about reproductive status, dominance status, or other social cues can be conveyed by pheromones, although it is still controversial whether humans have a vomeronasal organ and/or can sense pheromones. Those organisms using pheromones as chemosensory cues have developed mechanisms for depositing or releasing pheromones to "advertise" sexual competency or receptivity in order to attract a mate or to mark territory, to protect food supplies, mates, or offspring. Pheromones and the systems that mediate their effects play broader roles than those involved in reproductive physiology and behavior. Pheromones can dramatically influence the timing of sexual development and function. In female mice, exposure to male urinary pheromones accelerates the timing of pubertal development. Males respond to female urinary pheromones with sharp increases in luteinizing hormone release. It has also been reported that pheromones can coordinate the timing of reproductive cycles, even in humans, although the mechanisms and functions of these pheromones are still

BOX 38.2

ENDOCRINE-DISRUPTING CHEMICALS AND THEIR EFFECTS ON NEUROENDOCRINE SYSTEMS

Endocrine-disrupting chemicals (EDCs) are compounds in the environment that perturb endocrine systems. Recent interest has turned to whether, and how, EDCs might affect neuroendocrine function. Early life developmental periods—fetal, infant, and pubertal—are of particular interest because during these life stages, levels of endogenous hormones vary precipitously and are sex-specific. Thus, exposures of developing organisms to even very low levels of EDCs may have permanent organizational effects on the neuroendocrine system, affecting physiology and behavior in adulthood (Gore, 2008). Current research in the field is focusing on the molecular mechanisms by which developmental EDC exposure may "reprogram" the expression and regulation of neural steroid hormone receptors, including epigenetic mechanisms including altered DNA methylation and histone modifications.

Andrea C. Gore

controversial and poorly understood. Nevertheless, it is clear that pheromones play important roles in coordinating physiology and behavior.

Circadian Timekeeping

INTRODUCTION

Life on Earth has adapted to the cyclic variation in conditions imposed by our planet's daily rotation on its axis and its annual revolution around the sun. Almost all organisms studied, from cyanobacteria to *Homo sapiens*, have intrinsic time-keeping systems that adjust physiology and behavior to anticipate the daily cycles of light and darkness. Physiological processes that vary over the 24-hour day include activity, alertness, hormone secretion, organ physiology, and gene expression. These variations are not merely passive responses to a rhythmic environment, but instead reflect an underlying biological mechanism that can measure time in 24-hour increments. This mechanism orchestrates physiology to achieve predictive, rather than reactive, homeostasis.

Biological time measurement on the 24-hour time scale is achieved by a circadian timing mechanism. The term *circadian* is derived from the Latin words *circa* and *diem*, meaning "about a day," referring to the cycle length of these rhythms. Circadian rhythms are defined as rhythms that persist with a cycle length of approximately 24 hours in constant environmental conditions (Figs. 39.1 and 39.2). These rhythms are generated by a biological timing mechanism that is normally synchronized (entrained) to the 24-hour day by environmental cues. Light is the most widely used signal for entrainment of circadian clocks, but temperature, hormone levels, nutrient availability, and other cues can also affect oscillations.

In this chapter, we describe how circadian rhythms are generated, how they become synchronized to environmental cues, and their impact on physiology and behavior.

OVERVIEW OF THE MAMMALIAN CIRCADIAN TIMING SYSTEM

A biological timing system necessarily consists of an intrinsic clock mechanism that measures time, an input mechanism that allows the clock to become synchronized or reset by changes in the environment, and output pathways that lead to generation of overt rhythms such as daily changes in locomotor activity, sleep, and hormone levels. The mammalian circadian timing system is considerably more complicated than this simple linear scheme, because it is composed of a hierarchy of circadian oscillators (Fig. 39.3). At the pinnacle of this oscillatory system is a small brain area, the suprachiasmatic nuclei (SCN) of the anterior hypothalamus. The SCN are often called the master circadian clock, because these nuclei (one on each side of the brain) play a key role in coordinating oscillations in other tissues and in regulating behavior. Many other cells and tissues also have the capacity to display an approximately 24-hour rhythmicity. The molecular mechanism underlying these cell-autonomous circadian oscillations is a transcriptional feedback loop.

The primary input pathway to the SCN circadian clock is through retinal detection of light. Remarkably, the retinal photoreceptors that lead to visual image formation are not needed for circadian photoreception. Instead, a specialized population of retinal ganglion cells directly detect light, project to the SCN, and are necessary for photic entrainment of the SCN clock.

The main output of the SCN is encoded in neuronal firing rates. In addition, rhythmic neuropeptide secretion into the cerebrospinal fluid may be an important mechanism

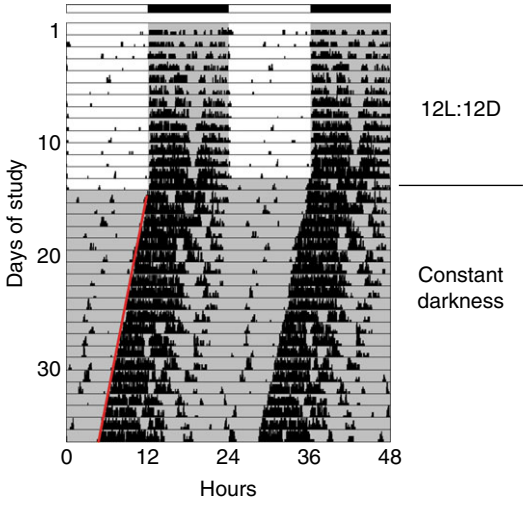

FIGURE 39.1 Locomotor activity rhythm of a mouse. This "double-plotted actogram" shows the activity pattern of an adult mouse housed individually in a cage with a running wheel. When the mouse rotates the wheel by running within it, a computerized system detects and records the wheel revolutions. Wheel revolutions are then plotted versus time, for weeks of data. Each horizontal line represents 48 hours of data. Wheel revolutions appear as bars coming up from the baseline, with their height proportional to the number of revolutions. On the first line of the record, the first 48 hours of data are shown. In the second line of the record, the data shown are from hours 24-72 of data collection. Thus, each 24-hour period of data after the first 24 hr is shown both to the right of the previous day's data and below it; this artificial reproduction of the data (double-plotting) helps to see the rhythmicity when the cycle length of rhythmicity differs from 24 hours. When housed in a 12 hours light, 12 hours darkness (12L:12D) lighting cycle, the mouse is active almost exclusively at night (shaded region). When the lighting cycle is disabled so the animal is in constant darkness (DD, starting on day 14), the animal continues to show rhythmicity but with a cycle length slightly less than 24 hours. This record reveals two defining principles of circadian rhythms: (1) circadian rhythmicity is intrinsic, rather than being generated in response to environmental variation, and (2) the circadian clock is normally synchronized to the 24-hour day length by light. It is easy to draw a "best-fit" line through the onset of activity each day (red line). Note the precision of the rhythmicity: the actual time of activity onset does not deviate far from this "best-fit" line, indicating the cycle length is measured with great accuracy. Spend a few minutes to think about how you would design a biological timekeeping system that can measure a day while having a variation between successive cycles that is less than 1% (15 minutes per 24 hours; the actual variation is often considerably less than this amount). *Figure courtesy of Jason DeBruyne, Morehouse School of Medicine.*

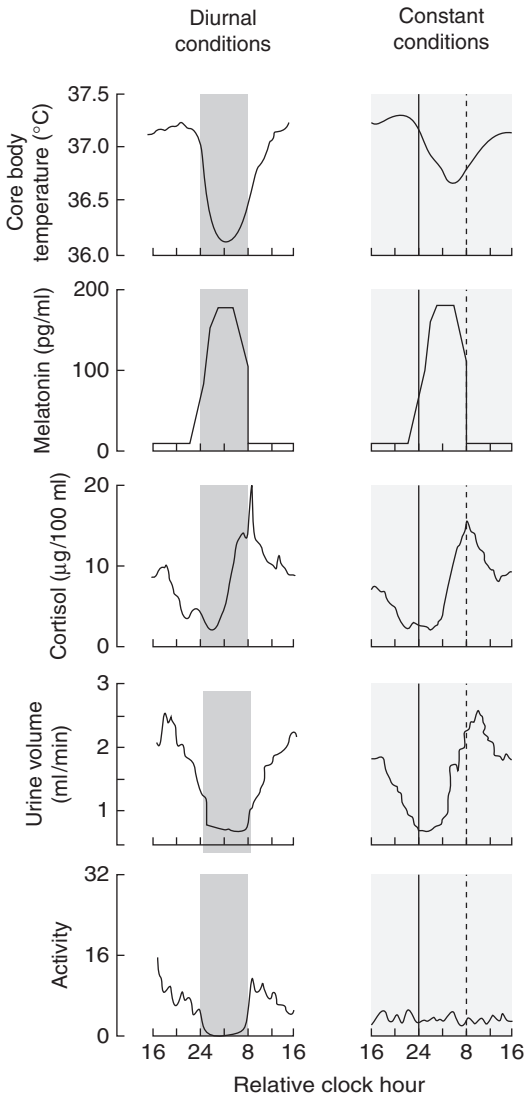

FIGURE 39.2 Diurnal and circadian rhythms in humans. The panels on the left show rhythms in several functions in human subjects maintained in a lighting cycle, with a period of sleep in the dark indicated by the shading. The panels on the right show the same endpoints studied in subjects maintained for 40 hours on a constant routine, with very low levels of illumination and with wakefulness maintained, while the subjects remain constantly in a semirecumbent posture and receive small meals at regular intervals throughout the study period. Persistence of the rhythms in constant conditions reveals they are true circadian rhythms. The apparent loss of the activity rhythm in constant conditions is due to the protocol-enforced inactivity of the subject. *Adapted from Czeisler, Buxton, & Khalsa, 2005, with permission Copyright 2005, Elsevier.*

for regulation of downstream targets. Anatomically, the outputs of the SCN are focused within the hypothalamus but have widespread influence, consistent with the pervasive influence of the SCN on physiological functions ranging from the modulation of cognitive function to neuroendocrine responses. Output rhythms dependent on the SCN synchronize autonomous oscillators in other tissues. Local circadian oscillators regulate gene expression in a tissue-specific manner. Microarray studies conducted on brain, liver, heart, and kidney tissue in mammals reveal that 5 to 10% of the genome is rhythmically transcribed, and many of the genes that are rhythmically expressed represent key, tissue-specific metabolic control points. Thus, the circadian timing system has a pervasive impact on physiological processes via its output pathways.

The Suprachiasmatic Nuclei are the Site of the Primary Circadian Pacemaker in Mammals

The SCN have been recognized as the master circadian clock in rodents since the early 1970s (see Weaver, 1998).

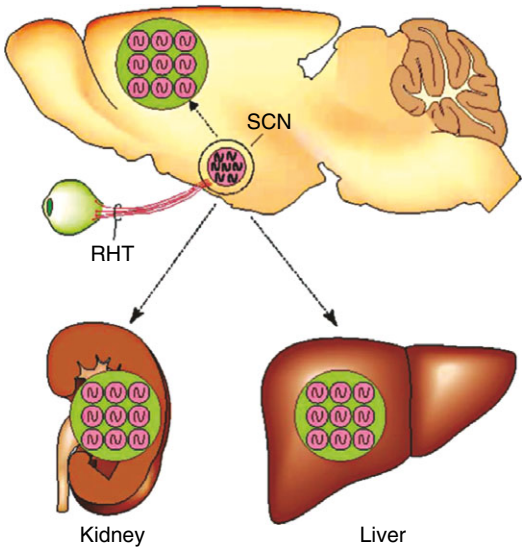

FIGURE 39.3 The mammalian circadian timing system consists of a hierarchy of oscillators. Oscillatory neurons in the SCN interact with each other to produce a set of coherent outputs. These outputs, which include behavioral and physiological rhythms, synchronize cell-autonomous oscillations in other brain regions and in peripheral tissues. *From Reppert & Weaver, 2002, with permission. Copyright 2002, Nature.*

At that time, "new" techniques for anterograde tract-tracing were used to assess retinal projections, and they revealed a direct retina-to-SCN projection, the retinohypothalamic tract. To determine if the SCN were an important node on the anatomical pathway for detection of light for regulating rhythms, Moore and Eichler (1972) destroyed the rat SCN and observed loss of rhythmic serum corticosterone in a population of rats. Using a similar approach, Stephan and Zucker (1972) discovered that the rhythm of drinking in individual rats was lost following destruction of the SCN. Together, these two studies demonstrated the necessity of the SCN for circadian rhythmicity. Hundreds of subsequent studies have confirmed the necessity of the SCN for rhythmicity in physiology and behavior (Weaver, 1998; Welsh, Takahashi, & Kay 2010).

SCN: Oscillator and Pacemaker

Lesion studies leading to loss of rhythmicity do not necessarily show that the SCN function as the primary circadian pacemaker. An alternative possibility is that the SCN could be a necessary element on a key output pathway leading to physiological rhythmicity. The presence of rhythms in SCN metabolic activity, electrical activity, and gene expression profiles *in vivo* do not distinguish between these possibilities. Studies demonstrating rhythms in neuropeptide secretion, metabolic activity, and electrical firing rate in SCN tissue maintained *in vitro* do show that the SCN contain a functional *oscillator*. The SCN do not simply oscillate, however: through its outputs, the SCN regulate rhythms in physiology and behavior, and thus serve as a circadian *pacemaker*. This unique pacemaker role of the SCN is revealed most clearly by studies showing that rodents made arrhythmic by SCN lesion can have rhythmicity restored by transplantation of fetal hypothalamic tissue containing the SCN into the third ventricle of the lesioned adult. Furthermore, transplants between hamsters with different circadian cycle lengths revealed that the period of restored rhythmicity is dictated by the genotype of the SCN tissue donor (Ralph, Foster, Davis, & Menaker 1990). Thus, the SCN serve as a pacemaker that communicates rhythmicity to tissues regulating behavioral rhythms.

Summary

The SCN function as the master circadian pacemaker in the mammalian brain. The SCN oscillate *in vivo* and also when placed *in vitro*. More importantly, however, the SCN generate output signals that lead to physiological and behavioral rhythms. The SCN is positioned at the interface between the outside world (detected by retinal photoreceptors) and light-insensitive effector tissues.

A HIERARCHY OF CELL-AUTONOMOUS CIRCADIAN OSCILLATORS

Single-Cell SCN Oscillators Are Coupled to Form a Coherent Clock

In rodents, the SCN contain approximately 10,000 neurons per side of the brain, with heterogeneity of neuropeptide phenotype, connectivity, and other properties (Silver & Schwartz, 2005; Morin, 2007). Despite this heterogeneity, most cells within the SCN are believed to have the capacity for cell-autonomous rhythmicity. Long-term rhythmicity in individual SCN neurons was first detected using extracellular recording of SCN neuronal firing rate (Fig. 39.4A). More recent studies reveal rhythmicity in single SCN cells using imaging methods designed to detect temporal variations in reporter gene expression (Fig. 39.4C).

The cycle length of individual oscillating SCN cells is more variable than the period of animal behavior or the period of rhythms detected from slices of SCN tissue maintained *in vitro*. Thus, some mechanisms for interaction among the heterogeneous SCN neurons must exist, allowing SCN neurons to synchronize their diverse periods.

Vasoactive Intestinal Peptide (VIP) plays a key role in synchronizing the activity of SCN neurons into a coherent, functional oscillator (Aton, Colwell, Harmar, Waschek, & Herzog, 2005; Maywood et al., 2006). VIP is expressed in a subset of neurons in the "core" region of the SCN (Fig. 39.5). VIP-containing neurons and other core neurons project heavily within the SCN core, to the surrounding "shell" region, and also beyond the SCN borders

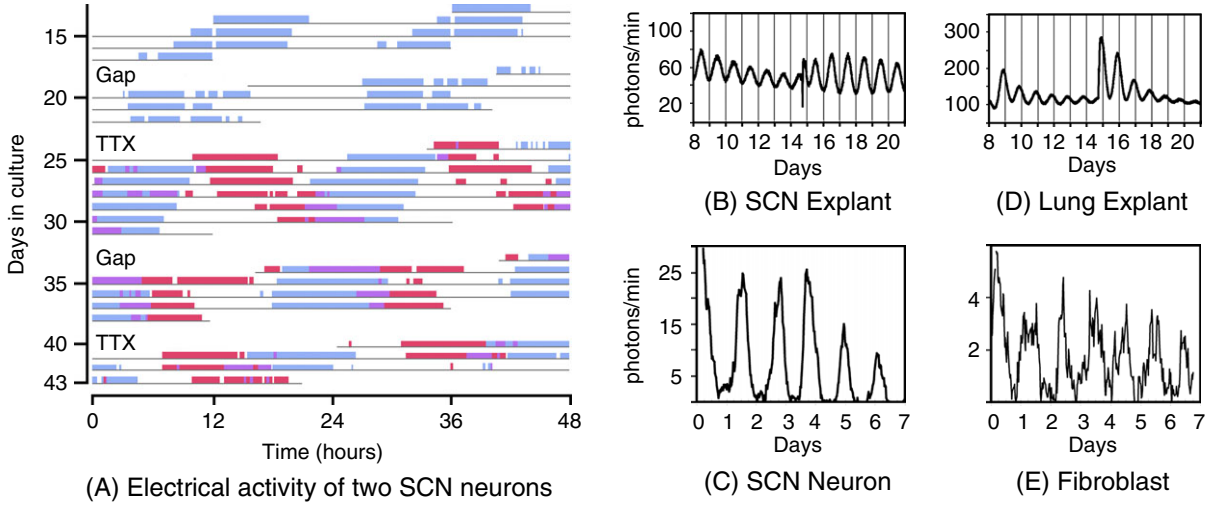

FIGURE 39.4 Cell-autonomous circadian rhythmicity *in vitro*. (A). Independently phased circadian rhythms in cultured SCN neurons. Spontaneous electrical activity of two SCN neurons in dispersed cell culture is shown in actogram-like format. Red bars represent one cell, while blue bars represent the other. The "activity" bars represent intervals when the neuronal firing rate for that cell is above its daily average. Where the active periods of the two cells overlap, they are shown in purple. Note that the two cells are cycling with independent period lengths. Gaps in the record represent days without recording. On two of these gaps, the culture was bathed with tetrodotoxin (TTX) for 2.5 days to block sodium-dependent action potentials. Note the molecular oscillations persist with unchanged period or phase despite TTX exposure. (*Adapted from D.K. Welsh, Logothetis, Meister, & Reppert, 1995, with permission. Copyright 1995, Elsevier.*) (B–E). Bioluminescence rhythms. Tissues and cells from mice with a rhythmically expressed luciferase reporter gene (encoding luciferase fused to PER2) were cultured in the presence of luciferin, and light emission was detected and plotted against time. Explants containing the SCN (B) or lung tissue (D) maintain rhythmicity in vitro. On the day labeled 14, culture media was changed, re-storing rhythm amplitude. Bioluminescence rhythms are also detectable, by imaging, from individual SCN neurons (C) and individual fibroblasts (E). *Adapted from A.C. Liu et al., 2007, with permission. Copyright 2007, Elsevier.*

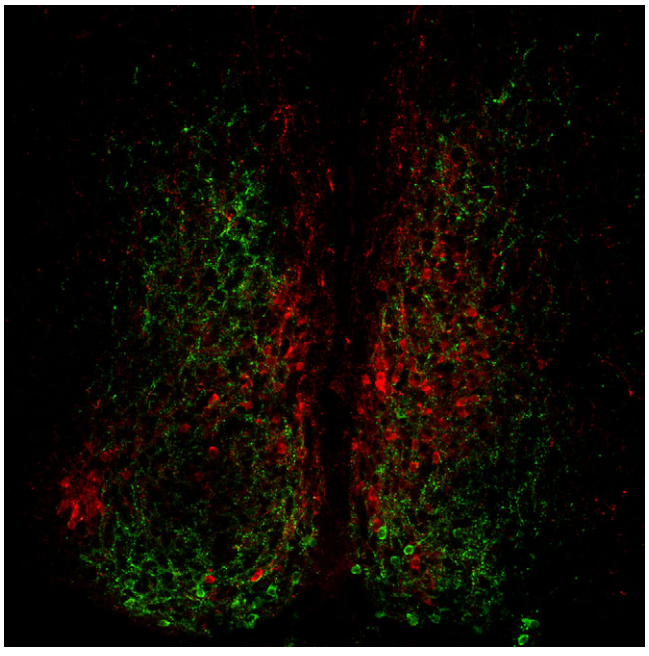

FIGURE 39.5 Neuropeptide expression in the mouse suprachiasmatic nucleus. Immunofluorescence image showing neurons expressing arginine vasopressin (AVP, red) in the dorsomedial aspect of the SCN, and neuronal cell bodies expressing VIP (green) in the ventral SCN. Note the extensive distribution of VIP-positive axons within the SCN. *Image courtesy of Nicola Smyllie and Mick Hastings, Laboratory of Molecular Biology, MRC, Cambridge, UK.*

(Fig. 39.5). Mice lacking VIP, or the VPAC2 receptor for VIP, have severely disrupted circadian rhythms. At the cellular level, the amplitude of individual neuronal oscillators is reduced in the absence of VIP or VPAC2 signaling, and the neurons are not coordinated to one another (Aton & Herzog 2005; Maywood et al., 2006). These findings strongly suggest that a "coupling deficit" leads to altered circadian rhythmicity in these lines of mice. VIP/VPAC2 acts through elevation of cAMP levels in SCN (Atkinson et al., 2011). Interestingly, the receptor for the insect neuropeptide Pigment Dispersing Factor (PDF) is closely related in structure to the VIP receptor (Helfrich-Förster, 2005). Moreover, PDF plays a role in the *Drosophila* (fruit fly) circadian system, which is strikingly similar to the role played by VIP in the mammalian SCN (Box 39.1). This indicates that the mechanisms underlying the communication between circadian neurons were established very early during the evolution of animals, at least 600 million years ago.

The entire population of SCN neurons usually functions in concert as an orchestrating oscillator. Under specific conditions, however, SCN cells can become coupled into two functionally distinct subpopulations that can independently influence circadian behavior. For example, hamsters exposed to constant light for long periods of time display "splitting," leading to two peaks of locomotor activity per 24 hours. Molecular analysis has revealed that

BOX 39.1

NEURONAL CONTROL OF *DROSOPHILA* CIRCADIAN BEHAVIOR

One of the greatest strengths of *Drosophila* as a model to study circadian behavior (and more generally any behavior) is the remarkably sophisticated set of tools available to manipulate specific populations of neurons. Using tissue-specific "drivers" to express various genes, neurons can be eliminated, electrically silenced or forced to fire action potentials, for example. Levels of gene expression can also be manipulated by overexpression or RNA interference. With this wide panoply of genetic tools, researchers are beginning to understand the role of the complex mosaic of circadian neurons.

There are about 150 circadian neurons in the fly brain, divided in several groups named by their anatomical locations (see Figure B39.1). These clusters of circadian neurons can be further divided based on their morphology, and the neuropeptides or neurotransmitters they express. The small ventral Lateral Neurons (s-LN_vs) function as pacemaker neurons in constant darkness (DD): they are necessary and sufficient for rhythmic locomotor behavior to persist in DD. These neurons secrete the neuropeptide Pigment Dispersing Factor (PDF). PDF is necessary for self-sustained behavioral rhythms and to synchronize molecular circadian rhythms in the brain. Interestingly, the phenotypes of flies mutant for either PDF or its receptor (PDFR, which is expressed on most circadian neurons) are remarkably similar to those of mice missing VIP or its receptor (VIPR): arrhythmicity and desynchronization between circadian neurons. Moreover, VIPR and PDFR share extensive sequences homologies. Thus, functional and molecular conservation of circadian rhythm mechanisms between mammals and insects is not limited to the circadian molecular pacemaker (see Box 39.2), but extend to circadian neural circuits.

Why have so many different circadian neurons if just 8 of them (the s-LN_vs) can generate robust behavioral rhythms in DD? A first answer is the need to divide tasks. Fruit flies are mostly active at dawn and dusk under Light:Dark (LD) cycles. The PDF positive s-LN_vs drive morning activity, but it is a different group of cells that drive evening activity: the dorsal Lateral Neurons (LN_ds). The s-LN_vs and the LN_ds might thus increase their electrical activity at different times of the day to generate morning and evening bouts of activity.

A second reason for the need of a complex circadian neural network is adaptation to an ever-changing environment. Day length (photoperiod) and overall temperatures cycle during the course of the year at most latitudes, and random weather changes influence daily environmental conditions. It is becoming increasingly clear that one of the main purposes for the diversity of circadian neurons is the integration of environmental inputs and a proper adaptation to external conditions. For example, some circadian neurons (DN2s, LPNs) are particularly sensitive to temperature cycles. Others (l-LN_vs, DN_1s) appear to be important for responses to light inputs. Finally, the contribution of a subset of DN_1s to circadian locomotor behavior is dependent on both ambient light intensity and temperature. Interestingly, the hierarchy between circadian neurons can change in response to light exposure. In the dark, or under short photoperiod, the PDF positive s-LN_vs play a particularly important role in the control of circadian behavior, while under constant light or under long photoperiod PDF negative circadian neurons (LN_ds, DN_1s) are dominant. This presumably helps flies to cope with seasonal changes in day length. Whether similar mechanisms act in mammals is not yet clear, but specific populations of SCN neurons adjust their firing cycles in response to changes in photoperiods.

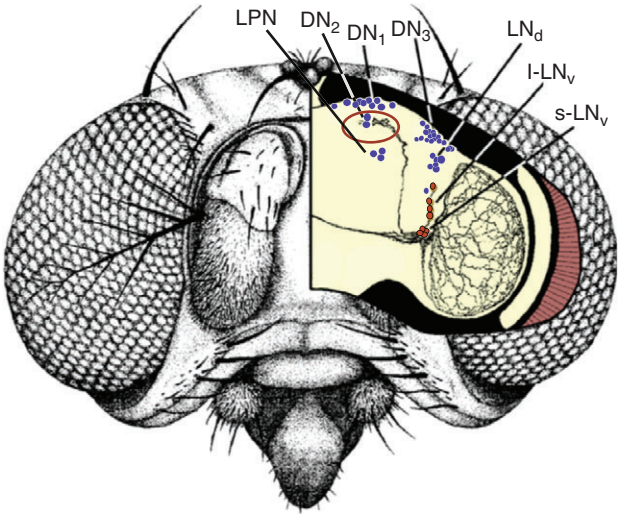

FIGURE B39.1 **Circadian neurons in the brain of *Drosophila melanogaster*.** Neurons expressing circadian proteins are shown in blue (Dorsal Neurons 1–3 [DN_1, DN_2, DN_3], dorsal Lateral Neurons [LNd], and Lateral Posterior Neurons [LPN]). Neurons expressing circadian proteins and the circadian neuropeptide Pigment Dispersing Factor (PDF) are shown in red (small and large ventral Lateral Neurons [s-LN_v and l-LN_v]). The PDF-positive neural projections are drawn in black. The most important projections for the synchronization of the circadian network are the s-LN_v projections directed toward the DN_1 and DN_2 groups. Indeed, PDF level oscillates in the termini of these projections (circled in red), presumably because PDF is rhythmically released. *Adapted from C. Helfrich-Förster, 2005, with permission. the left and right SCN are oscillating in opposite phases in "split" hamsters, with each side regulating locomotor activity (de la Iglesia, Meyer, Carpino, & Schwartz, 2000). In rats, complex lighting cycles can be used to dissociate ventrolateral and dorsomedial subdivisions of the SCN from each other, resulting in simultaneous expression of rhythms with two different periods; each activity component is apparently driven by a different region of the SCN. Imaging studies reveal waves of gene expression progressing through the SCN *in vitro*, and subpopulations of neurons are coupled with differing relationships to the environmental lighting cycle. These experiments emphasize that the multi-oscillatory nature of the circadian system can be appreciated even within the SCN, and that coupling among SCN neurons normally prevents conflicting output signals.

Peripheral Oscillators

Despite sporadic reports of rhythmicity in isolated mammalian tissues, for years the dogma in the circadian field was that only the SCN possessed the capacity for self-sustaining, autonomous rhythmicity. The identification of a family of mammalian *Period* genes helped to change this perception. The mammalian *Period* genes are widely expressed (Zylka, Shearman, Weaver, & Reppert, 1998), suggesting that rhythmicity could occur in additional tissues. In addition, widespread, cell-automonous circadian clocks were demonstrated in *Drosophila* at about the same time (Plautz, Kaneko, Hall, & Kay, 1997).

That the capacity for circadian rhythmicity is not limited to the SCN in mammals was clearly demonstrated in a landmark study by Balsalobre, Damiola, and Schibler (1998). The field was shocked to learn that brief exposure to a high concentration of serum ("serum shock") could lead to rhythmic gene expression in cultured fibroblasts. More recent single-cell analysis revealed that fibroblasts have ongoing (but uncoordinated) rhythms, and a serum pulse merely synchronizes these rhythms so that rhythmicity can be detected in the population (Nagoshi et al., 2004; Welsh et al., 2004; see Fig. 39.4). The serum shock is not a unique stimulus; acute activation of each of several pathways can induce rhythmicity in fibroblasts, suggesting that multiple signaling pathways converge upon the oscillator.

It is now generally believed that most mammalian cell types are capable of circadian oscillation. In normal circumstances, the rhythmicity in tissues outside the SCN is synchronized by SCN-dependent output signals. These signals include physiological and behavioral rhythms (e.g., body temperature and food intake) and daily fluctuations in hormone levels (e.g., glucocorticoids and melatonin). Thus, rhythms controlled by the SCN synchronize molecular rhythmicity among cells within a peripheral tissue (Fig. 39.3). In the absence of rhythmic input from the SCN, oscillators in some tissues become desynchronized, and thus the organ as a whole loses detectable rhythmicity. In the olfactory bulb, however, interactions among oscillating cells are sufficiently robust to maintain coordinated rhythmicity (Granados-Fuentes, Prolo, Abraham, & Herzog, 2004).

While the SCN function as the master circadian pacemaker in most circumstances, there is now compelling evidence that oscillators outside the SCN can regulate rhythmic behavior (Stephan, 2002; Taratoglu, Davidson, Benvenuto, & Menaker, 2006). While these oscillatory mechanisms are overshadowed in the presence of a functioning SCN, these studies reveal the potential impact of tissue-autonomous oscillators outside the SCN. Our understanding of the implications of the hierarchical nature of the mammalian circadian timing system is advancing rapidly.

Coordination of rhythms within a tissue may optimize organ-level physiological processes, while a circadian timing system in general may achieve "internal temporal order" among organs so that organs are prepared to function most efficiently. Circadian misalignment and disruption of internal coordination occur with shift work and following transmeridian travel (jet lag) (see Box 39.3).

Summary

Many cell types possess the capacity for oscillation with a cycle length near 24 hours. Neurons within the SCN oscillate and also communicate with one another, such that the SCN are able to provide a coherent output resulting in rhythmicity of other functions. Oscillating cells in other tissues generally require SCN-dependent signals, in the form of physiological rhythms, to remain synchronized, both within and between tissues.

THE MOLECULAR BASIS FOR CIRCADIAN OSCILLATION IS A TRANSCRIPTIONAL FEEDBACK LOOP

The preceding discussion emphasizes that circadian rhythmicity occurs within single, isolated cells. But how do individual cells measure 24-hour time intervals? Studies conducted in many labs over the past 15 years have revealed a great deal about the molecular mechanisms underlying mammalian circadian rhythmicity (Fig. 39.6).

Progress made in understanding the circadian clock mechanisms in the fruit fly, *Drosophila melanogaster*, was instrumental in developing our current understanding of mammalian clock mechanisms (Box 39.2). Most of the genes involved in the fly circadian mechanism have mammalian homologs, and their roles in circadian function have now been examined in mammals. While there have been some alterations in gene products performing specific functions, and gene duplication in mammals has led

to greater complexity, the general features of the core clock mechanisms are similar between flies and mammals (Box 39.2). This demonstrates again the ancient origin of circadian timing mechanisms in the animal kingdom.

The molecular mechanism for measuring time on a 24-hour time-scale is based on a self-sustaining transcriptional/translational feedback loop present within individual cells (Fig. 39.6). According to the current model for this molecular feedback loop (Reppert & Weaver, 2002; DeBruyne, 2008; Welsh et al., 2010), pairs of basic helix-loop-helix, PAS-domain containing (bHLH-PAS) transcription factors dimerize and activate transcription of several genes, including *Period* and *Cryptochrome* genes, through specific promoter elements called E-boxes. CLOCK and BMAL1 are the major transcriptional activator complex, but in a subset of SCN neurons, NPAS2 and BMAL1 heterodimers form and can maintain rhythmicity. High-amplitude rhythmicity in the expression of two *Period* genes (*Per1* and *Per2*; Fig. 39.7) is believed to be rate-limiting for formation of complexes between the PERIOD (PER) and CRYPTOCHROME (CRY) proteins. PER:CRY-containing protein complexes recruit other proteins, and this complex disrupts the activity of the CLOCK:BMAL1 complex. The temporally regulated nuclear accumulation of PER:CRY complexes is thought to be critical for closing the feedback loop. Thus, molecular oscillations occur with a cycle length of approximately 24 hours, in which a phase of CLOCK/NPAS2:BMAL1-mediated transcriptional activation is followed by phase of PER:CRY-mediated repression. It is important to note that this transcriptional feedback loop regulates additional genes, including other transcription factors, thus generating rhythmic expression of a large number of genes (Jin et al., 1999; Ueda et al., 2005; Kornmann, Schaad, Bujard, Takahashi, & Schibler, 2007; Miller et al., 2007; Atwood et al., 2011).

Post-translational modifications build a time delay into the circadian oscillation. Without this delay, transcription of *Per* genes would rapidly lead to nuclear accumulation of PER:CRY complexes and a premature inhibition of transcription. In this case, the clock would either cycle with a very short period or the system would equilibrate to a nonrhythmic steady state. Phosphorylation of the PER proteins is critical for this time delay. Phosphorylation alters their intracellular localization, protein:protein interactions, and stability, and thereby contributes to regulating circadian cycle length. Rhythmic phosphorylation of PER proteins is due at least in part to the activity of casein kinase 1 delta (CK1δ) and CK1 epsilon (CK1ε) and mutations of these kinase genes or their pharmacological inhibition alters circadian cycle length in flies, hamsters, mice, and humans. A circadian-based sleep disorder in humans is due to alterations in CK1-mediated phosphorylation of PER2 proteins, leading to rhythms having an unusually early phase (Box 39.3). Phosphorylation of clock proteins alters their activity and can also target them for proteosomal degradation; mutations in the gene encoding FBXL3, which participates in phosphorylation-dependent ubiquitination of CRY proteins, slow the circadian cycle in mice (Gatfield & Schibler, 2007). β-TRCP is responsible for the ubiquitination and degradation of PER proteins. The fine balance between kinases (including CK1δ/ε and CK2) and phosphatases (notably protein phosphatase 1), and subsequent phosphorylation-dependent degradation contribute greatly to regulating circadian period length.

An interlocked, second feedback loop is important for the rhythmic regulation of BMAL1. Two members of the orphan nuclear receptor gene family, *Rev-erb-alpha* and *Rora,* are among the genes regulated by CLOCK and BMAL1. The protein products of these genes compete for binding to an orphan nuclear receptor binding site in the promoter of the *Bmal1* gene and have antagonistic effects on *Bmal1* gene expression. Overexpression of the repressor, REV-ERB-α in the liver greatly reduces *Bmal1* expression, leading to liver-specific loss of rhythmicity (Kornmann et al., 2007). While BMAL1 is necessary for rhythmicity, *rhythmic* BMAL1 production appears relatively unimportant for maintaining rhythmicity.

Molecular Redundancies Revealed by Studies of Knockout Mice

The importance of the genes discussed above in the circadian mechanism has been revealed in part through studies of mice with targeted gene disruption. These studies reveal that, in most cases, there is at least partial redundancy of function among members of these gene families (Table 39.1). Mice homozygous for mutation of either *mPer1* or *mPer2* alone have period defects and/or a gradual loss of rhythmicity, while mice homozygous for disruption of both *mPer1* and *mPer2* become arrhythmic immediately in constant darkness. Notably, however, the phenotype of mice homozygous for mutation of either *Per* gene is markedly affected by genetic background; single *Per* mutations are almost without effect on the C57BL/6J background (Pendergast, Friday, & Yamazaki, 2010), indicating redundancy between the PER proteins.

Mice with targeted disruption of either *mCry1* or *mCry2* have altered circadian period lengths (~22.5 and ~24.5 hours, respectively), but the double-mutant mice completely lose circadian rhythmicity immediately upon placement in constant darkness.

While mice homozygous for a semidominant mutation in the *Clock* gene ($Clock^{\Delta 19}$) have significant behavioral and molecular phenotypes, mice completely lacking CLOCK protein retain behavioral rhythmicity (Fig. 39.8). As noted earlier, the closely related bHLH-PAS transcription factor NPAS2 (also called MOP4) maintains circadian rhythms in the SCN, even in the absence of CLOCK (Fig. 39.8).

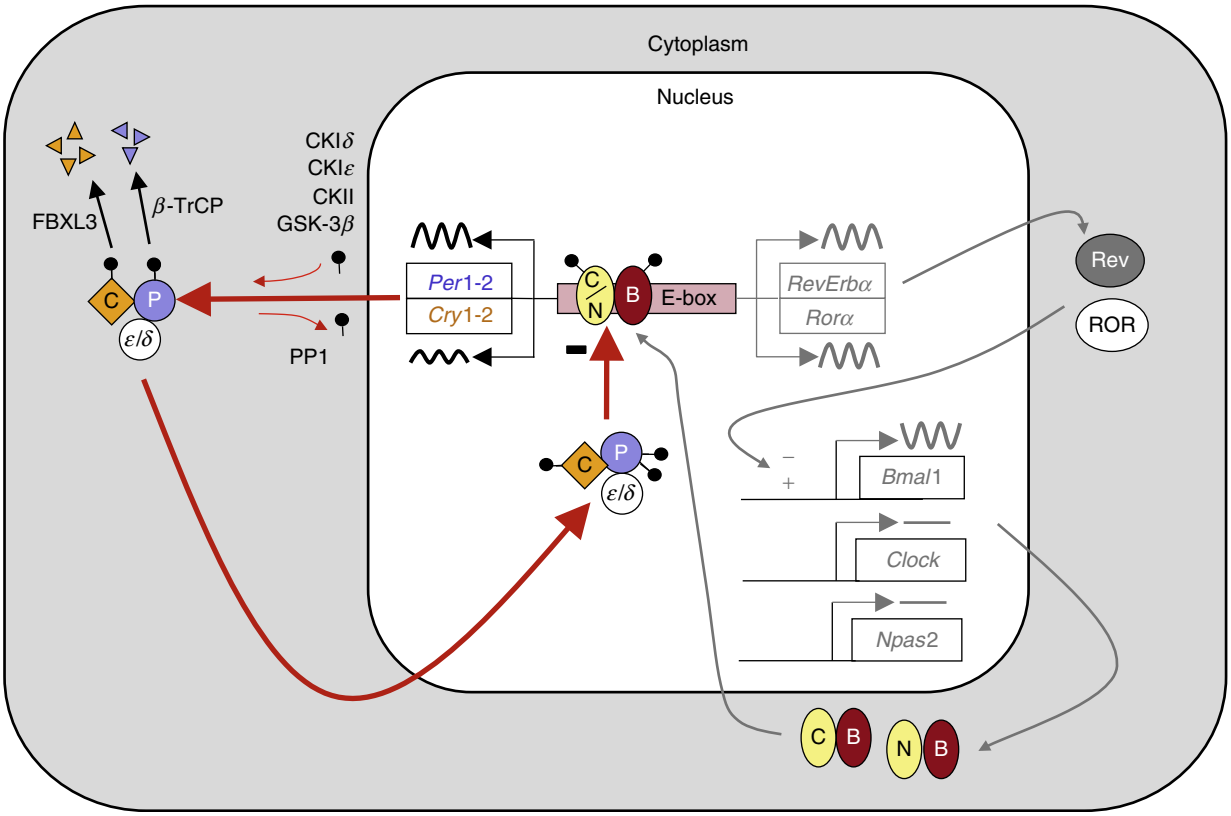

FIGURE 39.6 The molecular mechanism for circadian rhythms in mammals is a transcriptional feedback loop. Transcriptional activation leads to expression of *Per* and *Cry* genes. Posttranslational modifications, including phosphorylation (black lollipop) mediated in part by casein kinases (CKIδ, CKIε, CKII) and GSK-3β, affect the interactions of PER (P in blue circle) and CRY (C in gold diamond) proteins, promote their proteosomal degradation by F-box proteins (β-TrCP and FBXL3), and regulate nuclear entry of the inhibitory PER:CRY complex. The high-amplitude rhythm of PER production controls the timing of negative feedback. Collectively, these events lead to a delayed, negative feedback to shut off the transcriptional activation, resulting in a negative feedback loop (red arrows). The positive drive to the system comes from the transcription factors CLOCK (C in yellow oval) and BMAL1 (B in red oval), or NPAS2 (N in yellow oval) and BMAL1. The orphan nuclear receptors RORA (ROR) and REVERB-alpha (Rev) control the rhythmic expression of *Bmal1*, with peak levels occurring opposite to the peak in *Per* expression. The antiphase rhythmicity of this second feedback loop is not essential for rhythm generation, but BMAL1 itself is necessary.

BOX 39.2

MOLECULAR MECHANISMS OF CIRCADIAN TIMEKEEPING IN *DROSOPHILA*

Virtually nothing was known about the genetic and molecular mechanisms controlling circadian rhythms until the late 1960s, when Seymour Benzer and his graduate student, Ron Konopka, identified the first mutations affecting circadian behavior. Most scientists at the time were skeptical that individual genes could affect complex behaviors. Benzer was nevertheless determined to identify the genetic underpinnings of behavior, and embarked on an ambitious program using the animal model of choice for genetic studies, the fruit fly *Drosophila melanogaster*. Benzer and colleagues exposed large numbers of flies to a chemical mutagen to isolate mutant lines with abnormal behavior in various assays. To identify circadian genes, Konopka screened for mutant fly lines that had lost the ability to predict dawn, as assessed by observing the time of day at which the young flies emerged from their pupal cases. Using this approach, Konopka and Benzer isolated three mutant lines with abnormal circadian rhythms. In one line, the flies emerged from their pupal cases too early, in a second line they were too late, while in a third line the flies emerged at random times. All three mutations mapped to the same genetic locus, named *period (per)*. Importantly, the three *period*

BOX 39.2 (*cont'd*)

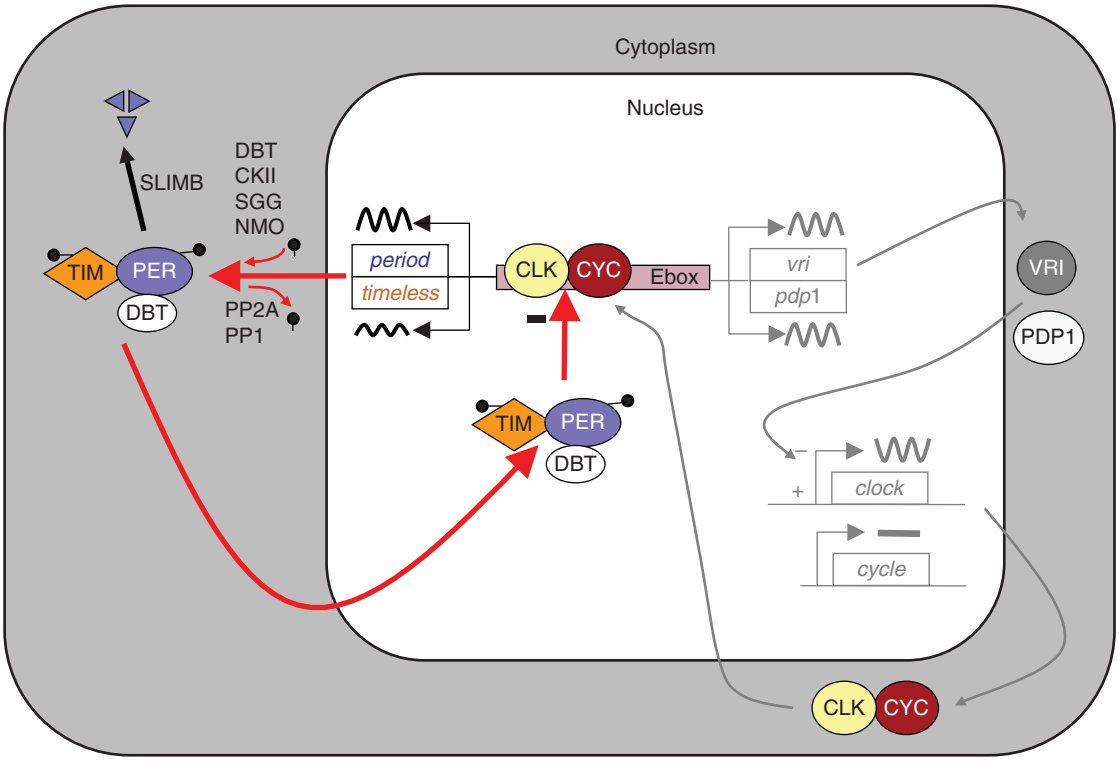

FIGURE B39.2 **Model of the molecular circadian clock in *Drosophila*.** In the core transcriptional feedback loop (left side of the figure), CLOCK (CLK) and CYCLE (CYC) positively regulate *period* (*per*) and *timeless* (*tim*) transcription. PER is phosphorylated by DOUBLETIME (DBT), CASEIN KINASE II (CKII]) and NEMO (NMO), while TIM is phosphorylated by SHAGGY (SGG) and CKII. PER and TIM phosphorylation levels are negatively regulated by PROTEIN PHOSPHATASE 1 and 2A (PP1 and PP2A). Hyperphosphorylated PER is ubiquitinated by SLIMB and degraded by the proteasome. PER and TIM enter into the nucleus with DBT to inhibit the activity of CLK/CYC. In a secondary feedback loop shown in grey, VRILLE (VRI) and PAR DOMAIN PROTEIN 1ε (PDP1) regulate *clk* transcription.

mutants had similar circadian defects in their locomotor activity rhythms, which provided strong evidence that Konopka and Benzer had identified a gene central to the circadian pacemaker.

Benzer's pioneering idea of using unbiased genetic screens to identify genes involved in circadian behavior has led to identification of additional "clock genes" by several other labs. The subsequent genetic, molecular, and biochemical studies have resulted in a remarkably detailed understanding of the *Drosophila* circadian pacemaker (see Figure B39.2). CLOCK (CLK) and CYCLE (CYC) are two basic helix-loop-helix transcription factors that heterodimerize and bind to E-boxes within the *per* and *timeless* (*tim*) promoters. PER and TIM dimerize in the cytoplasm, with TIM stabilizing PER. Several kinases (DOUBLETIME, CASEIN KINASE 2, NEMO, and SHAGGY [the *Drosophila* homolog of glycogen synthase kinase 3]) and at least two phosphatases (PROTEIN PHOSPHATASE 2A and PROTEIN PHOSPHATASE 1) regulate the stability and thus the rate of PER and TIM accumulation, and the timing of their nuclear entry. Once in the nucleus, the PER/TIM heterodimer binds to the CLK/CYC dimer and disrupts its transcriptional activity and its interaction with E-box sequences. The inhibition of *per* and *tim* gene expression is maintained for several hours until the hyperphosphorylated and unstable PER and TIM proteins decay. CLK/CYC can once again bind to E-box sequences and restart the circadian cycle. The kinase DOUBLETIME, which translocates into the nucleus with PER and TIM, also plays an important role for repression by regulating CLK phosphorylation and degradation. The CLK/CYC, PER/TIM feedback loop is essential for maintaining rhythms in *Drosophila*. A secondary feedback loop might contribute to the precision and robustness of circadian oscillations through the regulation of *clk* mRNA levels. The *Drosophila* molecular clock is primarily synchronized to environmental light/dark cycles by an intracellular photoreceptor, CRYPTOCHROME (CRY). Light activates CRY, and CRY then binds to and triggers the rapid degradation of TIM. Since TIM stabilizes PER, the degradation of TIM also results in a reduction in PER levels that resets the circadian pacemaker.

BOX 39.2 (*cont'd*)

As the first components of the mammalian molecular clock were identified in the late 1990s, it quickly became clear that important concepts learned from the *Drosophila* circadian clock also apply to mammals. The circadian pacemaker of both *Drosophila* and mammals involve homologous proteins in analogous transcriptional feedback loops. Strikingly, the first identified genetic cause of a human circadian rhythm disorder, Familial Advanced Sleep Phase Syndrome, is a mutation in human *Per2*, a homolog of the *Drosophila per* gene.

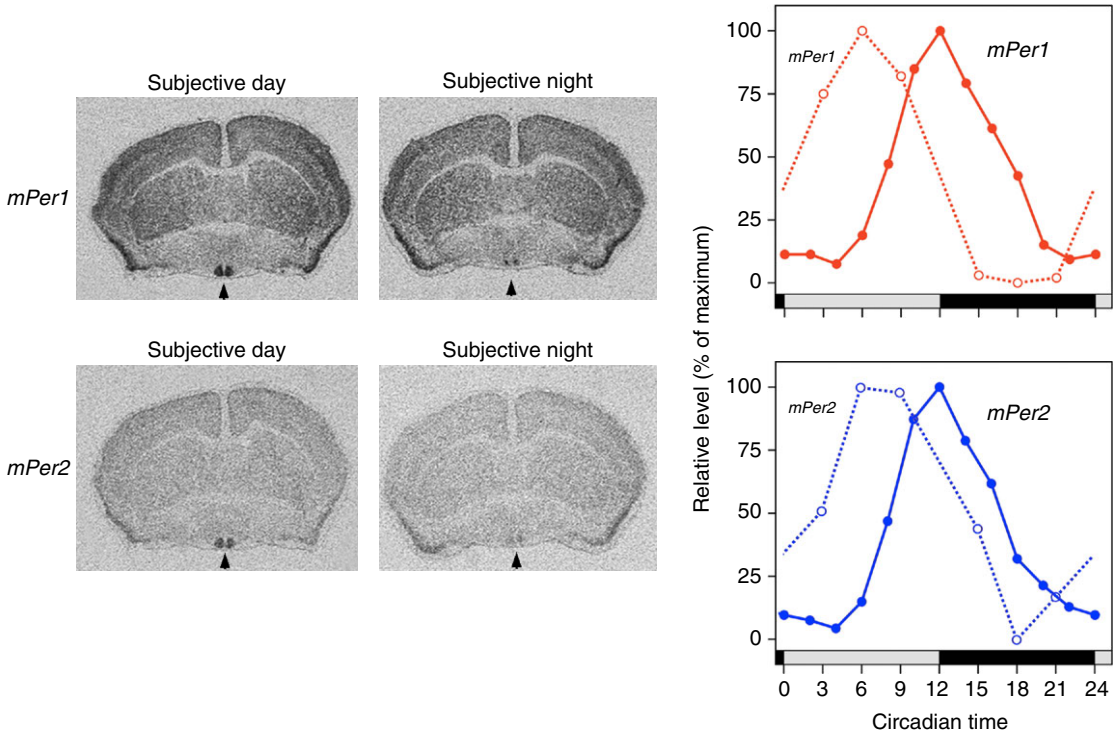

FIGURE 39.7 High-amplitude circadian rhythms of *mPer* gene expression in the mouse SCN. **Left:** Adjacent sections through the SCN from brains collected at the time of peak Per transcript levels during the subjective day (left column) or during the middle of the subjective night (right column) were processed for *in situ* hybridization to detect *mPer1* and *mPer2* mRNAs. "Subjective" refers to the fact that the animals were in constant darkness on the day of tissue collection, rather than in a lighting cycle. The SCN are indicated by an arrowhead in each panel. *Adapted from Shearman, Zylka, Weaver, Kolakowski, & Reppert, 1997, with permission. Copyright 1997, Elsevier.* **Right:** *Per* RNA (open circles and dashed lines) and PER protein (filled circles and solid lines) rhythms in mouse SCN. *mPer1* (upper panel) and *mPer2* (lower panel) RNA levels were assessed by *in situ* hybridization from samples collected on the first day in constant darkness. Protein levels were determined by counting nuclei within the SCN from sections processed for immunohistochemical detection of mPER1 and mPER2. The bar below the panel represents the lighting cycle the animals were exposed to on days prior to the day of tissue collection. Circadian Time 0–12 corresponds to subjective day, when the lights would have been on had the animals remained in a lighting cycle. (*Data from Shearman et al., 1997 and Hastings, Field, Maywood, Weaver, & Reppert, 1999.*)

BOX 39.3

CIRCADIAN-BASED SLEEP DISORDERS, CLOCK GENES AND NEUROPSYCHIATRIC DISEASES

The timing of sleep observed in adult humans normally is from approximately midnight to 8 a.m. Most people will voluntarily move sleep to a later time when free of work constraints and readily readjust their schedule back to an earlier time when the workweek begins again. There are developmental changes in the "normal" timing of sleep, with adolescents being prone to a later phase and the elderly typically assuming an advanced (earlier) phase. These developmental changes in preferred phase of activity and sleep mirror the natural variation within adult populations, with early-rising "larks" and late-rising "night owls" being readily recognizable patterns. At the extreme, however, these differences in timing of activity and sleep can disrupt social life and employment. These extreme cases are referred to as circadian-based sleep disorders (see Figure B39.3).

Advanced sleep phase syndrome (ASPS) is characterized by early-morning awakening and an inability to maintain wakefulness into the evening (the typical wake interval is from 0400 to 2000; see top panel of figure). Studies of familial cases of ASPS have identified two genes that, when mutated, contribute to ASPS. Remarkably, these genes were already discussed in the context of the core circadian feedback loop in mice. The mutations defined in humans that lead to familial ASPS are a Serine to Glycine mutation at position 662 of human PER2 (within the casein kinase interacting domain of PER2), and a Threonine to Alanine mutation at position 44 of casein kinase I delta (a mutation that increases the ability of the kinase to phosphorylate PER2).

Delayed sleep phase syndrome (DSPS) is characterized by late awakening and late bedtimes (typical wake interval from noon to 0400), and an apparent inability to reset the clock to earlier times of day. This disorder frequently begins in adolescence or young adulthood and tends to be sporadic rather than familial.

"Non-24-hour sleep wake syndrome" has also been described, in which individuals fail to entrain to the 24-hour day (see bottom panel of figure). This condition is relatively frequent in blind individuals. Affected individuals have intervals where their biological day and night coincide with the solar day and night, but then their free-running period (usually ~24.5 hours) causes them to drift out of phase with the environment. This results in periods of insomnia and daytime drowsiness (when the individuals are out-of-phase) alternating with periods of coordination with the environment. Melatonin, administered at 24-hour intervals, is useful in synchronizing some blind individuals to a 24-hour cycle length.

Several studies have identified genetic differences between "owls" and "larks." Specific haplotypes of the *Per3* gene, in particular, have been associated with delayed diurnal preference and with delayed sleep phase syndrome. Thus, even within the normal range of sleep timing, phase preference may have a significant genetic component.

Circadian rhythms are phase-advanced in depression, and rhythm alterations occur in other neuropsychiatric and neurodegenerative diseases. Recent studies reveal increased prevalence of certain disorders in subjects with specific alleles of circadian-relevant diseases. Circadian rhythm alterations may be a risk factor for neuropsychiatric disease.

David R. Weaver

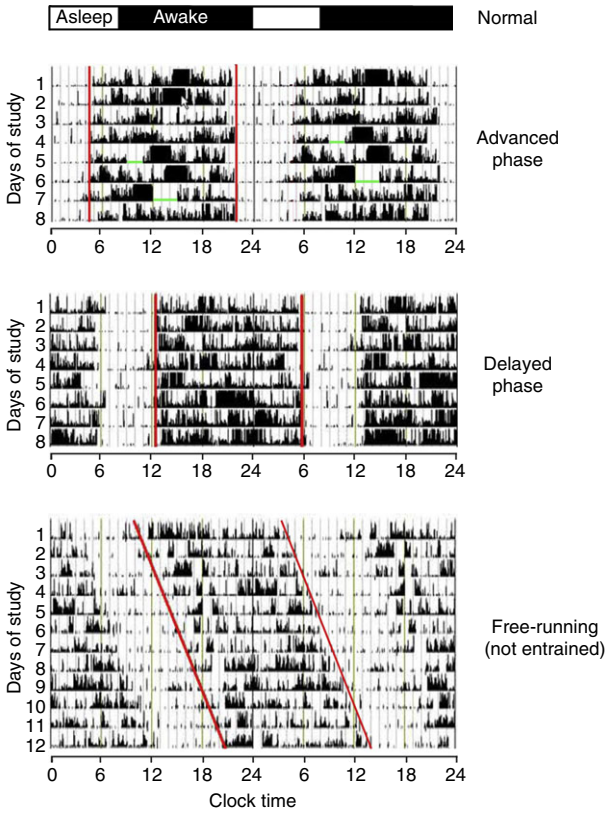

FIGURE B39.3 Disorders of sleep timing in humans. The typical timing of sleep and wake is shown at the top of the figure. Below are double-plotted activity records of three individuals. Activity was recorded by a motion-sensitive wristwatch. Activity appears as vertical deflections in the records. Intervals where the watch was taken off are indicated by green bars. Red lines mark activity onset and offset. The top actogram illustrates an individual with advanced sleep phase syndrome; activity occurs between 0400 and 2000. The second pattern shows delayed sleep phase syndrome; activity occurs from 1300 to 0600. The lower actogram shows an individual that is free-running due to failure to entrain to environmental cues. *Modified from Sleep, Medicine, vol 8, Barion, A., & Zee, P.C., "A clinical approach to circadian rhythm sleep disorders," pp. 566–677, Copyright 2007, with permission from Elsevier.*

CLOCK appears to be much more abundant than NPAS2 in the SCN, and transcriptional regulation occurs primarily through CLOCK:BMAL1 heterodimers in SCN and other tissues. BMAL1 is necessary for maintenance of behavioral rhythmicity (Bunger et al., 2000). Overexpression of BMAL2, a protein closely related to BMAL1, can restore rhythmicity in BMAL1-deficient mice (Shi et al., 2010). BMAL2 expression is greatly reduced in BMAL1-deficient tissues; the BMAL1-deficient mouse may be a functional double-knockout, explaining this apparent departure from the trend for functional redundancy among gene family members.

Posttranslational modifications were discussed briefly above. Disruption of CK1δ cause period lengthening,

TABLE 39.1 Gene Families Regulating Mammalian Circadian Rhythms

Gene Family	Gene	Mutation	Allele Type	Effect on Behavioral Rhythmicity in DD
bHLH/PAS	*Clock*	Clock$^{\Delta 19}$(exon skipped)	Dominant-negative	Long period, then arrhythmic
	Clock	Targeted disruption	Null	Slightly short period
	Npas2 (*Mop4*)	Targeted disruption	Deletion	Slightly short period
	Clock + *Npas2*			Immediately arrhythmic
	Bmal1 (*Mop3*)	Targeted disruption	Null	Immediately arrhythmic
Period	*Per1*	Targeted disruption	Null	Short period, gradual arrhythmicity
	Per2	Targeted disruption	Deletion	Short period, gradual arrhythmicity
	*Per2**	Missense (S662G)	Dominant-negative	Short period, advanced phase
	Per3	Targeted disruption	Null	Slightly short period
	Per1 + *Per2*			Immediately arrhythmic
	Per1 + *Per2* + *Per3*			Immediately arrhythmic
Cryptochrome	*Cry1*	Targeted disruption	Null	Short period
	Cry2	Targeted disruption	Null	Long period
	Cry1 + *Cry2*			Immediately arrhythmic
Casein Kinase	*CKIδ**	Missense (T44A)	Gain-of-function	Short period, advanced phase
	CKIδ	Targeted disruption	Deletion	Lethal when homozygous; tissues long period.
	*CKIε***	Missense (R178C)	Gain-of-function	Short period, advanced phase
	CKIε	Targeted missense	Gain-of-function	Short period, advanced phase
	CK1ε	Targeted disruption	Null	Slightly longer period/no effect
F box proteins (ubiquitin ligases)	*Fbxl3*	Missense (C358S)	Null	Long period
	Fbxl3	Missense (I364T)	Null	Long period
Orphan Nuclear Receptor	*Rev-erb-alpha*	Targeted disruption	Null	Short period
	RorA	Deletion (Staggerer)	Null	Rhythm instability

Mutations and mutant phenotypes listed were studied in mice, except as noted by asterisks: * indicates Human, ** indicates Syrian hamster. Missense mutations are those that lead to a change in a single amino acid residue; the residue and the change are indicated in single letter format: S662G indicates that a Serine residue at position 662 of human PER2 is mutated to Glycine.
Alleles designated as "Deletion" produce some protein products, but the deletion of genomic material results in deletion-mutant protein products that appear to lack functional activity. From a functional point of view, these are viewed as null alleles. "Null" alleles are those where there is either no product or the product is so truncated that it is irrelevant. "Dominant-negative" alleles result in protein products that are altered in activity, such that the mutant product interferes with the activity of the product from the normal allele, thus producing a mutant phenotype in heterozygotes and a more severe phenotype in homozygotes (semidominant inheritance). "Gain-of-function" alleles are hyperactive in performing the function of the mutated gene. Additional genes not listed may modify the circadian feeback loop in more subtle ways. Results of overexpression studies are not included.

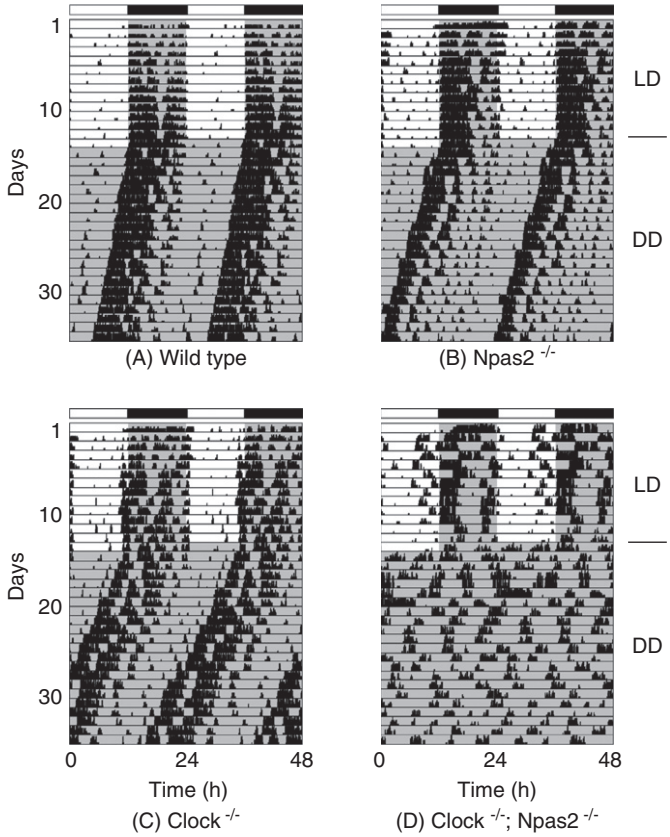

FIGURE 39.8 Molecular redundancy in the maintenance of mouse circadian rhythms. Panels A–D show double-plotted actograms from (A) a wild-type mouse, (B) an NPAS2-deficient mouse, (C) a CLOCK-deficient mouse, and (D) a double-mutant (CLOCK-deficient, NPAS2-deficient) mouse. The animals were initially housed in a light:dark cycle (LD), and then the lights were disabled and they entered constant darkness (DD). Note that the double-mutant mouse becomes arrhythmic in DD, while the mice of the other genotypes "free run" with a cycle length of less than 24 hours. The apparent rhythmicity when the double-mutant mouse is housed in LD is due to partial suppression of locomotor activity by light, a phenomenon called negative masking. Plotting conventions as in Fig. 1. *Modified from DeBruyne, Weaver, & Reppert, 2007, with permission from Nature Neuroscience.*

while null mutations of CK1ε have only a very modest effect. Pharmacological inhibition of both CK1δ and CK1ε greatly lengthens period, indicating compensation by one kinase in the absence of the other is occurring in the genetic models. "Activating mutations" of CK1δ or CK1ε shorten cycle length. Mutation or inhibition of ubiquitin ligases (Fbxl3 or β–TrCP) lengthens period.

The preceding discussion addresses the phenotype of intact mutant mice, using behavioral and physiological rhythms to assess the functional state of the SCN circadian clock. Notably, however, studies of dissociated SCN neurons reveal that a more severe phenotype is observed at the level of single SCN neurons from knockout mice, relative to SCN explants maintained under similar conditions or the *in vivo* phenotype (Liu et al., 2007; Welsh et al., 2010). A small population of weakly functional oscillators apparently can use the network properties of the SCN to generate coherent rhythmicity (DeBruyne, 2008; Welsh et al., 2010).

Clock-Controlled Genes: From the Core Clockwork to Cellular Rhythms

Genes that participate in the core negative feedback loop and whose gene family are necessary for its function are called "clock genes." The impact of the molecular feedback loop occurs through the rhythmic regulation of "clock-controlled genes," which are distinguished from clock genes by the fact that they do not feed back on the core oscillatory mechanism in a manner that makes them necessary for rhythmicity. Some clock-controlled genes with E-box elements in their regulatory regions are controlled in the same manner as *Pers* and *Crys*: their transcription is directly activated by CLOCK:BMAL1 and inhibited by the activity of the PER/CRY complexes disrupting this transcriptional activation. The neuropeptide arginine vasopressin (AVP) is a prototype for this mechanism (Jin et al., 1999). The rhythmic expression of AVP mRNA in the SCN leads to a high-amplitude circadian rhythm of AVP peptide in the cerebrospinal fluid that is insulated from the more well-known osmotic regulation of AVP in blood (see Chapters 37 and 38). The rhythmic synthesis and secretion of AVP from SCN neurons may modulate electrical activity of nearby neurons, increasing the amplitude of the ensemble SCN neuronal firing rhythm and thus affecting many rhythms. AVP of SCN origin also appears to play a role in regulation of the hypothalamo-pituitary-adrenal axis (Chapter 38).

Notably, products of some genes regulated by the CLOCK:BMAL1 complex are themselves able to regulate transcription through additional regulatory elements. For example, a family of D-element binding proteins (DBP/HLF/TEF and E4BP4) are controlled via E-box elements, and these proteins compete for occupation of elements in responsive genes. Regulation of *Rev-erb-α* and *Rora*, noted previously, also occurs through E-box mediated activation. Thus, the rhythmic regulation of these transcription factors, and the multiple regulatory element combinations that can occur in responsive genes, results in a cascade leading to rhythmic gene expression with many possible peak times of expression and with tissue-specific regulation (Ueda et al., 2005).

Summary

The basis for circadian oscillation is a molecular feedback loop. A phase of transcriptional activation alternates with a phase of transcriptional repression, and the cycle length of this rhythm is approximately 24 hours. The bHLH-PAS proteins CLOCK and NPAS2 heterodimerize

with BMAL1 to produce E-box-dependent transcriptional activation. Among the genes controlled primarily by E-box regulation are *Per1* and *Per2*; their high-amplitude temporal regulation is critical to determining the timing of transcriptional repression. PER protein abundance regulates the formation of inhibitory complexes containing PERs, CRYs, and casein kinase proteins. These complexes recruit transcriptional repressors and negate the activity of the activator complex. Post-translational events including phosphorylation and ubiquitination of PERs and CRYs are important for building a time delay into the feedback loop; altering these activities alters circadian cycle length. In parallel with the regulation of "clock genes," the molecular feedback loop regulates the expression of effector genes and also of transcription factors. Through these concentric waves of transcriptional activity, the circadian clock can affect the expression of key (often rate-limiting) genes, in a tissue-specific manner.

CIRCADIAN PHOTORECEPTION IN MAMMALS

In the following sections, we discuss the mechanisms by which the circadian clock in the mammalian SCN is synchronized to the daily light:dark cycle.

Entrainment of the SCN Pacemaker Occurs through Daily Phase Shifts

The intrinsic period of the circadian pacemaker is revealed by measuring it in constant environmental conditions, or in animals made insensitive to light by disruption of anatomical pathways from the eye to the SCN. Rhythms that are not entrained (e.g., not synchronized by a rhythmic environmental cue) are referred to as "free-running" rhythms. The period length of rhythms that are free-running is usually not exactly 24 hours (Fig. 39.1). Instead, the circadian oscillator has a species-typical intrinsic period. Rats housed in constant darkness have a free-running period of approximately 24.3 hr, while mice under the same conditions free-run with a period of approximately 23.6 hr. There are strain variations within these species as well.

For an animal to entrain to a light:dark cycle that has a 24-hour cycle length, light must shift the animal's clock each day by an amount equal to the difference between their intrinsic, free-running period and the 24-hour period of the lighting cycle. While it might seem simpler for the clock to have a cycle length of exactly 24 hours (and forget about daily readjustments), there is seasonal variation in lighting conditions in natural environments, most notably a seasonal change in the length of the light period each day. A timekeeping system that tracks dusk and dawn each day is needed for accurate entrainment under these circumstances.

In assessing the response of the circadian system to light, it is often more informative to assess the response of animals to brief light pulses rather than to full light-dark cycles. A brief pulse of light is provided when an animal is free-running in constant conditions, allowing control over the timing, intensity, and even wavelength of the stimulus. Experiments of this type reveal that the response of the circadian system to light depends strongly on the time of the day at which the light exposure occurs (Fig. 39.9). In constant conditions, the time when the animal "thinks" it is night (as reported by its locomotor activity rhythm) is referred to as "subjective night," while the time that corresponds to internal daytime is "subjective day." Light falling early in the subjective night leads to a phase delay—for example, activity on subsequent days begins at a later time, consistent with a light-induced shift in the timing of the oscillator (Fig. 39.9C). Conversely, light exposure late in the night will cause a phase advance (Fig. 39.9D, E). During large portions of the animal's subjective day, light exposure does not lead to a phase shift (Fig. 39.9A). Plotting the response to brief pulses of light against the time of the light exposure leads to a phase response curve (PRC; Fig. 39.9F). In general, the shape of the PRC to brief light pulses is very similar across species, whether nocturnal, diurnal, or crepuscular, and regardless of whether their intrinsic period is less than or greater than 24 hours. With very strong stimulation (e.g., long duration or bright light exposure) the clock can be reset to a specific point in the circadian cycle (so-called "type 0 resetting"). Many pharmacological stimuli also cause phase-dependent phase shifts of the SCN oscillator, and the shape of the PRC to nonphotic stimuli differs from the PRC to light.

A Specific Retinal Photoreceptive System Mediates Circadian Entrainment to Light

In mammals, detection of light by the circadian system requires the presence of the retina. A direct anatomical connection from the retina to the SCN was first identified in the early 1970s. This retino-hypothalamic tract is necessary and sufficient for photic entrainment of circadian rhythms.

Remarkably, the retinal photoreceptors required for visual image formation are not necessary for circadian photoreception. Studies of mutant mice show that circadian sensitivity to light persists even with virtually complete loss of the rods and cones. Other nonvisual responses to light (inhibition of locomotor activity, suppression of nocturnal melatonin secretion, and constriction of the pupil in response to light) also occur in the absence of rods and cones. These findings suggested that a nonrod, noncone photoreceptive cell mediates these "nonvisual" responses to light.

An opsin-like pigment, melanopsin, was initially identified as a putative photopigment in the light-responsive

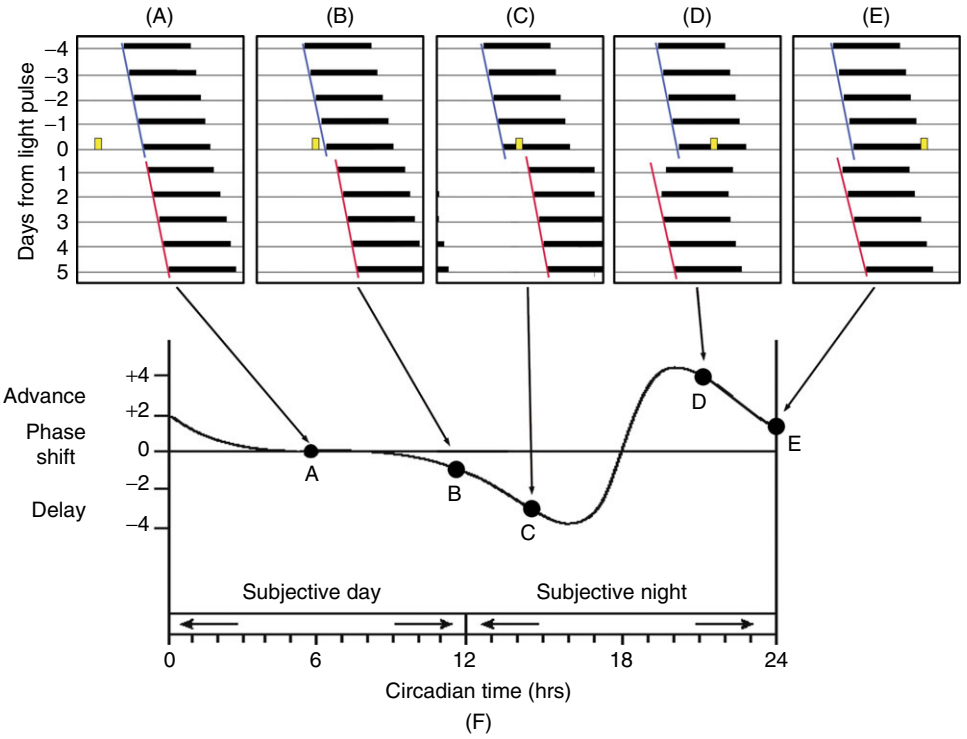

FIGURE 39.9 Phase-dependent effects of light on circadian rhythmicity. (A–E) Schematic representation of the phase-dependent phase shifts that occur following exposure of free-running animals to brief pulses of light. Each panel represents an actogram of one animal housed in constant darkness and exposed to a single 1-hour light pulse (yellow box). The phase shift is the difference, on the day of the light pulse, between a line drawn through activity onsets before the light pulse (blue lines) with a line through activity onsets after the light pulse (red line). In some cases, the behavioral shift is not complete on the first cycle after the light exposure, and the shift seems to occur over several days. The intermediate activity onsets are called "transients" and are ignored when determining the phase after the shift. (F) Phase Response Curve. The phase shift induced by a brief light pulse is highly dependent on the time at which the light exposure occurred. Circadian Time (CT)12 is defined as the time of activity onset in a nocturnal animal. Light exposure occurring during the biological daytime (CT0–12) does not cause a shift. Responses occur only during the animals' biological nighttime. Early in the subjective night, light exposure delays the clock, so activity begins at a later time on subsequent cycles. Late in the subjective night, light exposure causes a phase advance, as detected by earlier activity onsets on the days after the light pulse. Phase-dependent phase shifts allow the circadian oscillator to be entrained to environmental cycles.

melanophores of frog skin, and was later found to be expressed in a subset of retinal ganglion cells (RGCs) in the mammalian retina (Provencio, Jiang, De Grip, Hayes, & Rollag, 1998; Provencio, 2011). More recently, melanopsin has been shown to contribute to circadian photoreception in the mammalian retina. Melanopsin is expressed in a relatively small population (~2400) of RGCs in each mouse eye (Fig. 39.10A). Melanopsin-containing retinal ganglion cells respond directly to light, even when isolated from the rods and cones. Their intrinsic photosensitivity requires the presence of melanopsin.

The population of intrinsically photosentitive RGCs (ipRGCs) is heterogeneous in laminar distribution of dendritic arborization, cellular morphology, level of expression of melanopsin, central projections, and also in function (Schmidt, Chen, & Hattar, 2011). Five subtypes (M1–M5) are recognized (Ecker et al., 2010). Melanopsin can be detected in the M1 subtype by immunohistochemistry (Fig. 39.10B). Mice in which lacZ is inserted into the melanopsin locus provide another way to view melanopsin-expressing cells, although beta-galactosidase staining is detectable only in the M1 subtype. This blue stain is also readily detected in the M1 cells' projections into the central nervous system (Fig. 3.10C,D). The M1's densely innervate the SCN, the intergeniculate leaflet (IGL), and the olivary pretectal nucleus (OPN), a site critical for pupillary constriction in response to light. Additional projections of the M1 class provide innervation to the ventrolateral preoptic area, important in the regulation of sleep, and to the ventral subparaventricular zone (vSPZ), implicated in the inhibition of locomotor activity by light. The M1 class (~700 RGC's) can be further subdivided based on expression of the transcription factor Brn3b. The Brn3b-negative M1 group (~200 cells) is critical for circadian photoentrainment (Chen, Badea, & Hattar, 2011). The Brn3b-expressing M1's mediate pupillary constriction in response to light (Güler et al., 2008). Remarkably, ipRGCs are sufficient for visual pattern discrimination and photic induction of immediate-early gene expression in visual cortex, even in the absence of rod-cone signaling (Ecker et al., 2010).

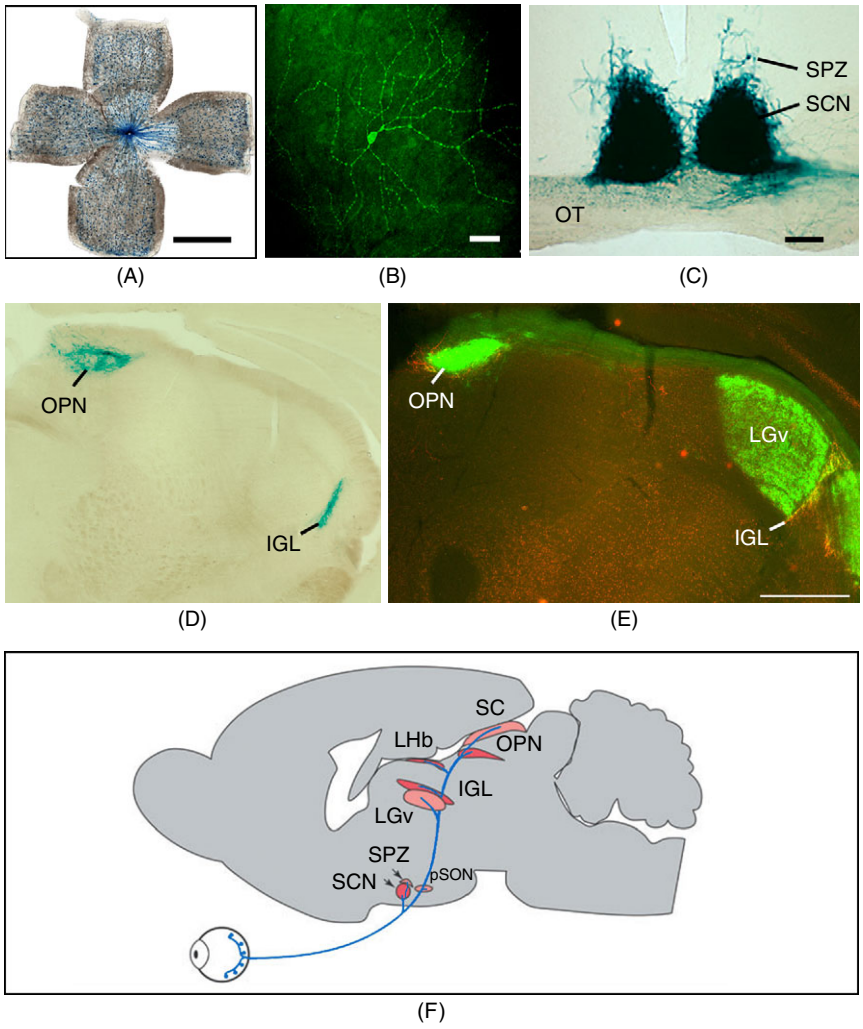

FIGURE 39.10 Retinal ganglion cells containing melanopsin innervate the SCN and other "nonvisual" targets. (A) Melanopsin-expressing retinal ganglion cells. Melanopsin-expressing retinal ganglion cells were detected in this whole-mount preparation of a postnatal day 5 mouse retina using a beta-galactosidase reporter gene inserted into the melanopsin locus. Tissue was processed for histochemical detection of beta-galactosidase activity, resulting in deposition of blue reaction product in cells and processes containing melanopsin. Note the sparse distribution of labeled retinal ganglion cells (individual blue dots); axons course toward the head of the optic nerve in the center of the field. Scale bar is 1 mm. *Images in panels A, C, D, E, and F provided by Samer Hattar, Johns Hopkins University.* (B) Immunofluorescence image of a ganglion cell in the human retina stained for melanopsin. Melanopsin immunoreactivity appears green. Note the large dendritic field of the cell, the localization of melanopsin throughout the dendritic tree, and dendritic varicosities. These cells are ill-suited for spatial localization, but are ideally suited for luminance detection because the entire cell is photosensitive. Scale bar = 100 microns. *Image provided by Ignacio Provencio, University of Virginia.* (C) The SCN receives a strong, bilateral input from melanopsin-containing RGC's. Central projections of melanopsin-expressing retinal ganglion cells were detected using a beta-galactosidase reporter gene inserted into the melanopsin locus as described in Panel A. Melanopsin-containing cell bodies are present only in the retina, so the blue staining seen in the brain represents axonal projections of these retinal neurons. The right eye of the animal had been removed over 2 weeks prior to staining. Labeled, retinal fibers in the optic tract (OT) have degenerated on the apparent left side of the image, leaving weak, granular labeling. The staining in the SCN remains strong on both sides, indicating the extensive, bilateral projections to the SCN. Melanopsin-containing processes also extend into the subparaventricular zone (SPZ). Scale bar = 100 microns. (D) Central projections of melanopsin-containing retinal ganglion cells, revealed by beta-galactosidase staining. The olivary pretectal nucleus (OPN) and intergeniculate leaflet (IGL) receive a crossed input from melanopsin-expressing retinal ganglion cells. (E) Melanopsin is localized within a subset of retinal projections. The anatomical level is comparable to Panel D. Projections of the entire population of retinal ganglion cells were revealed by intraocular injection of cholera toxin B subunit three days prior to tissue collection, allowing anterograde labeling of the fibers of all retinal ganglion, followed by detection of the toxin which appears green. Note the intense labeling in the dorsal lateral geniculate nucleus (LGd). Melanopsin expression in retinal terminals was detected by red immunofluorescence; in this merged image, the overlap of red and green channels in the melanopsin-containing retinal ganglion cells yields yellow labeling in the IGL and OPN. Scale bar (for panels D and E) = 500 microns. (F) Schematic illustration of the axonal projections of the M1 class of melanopsin-expressing retinal ganglion cell as revealed by beta-galactosidase staining. Principle targets (SCN, OPN, IGL, and lateral habenula [LHb]) are indicated by dark red shading. Less extensively innervated structures indicated by light red shading are the SPZ, superior colliculus, peri-supraoptic nucleus, and ventral subdivision of the lateral geniculate nucleus. Minor targets (not shown) include the preoptic area, bed nucleus of the stria terminalis, medial amygdaloid nucleus, anterior hypothalamic area, lateral hypothalamus, LGd, and periaqueductal gray. (See Hattar *et al.*, 2006.)

The phototransduction mechanism in melanopsin-containing cells appears to be more similar to the invertebrate visual signaling cascade (in which phosphoinositide signaling activates cation channels of the transient receptor potential channel type), rather than through the typical vertebrate photoreceptor cascade involving transducin, cGMP, and cyclic nucleotide gated ion channels.

Despite being well positioned to serve as the circadian photoreceptive molecule, melanopsin is in fact not the only photopigment involved in circadian photoreception. Melanopsin-deficient mice have a reduction in the effects of light on phase shifting, negative masking of locomotor activity, and pupillary responses at high light intensities, but these responses to light are not completely absent (Provencio, 2011). Importantly, mice that lack rod and cone function and also lack melanopsin appear completely blind with respect to both image formation and nonimage forming responses to light (Fig. 39.11). Rods and cones can signal through the melanopsin-expressing RGC's, even if the latter cells are melanopsin-deficient. Destruction of the melanopsin-expressing cells, however, blocks nonvisual photoreception (Güler et al., 2008; Hatori et al., 2008). Thus, rod-cone input converges on the melanopsin-containing retinal ganglion cells, and parallel pathways that control different nonvisual image formation functions arise from defined subsets of these ipRGCs (Schmidt et al., 2011).

Retinal Input to the SCN: Anatomy and Neurochemistry

The melanopsin-expressing retinal ganglion cells that project to the SCN use glutamate as their primary neurotransmitter. A large percentage of these retinal neurons also contain the neuropeptide Pituitary Adenylate Cyclase Activating Peptide (PACAP). Application of these agents to SCN slices *in vitro* causes phase-dependent phase shifts of intrinsic SCN rhythms. Furthermore, glutamate receptor antagonists block light-induced phase shifts *in vivo*, revealing the functional importance of glutamatergic input to the SCN.

Axon collaterals of the melanopsin-positive retinal ganglion cells innervate neurons in the intergeniculate leaflet (IGL) that express neuropeptide Y (NPY). These NPY-containing neurons project to the SCN as the geniculohypothalamic tract. The geniculohypothalamic tract is thought to play a major role in nonphotic phase shifting, a phenomenon in which behavioral arousal (usually accompanied by intense locomotor activity) during the circadian day leads to increased NPY release within the SCN and leads to a phase shift of activity rhythms. The indirect retinal pathway through the intergeniculate leaflet also appears to modulate photic entrainment. The direct retino-hypothalamic tract and the indirect retino-geniculo-hypothalamic pathway converge in the SCN, in the "core" region defined by the dense retinal input and by a subpopulation of neurons expressing vasoactive intestinal peptide (VIP). Another major input to the SCN core is a serotonergic input from the raphe nuclei, which modulates the impact of light input to the SCN through presynaptic serotonin receptors on retinohypothalamic tract terminals.

Molecular Mechanisms of Entrainment: Light-Induced *Per* Expression

Per1 and *Per2* gene expression levels are rhythmic in the SCN, with high levels during the daytime (Fig. 39.7). These molecular rhythms persist in constant darkness. Exposure

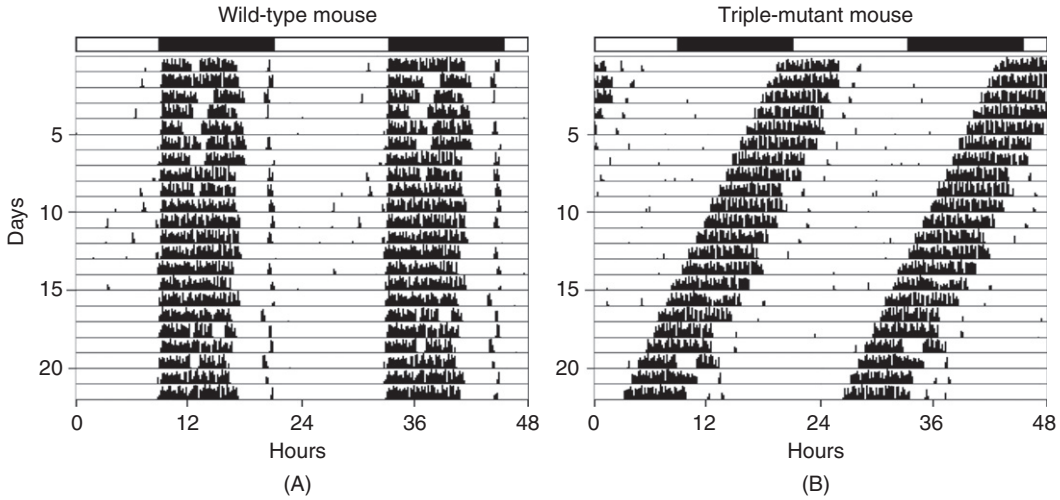

FIGURE 39.11 Rods, cones, and intrinsically photosensitive retinal ganglion cells expressing melanopsin mediate circadian entrainment. (A) is a double-plotted actogram of a control mouse showing normal entrainment to the light:dark cycle. (B) shows a double-plotted actogram from a triple-mutant mouse, lacking rod and cone phototransduction mechanisms and also lacking melanopsin. Triple-mutant animals free-run as though there is no lighting cycle. Triple-mutant animals also lack pupillary constriction responses and acute inhibition of locomotor activity by light (Hattar et al., 2003). The disruption of rod and cone signaling is accomplished by breeding to generate animals homozygous for disruption of the alpha subunit of rod transducin and the cone cyclic nucleotide gated channel A3 subunit. *Actograms provided by Samer Hattar, Johns Hopkins University.*

to light at night causes a large, transient increase in both *Per1* and *Per2* transcript levels. *Per* gene expression in the SCN is unresponsive to light exposure during the subjective daytime, when light exposure does not cause phase shifts. The temporally "gated" induction of *Per1* and *Per2* gene expression is likely mediated by activation of MAP kinase and CREB phosphorylation by retinal input, leading to induction of *Per1* and *Per2* expression through Ca^{2+}/cAMP response elements (CRE) in the promoters of these genes. (A third *Period* gene, *Per3*, lacks a promoter CRE element and is unresponsive to light even at night. *Per3* has, at most, a very modest contribution to the core circadian oscillatory mechanism or the resetting mechanism).

Increased *Per1* and *Per2* expression are the only widely reproducible changes in clock gene expression that occur in response to light, focusing attention on these genes as important transducers of the effects of light on the molecular clock. Studies in mutant mice reveal that neither gene is necessary for phase shifting responses to light, however (Pendergast et al., 2010). *Per1* and *Per2* may be redundant in function for phase shifting, with either gene able to mediate the re-setting response in the absence of the other.

Peak nuclear PER1 and PER2 protein levels occur at the time of the light-to-dark transition (Fig. 39.7). Light-induced increases in PER1 and PER2 protein early in the night would extend the period of transcriptional inhibition by the PER/CRY complex. This may be the mechanism by which light exposure early in the night causes a phase delay. In contrast, light-induced PER expression late in the night would lead to an earlier-than-normal initiation of PER/CRY-mediated inhibition, resulting in an advance of SCN molecular rhythmicity in subsequent cycles. Thus, light-induced alterations of PER expression and interaction of the light-induced PER with the molecular feedback loop may explain the phase-dependent phase shifting effect of light shown in Figure 39.9.

While light does not influence *Per* levels during the animal's subjective daytime and does not cause phase shifts at this time, nonphotic manipulations can cause phase shifts when administered during the daytime (e.g., novelty-induced voluntary locomotor activity, arousal, serotonin receptor activation). These manipulations lead to *reduced Per* gene expression in the SCN. Thus, acute regulation of *Per* gene expression may be the mechanism by which a variety of manipulations affect circadian phase.

Summary

The circadian clock in the SCN is entrained to the daily light-dark cycle by light causing phase-dependent phase shifts each day. While the retinae are required for entrainment, the retinal photoreceptors necessary for visual image formation, the rods and cones, are not needed. Instead, a population of intrinsically photoreceptive retinal ganglion cells conveys information about the level of light to the SCN and to other brain regions that regulate nonvisual photoreception. The photopigment in these retinal ganglion cells is melanopsin, and they utilize glutamate and PACAP as their transmitters. In the absence of melanopsin, rods and cones appear capable of signaling through the ipRGC's to result in nonvisual responses to light, including entrainment. Specific subsets of melanopsin-expressing cells have distinct functions. The impact of nocturnal light exposure on SCN physiology includes numerous signaling responses and induction of *Per* gene expression. Light-induced alterations in *Per* gene expression likely provide a key role in resetting of the molecular feedback loop within SCN neurons.

CIRCADIAN OUTPUT MECHANISMS

From Molecular Feedback Loops to Firing Rate Rhythms

The molecular feedback loop within individual SCN neurons ultimately has its impact on physiological processes through regulation of SCN neuronal firing rate (Kuhlman & McMahon, 2006). Rhythmic regulation of potassium channels in the membrane of SCN neurons appears to be critical for producing circadian rhythms in membrane potential and firing rate.

Large-conductance, calcium-activated potassium channels (BK channels) are rhythmically expressed in the SCN, with high levels of transcript levels and BK channel activity during the night contributing to the reduction in firing rate at night (Meredith et al., 2006). Disruption of the BK channel (*Kcnma1*$^{-/-}$) results in higher SCN firing rate selectively at night, and the mutant mice have greatly reduced amplitude of several circadian output rhythms.

In addition, the fast delayed rectifier (FDR) current is critical for robust circadian rhythms in behavior. The Kv3.1 and Kv3.2 potassium channels and their activity are more abundant in the SCN during the circadian daytime, and blocking their activity reduces SCN rhythmicity (Itri, Michel, Vansteensel, Meijer, & Colwell, 2005). Mice lacking both the *Kcnc1* and *Kcnc2* genes do not express the Kv3.1 and 3.2 channels in the SCN, have greatly reduced FDR current, and have severely disrupted circadian behavioral rhythms (Kudo, Kuljis, Constance, & Colwell, 2011). It thus appears that multiple ionic mechanisms contribute to rhythmicity in SCN neuronal firing rate, and regulation of channel activity is probably accomplished through both transcriptional and post-transcriptional mechanisms.

Rhythmic firing of SCN neurons not only serves as its mechanism of communication with downstream target regions, but also plays an important role in synchronizing the cellular oscillators within the SCN to each other. When

sodium-dependent action potentials are blocked for several days, SCN neurons become desynchronized from one another. The mechanism for this may be as simple as the loss of rhythmic, synaptic release of neurotransmitters, including VIP. Indeed, synaptic vesicle cycling plays an important role in the regulation of circadian rhythms (Deery et al., 2009).

Humoral Outputs from the SCN Also Influence Locomotor Activity Rhythms

The rhythmic electrical activity of SCN neurons likely leads to rhythmic neurotransmitter release and modulation of downstream, synaptic targets along defined anatomical pathways as discussed in greater detail below. Several lines of evidence indicate that the SCN also influences locomotor activity through secretion of humoral output molecules. Among these lines of evidence are the findings that (1) transplants of fetal SCN tissue that restore locomotor activity rhythms do not restore other rhythms, including endocrine rhythms, and (2) transplanted SCN tissue encapsulated so as to allow diffusion of small molecules while preventing axonal outgrowth nevertheless can restore locomotor activity rhythms in SCN-lesioned hamsters (Silver, LeSauter, Tresco, & Lehman, 1996). The latter finding suggests that substances secreted by the SCN act in regions near the SCN (but not in the SCN itself) to regulate locomotor activity. Three substances proposed to play a role in regulating locomotor activity rhythms in rodents are transforming growth factor alpha, cardiotropin-like cytokine 1, and prokineticin 2.

Summary

For oscillations in the abundance of circadian clock gene products in SCN neurons to affect physiology and behavior, the molecular feedback loop must impact on more overt aspects of cellular rhythmicity. One mechanism for this to occur is through circadian regulation of transcripts encoding ion channels; indeed, potassium channels have been identified that contribute to circadian rhythmicity. Through regulation of potassium channel activity, rhythmic transcription factor activity is translated into rhythmicity in neuronal firing rate and neurotransmitter release. While much of the output of the SCN comes via synaptic interactions to downstream targets, substances released from the SCN by a humoral mechanism can also influence locomotor activity.

DIVERSITY OF OUTPUT PATHWAYS LEADING TO PHYSIOLOGICAL RHYTHMS

Animals that lack circadian rhythms (those with destruction of the SCN or genetic disruption of key circadian clock genes) survive, and these animals generally can reproduce. Nevertheless, the circadian timing system is thought to optimize "internal temporal order" by coordinating rhythms in different tissues, and to allow anticipation of physiological demands imposed by the predictably changing environment. The impact of the circadian oscillator is exerted through the rhythmicity it imposes on physiological functions.

The following sections address the regulation of several physiological rhythms. In most cases, we emphasize how these rhythms are "wired" to the SCN through neuroanatomical pathways and emphasize rhythms for which the SCN can be viewed as a driving pacemaker. It is important to note that SCN-generated physiological rhythms can also entrain peripheral oscillators, without a direct SCN-to-target output (Kornmann et al., 2007; Vollmers et al., 2009; Buhr, Yoo, Takahashi, 2010; see Fig. 39.3). Subsequent tissue-autonomous rhythmicity can profoundly influence physiology and response to perturbations (Box 39.4) (Kornmann et al., 2007; Marcheva et al., 2010; Sadacca, Lamia, deLemos, Blum, & Weitz, 2011)

Amplification of SCN Output and Divergence of Output Pathways

Considering the pervasive influence of the SCN on rhythmic physiology, the direct anatomical output of the SCN is surprisingly limited. SCN efferents project heavily to a column of cells dorsal and caudal of the SCN, including the subparaventricular zone (SPZ) and the dorsomedial nucleus of the hypothalamus (DMH) (Figs. 39.12 and 39.13). Neurons in the SPZ and DMH in turn project to brain regions that ultimately regulate rhythmic activities (Fig. 39.13). Many effector regions receive a small, direct innervation from the SCN that converges with the larger, indirect output via the SPZ. The SPZ thus appears to relay and reinforce the direct output of the SCN, and allows convergence of influences from other brain areas. Lesions that kill cell bodies in the ventral SPZ (while leaving axons passing through the region intact) disrupt the circadian rhythms of sleep/wakefulness and locomotor activity (Lu et al., 2001). Amplification of SCN output in the vSPZ is thus necessary for these rhythms; direct SCN output to target sites is insufficient. In a similar manner, fiber-sparing lesions of the dorsal part of the SPZ (dSPZ) selectively disrupt the body temperature rhythm while leaving sleep and activity rhythms intact.

Another level of amplification and integration occurs in the DMH, which is heavily innervated by the ventral SPZ as well as receiving direct innervation from the SCN (Figs. 39.12 and 39.13). Lesions of the DMH specifically disrupt circadian rhythms of sleep, locomotor activity, corticosterone secretion and feeding, but not body temperature (Chou et al., 2003).

BOX 39.4

CHRONOPHARMACOLOGY

Many drugs, toxins, and stressors have effects that vary over the 24-hour day. Many of these variations represent true circadian rhythms in responses—for example, they persist in constant environmental conditions. Chronopharmacology is the subdiscipline of chronobiology that seeks to identify and understand these rhythms, and it is an important field, since altering the time of drug administration can have a profound impact on its efficacy, toxicity, and the ratio between these two measures (the therapeutic index). For this reason, there is often a specific time for optimal response to a chemotherapeutic agent, and this optimal timing varies between agents depending on their mechanism of action. Rhythmicity in drug effects could be due to alterations in bioavailability (absorption, metabolism, or excretion) or in end organ sensitivity. Rhythmic variation in therapeutic index has been well documented for several chemotherapeutic agents and anesthetics. There are also robust rhythms in responses to toxic agents, including infectious agents such as *E. coli* and endotoxin derived from bacterial cell walls. Recent studies have begun to unravel the molecular mechanisms underlying rhythms in detoxification and drug sensitivity, and focus attention on rhythmicity within target cell populations.

Circadian Regulation of Sleep and Wake

Among the most widely recognized roles of the circadian timing system is in the regulation of behavioral state. Our level of alertness is strongly influenced by two biological factors: the time previously spent awake and the circadian time (see Chapter 40). There is a strong and opposing influence of circadian time and the time spent awake, a phenomenon described as the "opponent-process" model for behavioral state control. With increasing time awake, subjects experience a greater homeostatic drive to sleep. The circadian timing system opposes this drive, by providing an arousing signal that reaches peak levels late in the afternoon/early evening in humans.

The influence of the circadian timing system on sleep is mediated by SCN efferents that indirectly reach the brain regions regulating sleep. As noted above, a pathway from the SCN via the vSPZ and DMH is necessary for circadian regulation of sleep. In contrast to the sparse connections of the SPZ to sleep-regulatory areas, the DMH is a primary source of input to the ventrolateral preoptic area (VLPO) and to the neurons of the lateral hypothalamus that secrete the neuropeptide orexin, that are critical for regulation of sleep. The output from the DMH to the VLPO is GABAergic, therefore promoting wakefulness by inhibiting the "sleep switch" neurons. The output from the DMH to the orexin neurons in the lateral hypothalamus contains glutamate and thyrotropin-releasing hormone, and is

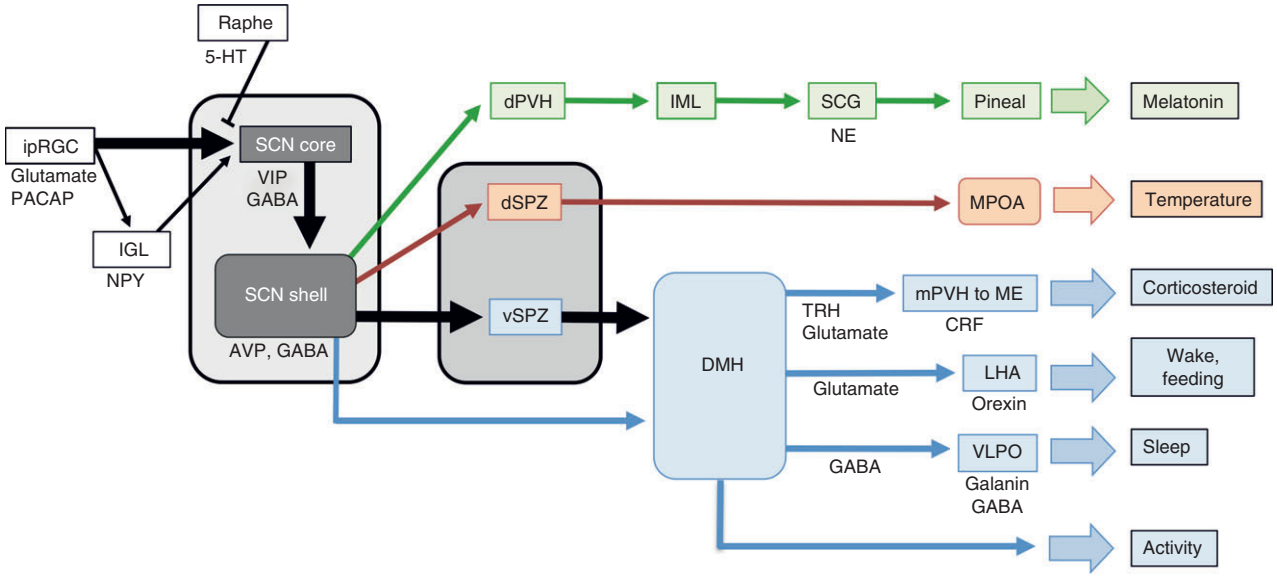

FIGURE 39.13 Schematic of the rodent circadian system, with emphasis on the divergence of output pathways. Rhythmically regulated events are listed on the right, and the pathways leading to their circadian regulation are shown. Major inputs to the SCN are the melanopsin-containing ipRGC's, neuropeptide Y (NPY)-containing neurons in the intergeniculate leaflet (IGL), and serotonergic afferents from the raphe that influence the RHT input. Inputs converge primarily in the core region, although many additional regions project into the SCN (not shown). The SCN core region projects extensively to the shell. The major output of the SCN arises from the shell and is directed caudally to the subparaventricular zone (SPZ). The dorsal subparaventricular zone (dSPZ) projects to the medial preoptic area (MPOA), and is important for circadian regulation of core body temperature. Axons from the ventral SPZ (vSPZ) and direct SCN projections converge in the dorsomedial hypothalamic nucleus (DMH). From the DMH arise distinct projections critical for the circadian regulation of the hypothalamic-pituitary-adrenal axis, sleep/wake and feeding; the next anatomical site along each of these pathways is indicated. The DMH is also critical for regulation of locomotor activity rhythms, but effector structures are not clear. Regulation of the adrenal rhythm and of pineal melatonin secretion occur through the medial parvicellular paraventricular nucleus (mPVH) and dorsal parvicellular PVH (dPVH), respectively. Where known, neurotransmitters are indicated. Abbreviations: LHA, lateral hypothalamic area; VLPO, ventrolateral preoptic area; ME, median eminence; NE, norepinephrine; PACAP, Pituitary adenylate cyclase activating peptide; TRH, thyrotropin releasing hormone.

presumably excitatory, thus promoting wakefulness. While the DMH has few direct projections to the brainstem areas that comprise the ascending arousal system, the orexin neurons have extensive, excitatory projections to these regions (Saper, Lu, Chou, & Gooley, 2005). Thus, a multistage pathway from the SCN to sleep regulatory centers allows integration of other inputs (emotional and cognitive inputs as well as the homeostatic drive for sleep) and promotes sharp transitions between states, rather than direct control of behavioral state. The importance of orexin neurons in coordinating the activity of this system is revealed by narcolepsy, a sleep disorder caused by autoimmune destruction of the orexin-containing neurons in the lateral hypothalamus, and mimicked in animal models by disruption of orexin or orexin receptors (see Chapter 40).

One relatively small subclass of sleep disorders are the circadian-based sleep disorders (Box 39.3). While most insomnias are due to difficulty in initiation or maintenance of sleep, or are related to airway patency during sleep (sleep apnea), circadian-based sleep disorders involve problems with the relative timing of sleep. Transient disruption of sleep often occurs with attempts to shift the relative timing of sleep, as occur in shift work and jet lag (Box 39.5)

Circadian Regulation of Neuroendocrine Functions

The SCN output pathway leading to rhythms in adrenal corticosteroid secretion starts with a projection to the paraventricular nucleus of the hypothalamus (PVN). A subset of neurons in the PVN contain corticotrophin releasing hormone (CRH), and project to the external zone of the median eminence. CRH, released into the pituitary portal system, regulates the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary. ACTH, in turn, is carried in the bloodstream to the adrenal gland, where it stimulates secretion of adrenal steroids. Adrenal steroids feed back to inhibit CRH and ACTH release in a typical neuroendocrine feedback loop (see Chapter 38). This feedback loop is modulated by the circadian timing system, however: the set point for steroid feedback apparently varies over the course of the day (e.g., higher corticosteroid levels are required to reduce ACTH release at some times of day than at others). As a result, corticosteroid levels vary over the course of the day with a sinusoidal rhythm. Light exposure at night can activate the sympathetic innervation of the adrenal gland via the SCN,

BOX 39.5

JET LAG AND SHIFT WORK

Jet lag is induced by flying across several time zones and represents the lack of coordination of the flyer's body to the new local time. Individuals usually entrain to a phase-shifted environment at the rate of about 1 hour per day, although careful control over when light exposure occurs may improve this rate.

Another environmentally imposed disruption of circadian rhythms occurs with shift work. Most people working the night shift remain entrained to the solar day, so that their biological rhythms (e.g., alertness, temperature and hormonal rhythms) are in opposition to the demands of the work schedule. Some of the negative health effects of shift work may be due to the stress caused by trying to sleep when the biological clock dictates it is time to be awake, and trying to be alert and productive when the body expects rest. Clear performance deficits occur when individuals attempt to work for extended periods, ignoring the need for sleep. Performance deficits also occur at specific times of day, irrespective of prior sleep history.

In rodent models, repeated shifting of the light-dark cycle, as occurs with jet lag or shift work, can have significant adverse consequences on health. Circadian clocks normally coordinate internal rhythms to each other and to the environment. Disrupting this coordination may similarly have adverse consequences on human health.

bypassing the pituitary and directly increasing corticosteroid production (Ishida et al., 2005).

The SCN also regulates circadian rhythms in other neuroendocrine activities. In rodents, the timing of ovulation is strictly regulated and occurs early in the active period on the day of behavioral estrus (de la Iglesia & Schwartz, 2006). Ovulation is blocked by injection of the anesthetic pentobarbital early in the afternoon on the day of estrus. Remarkably, ovulation then occurs the following day—exactly 24 hours after it should have occurred. Ovariectomized, estradiol-treated female rats also have daily surges of luteinizing hormone in the late afternoon. This is the neuroendocrine equivalent of ovulation, occurring in the absence of the ovaries. These luteinizing hormone surges persist when animals are housed in constant darkness and are not present in animals with SCN lesions. An SCN-dependent neuronal output leads to daily activation of gonadotropin releasing hormone-containing neurons (de la Iglesia, Meyer, Schwartz, 2003).

Twice-daily prolactin surges can be induced in female rats by mating (or by vagino-cervical stimulation that mimics mating, induces pseudopregnancy). The prolactin surges are timed by the SCN. These prolactin surges are ultimately regulated by dopamine released from the median eminence. Feedback of prolactin on the hypothalamic dopamine neurons is also important. VIP neurons in the SCN and oxytocin neurons in the PVN appear to be involved in regulating the hypothalamic dopamine neurons and thus the prolactin surges (Egli, Bertram, Sellix, Freeman, 2004).

Circadian Regulation of Autonomic Function

Many physiological rhythms are regulated by autonomic function. Pathways resulting in rhythmic autonomic activity originate in the SCN, utilize GABA as a neurotransmitter, and generally project to the paraventricular nucleus of the hypothalamus (PVN). Neurons in the PVN (many containing oxytocin) have direct projections to the spinal cord, where they regulate the activity of autonomic preganglionic neurons. Additional pathways include modulation of vagal activity. These pathways regulate

autonomic responses leading to circadian variation in blood pressure and heart rate. These pathways also influence metabolism through direct innervation of fat pads and the liver, the latter of which contributes to the circadian rhythm in plasma glucose levels (Cailotto et al., 2005; Kalsbeek et al., 2006).

Circadian Regulation of Pineal Function

One very well-characterized output rhythm regulated via the autonomic nervous system is the rhythmic production of melatonin. This rhythm is regulated by an anatomical pathway pathway from the SCN via the PVN to the pineal gland (Fig. 39.14A). GABA released from SCN neurons inhibits neurons in the PVN during the day, while the reduction in SCN GABA release at night apparently allows the PVN neurons to be more active, driving melatonin synthesis (Kalsbeek et al., 2000). The PVN neurons project to autonomic preganglionic neurons in the intermediolateral cell column of the spinal cord. The preganglionic neurons project to the superior cervical ganglion, whose fibers innervate the pineal gland. Norepinephrine from these fibers increases the activity of the penultimate enzyme in melatonin biosynthesis, arylalkylamine N-acetyltransferase (AANAT), leading to melatonin synthesis (Fig. 39.14B). AANAT activity is controlled by a combination of transcriptional mechanisms and switch-like regulation of proteasomal degradation of AANAT protein.

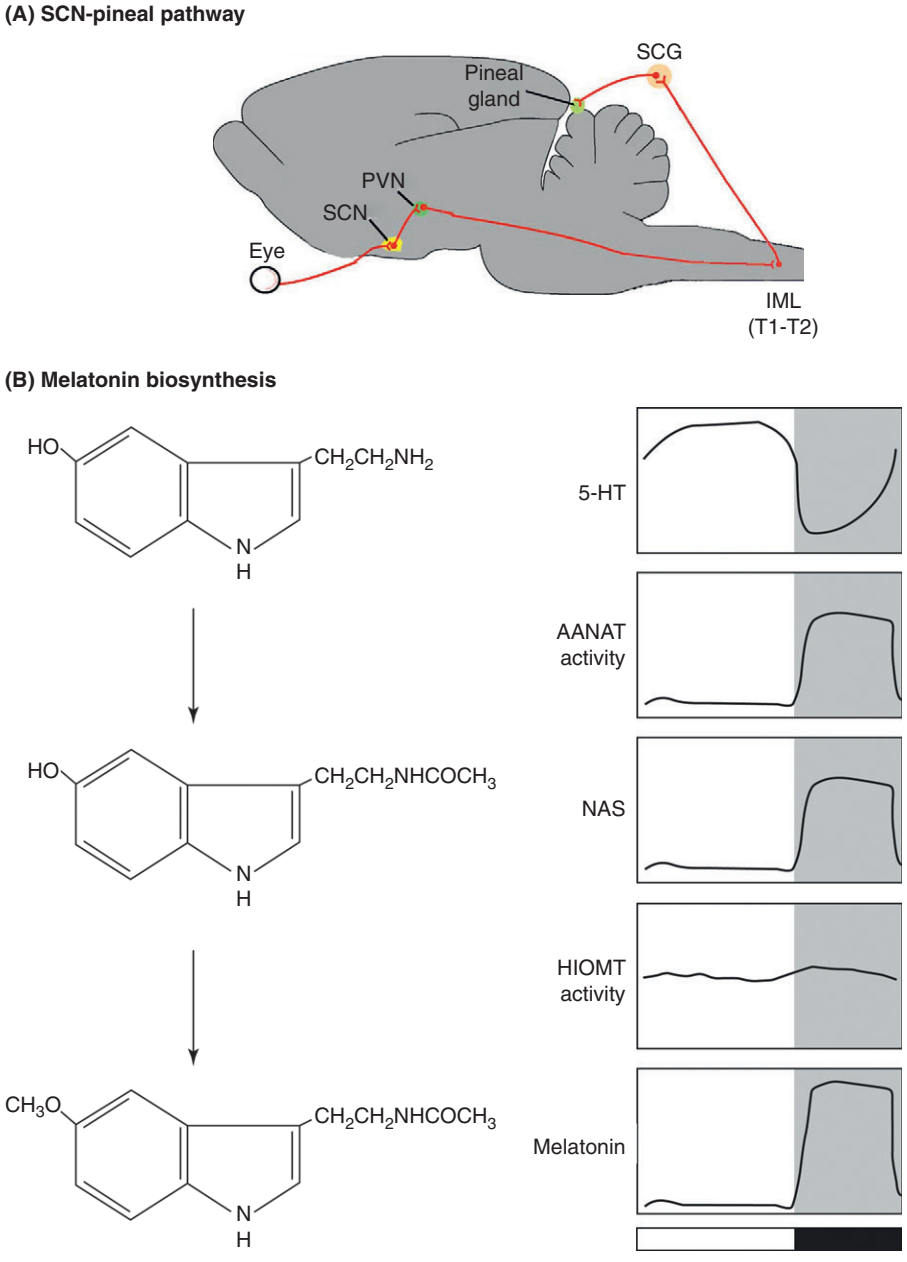

FIGURE 39.14 (A) Schematic illustration of the neuroanatomical circuit regulating pineal melatonin secretion. Photic input detected in the retina is relayed to the suprachiasmatic nucleus (SCN), and then to the paraventricular nucleus of the hypothalamus (PVN). A subset of PVN neurons projects to the intermediolateral cell column (IML) of the spinal cord. Preganglionic sympathetic cell bodies at thoracic levels T1 and T2 project to the superior cervical ganglion (SCG), which innervates the pineal gland. Norepinephrine released from the terminals of SCG neurons is the primary input to the pineal responsible for stimulating melatonin production at night. Light entrains the SCN clock controlling melatonin, but light at night also acutely inhibits melatonin synthesis by disrupting the sympathetic input to the gland. Blood melatonin levels drop within minutes after exposure to light at night. (B) Biosynthesis of melatonin from serotonin (5-hydroxytryptamine, 5-HT). The rate-limiting and highly rhythmic step is the regulation of arylalkylamine N-acetyltransferase activity, which modestly depletes the pineal gland of 5-HT at night as it converts 5HT to N-acetyl-serotonin (NAS). Hydroxy-indole-O-methyltransferase (HIOMT) converts NAS to melatonin (N-acetyl,5-methoxytryptamine). There is no storage mechanism for melatonin; melatonin diffuses into the cerebrospinal fluid and bloodstream as it is produced, making blood melatonin levels a good reflection of the sympathetic input to the pineal gland.

Circadian Regulation of Melatonin Is Critical for Seasonal Reproduction

Several strategies exist to deal with the varying environmental conditions and varying levels of resources that occur over the course of the year. These strategies include seasonal migration to allow highly mobile species to escape challenging conditions (Box 39.6), and, for those species that remain, seasonal regulation of physiology and behavioral adaptation (see Box 39.1).

Many mammalian species restrict breeding activity to specific times of year, resulting in birth of young in the spring and summer months when food is abundant and conditions are most favorable for their survival. Responses to seasonal changes in day length (so-called "photoperiodic responses") include seasonal reproduction, but also extend to an array of physiological responses including seasonal molting of the coat (mediated by seasonal alterations in prolactin secretion), thermoregulatory adjustments (daily torpor and hibernation), alterations in metabolism and body weight, and alterations in behavior. These adjustments improve the probability of survival through challenging times. Like circadian rhythms, these seasonal responses are driven by a system that anticipates predictable environmental changes and prepares for them in a predictive, rather than reactive, manner.

BOX 39.6

LOST WITHOUT A CLOCK

A most fascinating function of circadian clocks is their use in time-compensated sun compass orientation, a phenomenon that was first described by Karl von Frisch in foraging honeybees and by Gustav Kramer in migratory birds. Time-compensated sun compass orientation is also used by eastern North American monarch butterflies (*Danaus plexippus*) during their spectacular fall migration. During the fall journey, the butterflies use their navigation skills to fly south from the United States and southern Canada to overwinter in a few restricted sites atop the Transvolcanic Mountains in central Mexico, some having traveled distances approaching 4000 kilometers.

The amazing navigation abilities of monarch butterflies are part of a genetic program initiated in the migrants, as those that make the trip south are at least two generations removed from the previous generation of migrants. Time-compensated sun compass orientation is believed to be an essential component of navigation required for successful migration. Time compensation is provided by the butterfly's circadian clock. The clock allows the butterflies to continually correct their flight direction, relative to changing skylight parameters, to maintain a fixed flight bearing as the sun moves across the sky during the day (Fig. B39.6A). The importance of the circadian clock in regulating the time-compensated component of flight orientation in monarch butterflies has been shown in two ways. First, clock-shift experiments, in which the light-dark cycle is either advanced or delayed, cause predictable alterations in the direction the butterflies fly (Fig. B39.6B). Second, removing the time compensation clocks abolishes the time-compensated component of flight orientation (Fig. B39.6C). It is thus clear that time compensation is a requirement for successful migration.

Steven M. Reppert

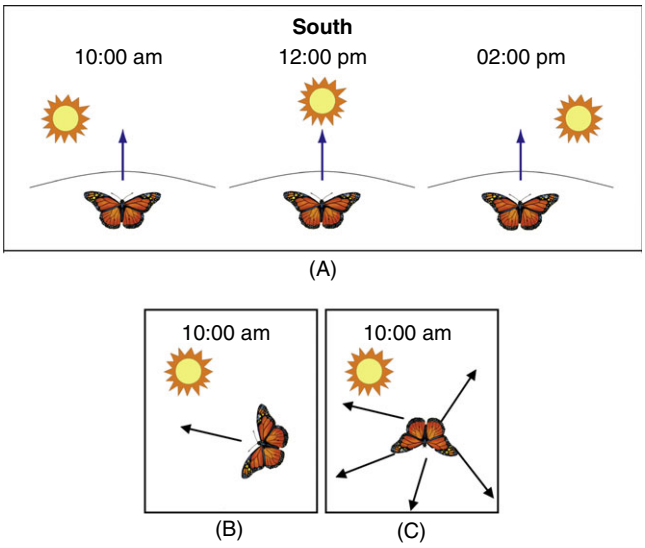

FIGURE B39.6 (A) Monarch butterflies use a time-compensated sun compass to orient south during their fall migration. The butterfly circadian clock allows the butterflies to compensate for the movement of the sun. They are thereby able to maintain a constant bearing in the southerly direction over the course of the day. (B) Clock-shift experiment. When monarch butterflies are housed in a light-dark cycle that is advance by 6 hours, relative to ambient lighting, the butterflies perceive the 10:00 a.m. sun to be a 4:00 p.m. sun and shift their orientation counterclockwise to the southeast. (C) Removal of the time-compensation clocks, which reside in the antennae and not in brain, disrupts the migration south, and the butterflies are not able to successfully travel to their overwintering grounds. The arrows depict disrupted flight directions.

The SCN-controlled circadian rhythm of pineal melatonin production controls photoperiodic responses in mammals. Melatonin is secreted into the bloodstream at night by the pineal gland. The nocturnal duration of melatonin secretion changes in parallel with the length of the night: the melatonin secretory duration thus encodes season. Removal of the pineal gland prevents seasonal responses to changes in day length, while administration of melatonin in patterns that mimic the profiles occurring at different times of year can predictably drive reproduction and other photoperiodic responses.

The actions of melatonin are mediated by specific, G-protein coupled receptors. Two receptors subtypes with high affinity for melatonin have been identified in mammals. The MT1 (Mel_{1a}) receptor subtype is responsible for the majority of melatonin receptor binding found in SCN and elsewhere in brain, while the MT2 (Mel_{1b}) receptor is expressed at considerably lower levels. Several photoperiodic species lack a functional MT2 receptor gene, suggesting that the MT1 receptor may be key for regulating seasonal responses.

A site containing a high concentration of MT1 receptors is the pituitary pars tuberalis (PT). Melatonin acting in the PT affects prolactin release from the anterior pituitary gland. In addition, melatonin acts in the PT to affect gonadotrophin secretion by a circuitous route that has just been unraveled. Melatonin regulates thyroid stimulating hormone (TSH) beta expression in the PT by controlling the expression of Eya3. This transcriptional coactivator interacts with the circadian transcription factor, TEF, which binds to a D-box in the TSHβ promoter, stimulating expression (Dardente et al., 2010). TSH from the PT then acts through TSH receptors located in the mediobasal hypothalamus, altering the balance between synthetic and catabolic enzymes regulating thyroid hormone. A local increase in the biologically active form of thyroid hormone, T_3, within the mediobasal hypothalamus promotes GnRH secretion, leading to gonadotropin secretion and reproduction function. Melatonin, by regulating this local TSH-to-T_3 cascade, has a profound impact on reproductive function in seasonally breeding species.

Summary

The proximate output of the SCN is a rhythm of neuronal firing, which results in rhythmic synaptic and perhaps humoral activation of additional brain regions. The major SCN target is a region dorsal and caudal of the SCN, including the subparaventricular zone (SPZ) and extending into the dorsomedial hypothalamic nucleus (DMH). This extensive projection appears to amplify SCN synaptic output and provides a mechanism for the SCN to influence a wide variety of downstream targets in a manner that can be site-specific. The anatomical pathways leading to specific behavioral and physiological rhythms have been defined to varying extents. Already within the subparaventricular zone, there is divergence of the output pathway controlling rhythms in sleep/wake and locomotor activity (which requires the ventral SPZ) from the pathway regulating body temperature (which requires the dorsal SPZ).

One of the most extensively studied outputs is the pathway regulating melatonin production, involving the SCN, PVN, and sympathetic innervation of the pineal gland. The circadian regulation of melatonin secretory duration regulates reproduction and other photoperiodic responses in seasonally breeding species. The regulation of photoperiodic responses is the most obviously adaptive role for circadian rhythmicity in mammals.

GENERAL SUMMARY

Behavioral and physiological rhythmicity is widespread throughout the animal kingdom. A capacity for cell-autonomous rhythmicity exists in many cell types. Circadian rhythmicity in vertebrates and flies is based on an intracellular molecular feedback loop. Many components of this molecular feedback loop have been elucidated in the past 20 years. There is frequently redundancy of function between closely related genes in mammals. The SCN serve as the coordinating pacemaker in the mammalian circadian timing system. In the absence of the SCN, rhythms in other tissues generally degrade because the synchronization between oscillators is lost. The SCN clock is entrained primarily by light. Lighting information is detected by a specific luminance-coding retinal system that involves intrinsically photosensitive retinal ganglion cells that also serve as a conduit for information originating in rod and cone photoreceptors. SCN axonal output is focused dorso-caudally to the subparaventricular zone, and then diverges along specific anatomical pathways to control a diverse array of rhythmic functions. Among the most physiologically important output rhythms in mammals is the regulation of pineal melatonin, as this hormone is key to regulating photoperiodic adjustments in response to changing day length. Other circadian outputs are of less obvious survival value, but an increasing understanding of the importance of the circadian influence on sleep/wake, metabolism, cardiovascular and neuroendocrine function, and resistance to toxicological challenges indicates that the circadian system dictates an "internal temporal order" that improves physiological and mental performance.

CHAPTER

40

The Neurobiology of Sleep and Dreaming

Sleep is a behavioral state that alternates with waking and occupies one-third of our lives. It is characterized by a recumbent posture, a raised threshold to sensory stimulation, a low level of motor output, and a unique behavior: dreaming.

In contrast to sleep, the conscious behavior of waking is characterized by an active and deliberate sensorimotor discourse with the environment. For maintenance of waking behavior, neural gates must remain open for sensory input and motor output, the brain must be tuned and activated, and the chemical microclimate must be appropriate for processing and recording of information.

THE TWO STATES OF SLEEP: RAPID EYE MOVEMENT (REM) AND NON–RAPID EYE MOVEMENT (NREM) SLEEP

Sleep Architecture

The electrical activity of the brain during sleep reveals two distinct substates—rapid eye movement (REM) and non-REM (NREM) sleep—that alternate with a cycle of about 90 minutes (Fig. 40.1B), indicating their control by an endogenous neuronal oscillator. NREM phases are deeper and longer early in the night, whereas the proportion of each cycle occupied by REM is much greater during cycles later in the night (Fig. 40.1A).

NREM and REM sleep are characterized and distinguished using polysomnography (PSG), an electrophysiological recording technique that employs electroencephalography (EEG), electrooculography (EOG), and electromyography (EMG) (Fig. 40.2, middle panel). Combinations of tonic (enduring) and phasic (transient) events in these three types of channels traditionally define sleep stages and substages using the Rechtschaffen and Kales (1968) manual, recently revised with new nomenclature (Iber, Ancoli-Israel, Chesson, & Quan, 2007). The EEG channel tracings of each of these stages are shown in Figure 40.3.

Sleep onset—that is, the onset of Stage 1 NREM sleep (N1 in new nomenclature)—is gradual and characterized by slowing in brain wave frequency from the waking EEG that consists predominantly of beta (14–25 Hz) and gamma (30–80 Hz) frequencies when the eyes are open (Fig. 40.3, first trace) and alpha (8–13 Hz) when the eyes are closed (Fig. 40.3, second trace), to a predominance of theta rhythm (4–7 Hz) in N1 (Fig. 40.3, third trace). During N1, characteristic slow eye movements are recorded in the EOG, EMG muscle tone is diminished relative to waking, awareness of the outside world is lost, and "hypnogogic" dreamlike imagery may occur. As NREM sleep deepens through NREM Stages 2, 3, and 4 (now termed N2 and N3, in which N3 encompasses prior Stages 3 and 4), muscle tone further diminishes, and, in the EEG, changes consist of a progressive decrease in the predominant EEG frequency that is accompanied by a progressive increase in average wave amplitude.

As N1 transitions to N2 (Fig. 40.3, fourth trace), the EEG further slows in the predominantly theta range, and two distinctive phasic wave forms, sleep spindles (De Gennaro & Ferrara, 2003) and K-complexes (Colrain, 2005) occur. Sleep spindles are intermittent clusters of spikes at sigma frequency (12–16 Hz) with characteristic waxing and waning morphology. Spindles occur in two varieties: slow spindles with frequencies approximately 12–14 Hz that appear most strongly in frontal scalp EEG leads and fast spindles (approximately 14–16 Hz) that appear most strongly at centro-parietal EEG leads (Merica, 2000). Sleep spindles are generated by a distinct thalamocortical circuitry detailed in a later section. K-complexes consist of a large negative (upward) deflection in the EEG followed by a positive (downward) deflection and are also generated by thalamo-cortical interactions.

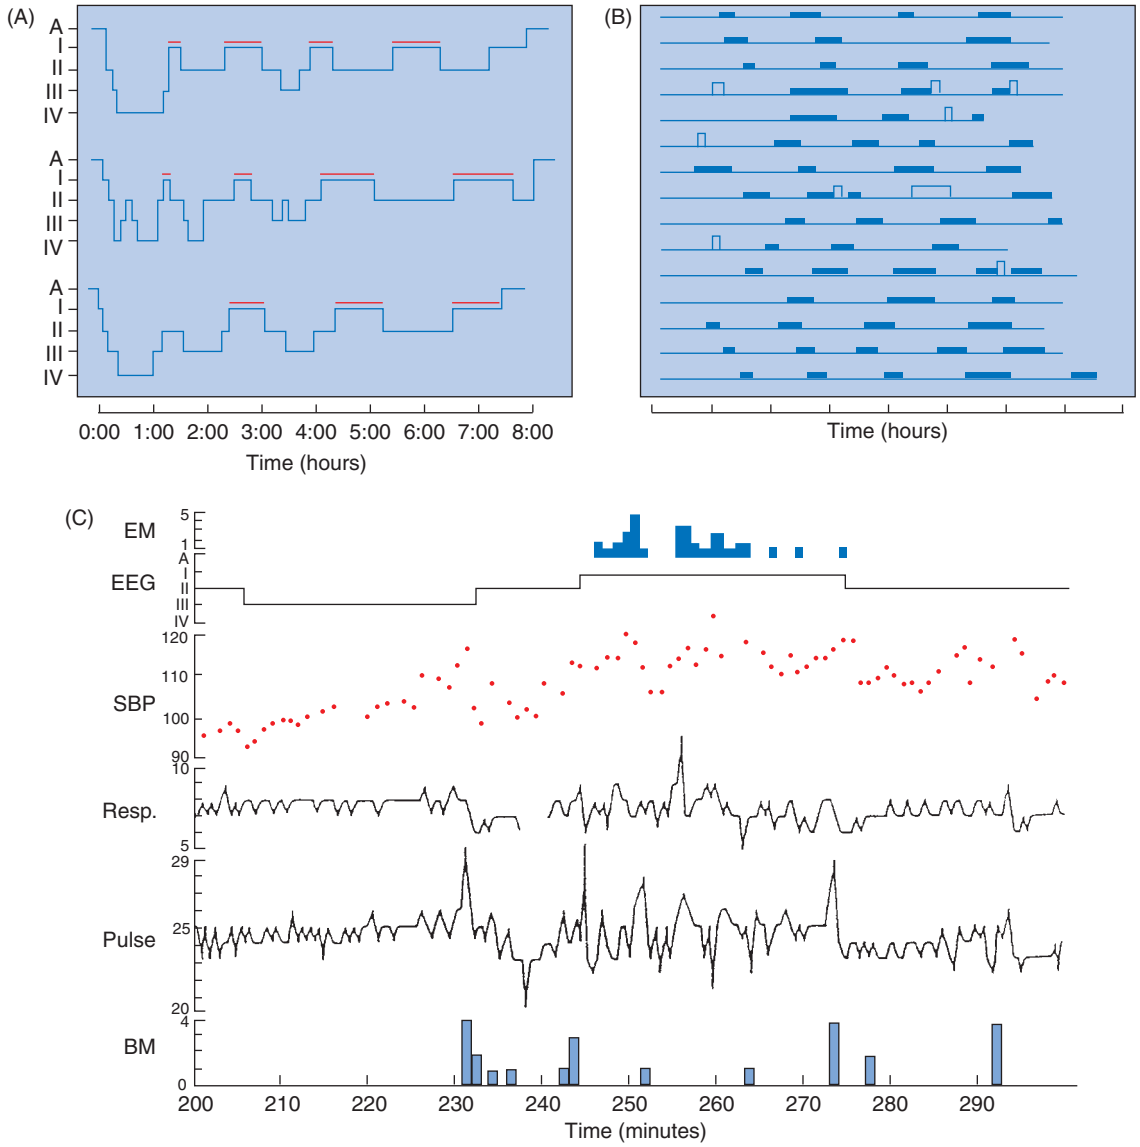

FIGURE 40.1 Periodic activation in sleep cycles. (A) The sleep stages of three people are graphed. The first two or three cycles of the night are dominated by deep stages (3 and 4) of NREM sleep, and REM sleep (indicated by red bars) is brief or nonexistent. During the last two cycles of the night, NREM sleep is lighter (stage 2), and REM episodes are longer, sometimes more than an hour. (B) Fifteen nights of sleep. Each line represents one night of sleep, with REM periods shown as solid bars and periods of wake as taller, open bars. Each record begins at the onset of sleep. The amount of time before the first episode of REM varies, but once REM has begun, the interval between episodes is fairly constant. (C) Eye movements (EM) in numbers per minute, EEG (as scored sleep stage), systolic blood pressure (SBP) in mmHg, respiration (Resp.) in breaths per minute, pulse in beats per quarter minute, and body movement (BM) in numbers per minute over 100 minutes of uninterrupted sleep. The interval from 242 to 273 minutes is considered the REM period, although eye movements are not continuous during that interval.

In N3, also known as slow wave (SWS) or delta sleep (Fig. 40.3, fifth trace), many fewer sleep spindles occur, and EEG frequency further slows and displays increasing predominance of high amplitude delta (0.5–4.0 Hz) waves (Dijk, 2009). In the early 1990s, a yet slower oscillatory rhythm of less than 1 Hz, the "slow oscillation," was described in cats and, shortly afterward, in humans (Steriade, 2006). The slow oscillation shows maximal spectral power in SWS and exerts an organizing or "grouping effect" on delta oscillations, spindles, and K-complexes (Steriade, 2006). As NREM deepens from N1 to N3, the threshold for arousal rises in proportion to the degree of EEG slowing, and during N3, awakenings are difficult, incomplete and brief. Those awakened from this state are confused, have difficulty reporting conscious experience, and return to sleep rapidly, especially early in the night. While dreaming also occurs during NREM sleep (Fig. 40.2, bottom panel), it is much more strongly associated with the activated brain state of REM.

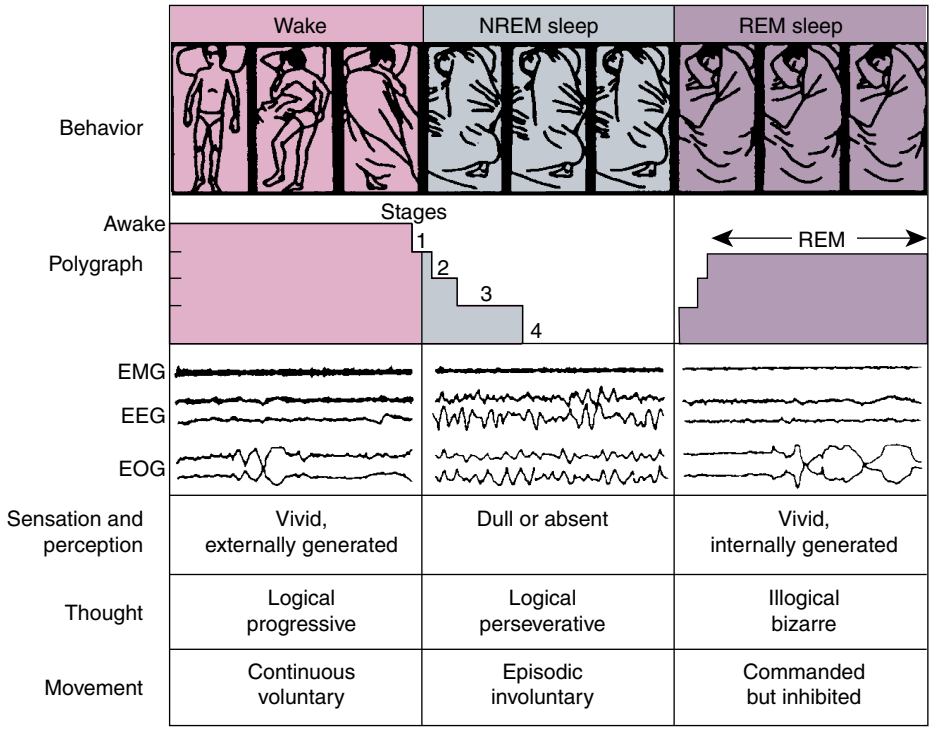

FIGURE 40.2 Behavioral states in humans. Body position changes during waking and at the time of phase changes in the sleep cycle. Removal of facilitation (during stages 1–4 of NREM sleep) and addition of inhibition (during REM sleep) account for immobility during sleep. In dreams, we imagine that we move, but no movement occurs. Tracings of electrical activity are shown in ~20-s sample records. The amplitude of the electromyogram (EMG) is highest in waking, intermediate in NREM sleep, and lowest in REM sleep. The electroencephalogram (EEG) and electrooculogram (EOG) are activated in waking and REM sleep and inactivated in NREM sleep. *Reprinted with permission from Hobson and Steriade (1986).*

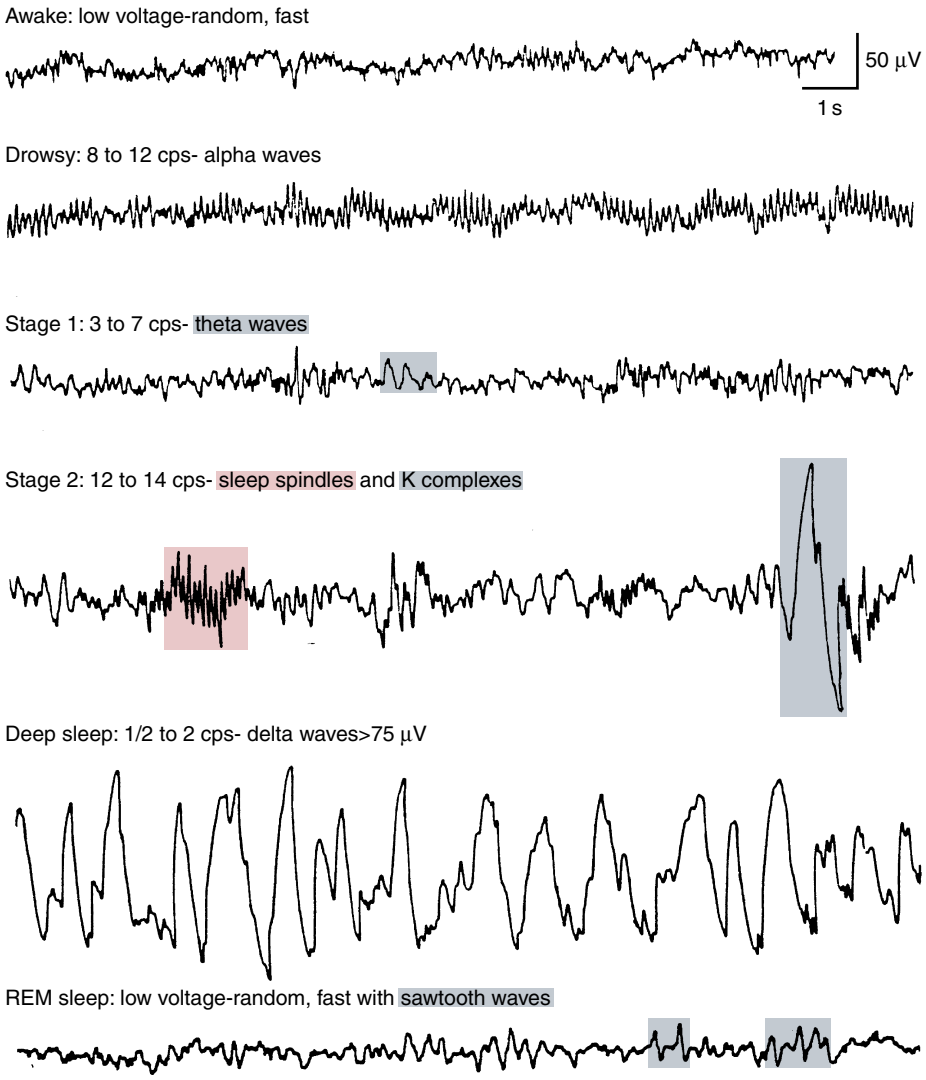
REM sleep, discovered in 1953 by Eugene Aserinsky and Nathaniel Kleitman (Aserinsky & Kleitman, 1953), has also been termed "paradoxical" sleep because, whereas its fast mixed-frequency EEG resembles waking (Fig. 40.3, sixth trace), muscle tone reaches its minimum level (see Mallick et al., 2011, for extensive reviews). This EMG minimum in REM results from central, brainstem-mediated inhibition of spinal alpha motor neurons ("REM atonia"; Chase, 2008). Postural shifts precede and follow REM sleep (Fig. 40.2, upper panel). REM has also been termed "active" sleep because of its wakelike low-amplitude, high-mixed-frequency EEG, as well as "desynchronized" sleep, in contrast with "synchronized" NREM, especially SWS, in which high-amplitude waves reflect synchronous activity of thalamic and cortical neurons (described below). A characteristic EEG feature of REM sleep in humans is the "sawtooth wave" (Fig. 40.3, sixth trace). During REM, unlike waking, there is inhibition of sensory input and motor output. Subjects aroused from REM sleep, especially during periods with frequent eye movements, often give detailed reports of dreams characterized by vivid hallucinations, bizarre thinking, and intense emotion (Fig. 40.2 bottom panel).

As its name suggests, saccadic (rapid) eye movements (REMs) occur during REM (Fig. 40.1C), singly and in clusters, reflecting the fact that, unlike skeletal muscles, oculomotor muscles maintain tonus in REM. REMs are believed to reflect underlying, central phasic neuronal events also appearing as peripheral muscle twitches (that briefly overcome atonia), middle-ear muscle movements (MEMAs), and peri-orbital potentials (PIPs). In humans, phasic REM events are likely related to ponto-geniculo-occipital (PGO) waves. PGO waves are phasic field potentials that, in the REM sleep of cats, are recorded sequentially in the pons (P), lateral geniculate body of the thalamus (G), and the occipital cortex (O) (Datta & Maclean, 2007), and which also have recently been demonstrated in humans (Lim et al., 2007). In contrast to such phasic events, the tonic wakelike REM EEG reflects cortical activation by the cholinergic ascending arousal systems described below (Saper, Fuller, Pederson, Lu, & Scammell, 2010).

Central Autonomic Control Systems Are State Dependent

Sympathetic outflow diminishes in the transition from waking to NREM, and during SWS, parasympathetic outflow is predominant. Many autonomic and regulatory functions, such as heart rate, blood pressure, and respiration rate, diminish in NREM sleep (Fig. 40.1C), but some neuroendocrine activity, such as release of growth hormone from the pituitary, increases (Pannain & Van Cauter, 2007). With the onset of REM, sympathetic influence increases, although not to the level of waking, and cardiovascular and respiratory measures become more variable (Trinder et al., 2001; Fig. 40.1C). Active temperature and respiratory control are greatly diminished in REM sleep (Hobson, 1989). In mammals, sleep and thermoregulation can exert reciprocal influence on one another through shared circuitry in the preoptic anterior hypothalamus (Parmeggiani, 2003).



Awake: low voltage-random, fast
50 μV
1 s
Drowsy: 8 to 12 cps- alpha waves
Stage 1: 3 to 7 cps- theta waves
Stage 2: 12 to 14 cps- sleep spindles and K complexes
Deep sleep: 1/2 to 2 cps- delta waves>75 μV
REM sleep: low voltage-random, fast with sawtooth waves

FIGURE 40.3 Electroencephalograms showing electrical activity of the human brain during different stages of sleep.

NEURAL CONTROL OF THE SLEEP–WAKE AND REM/NREM CYCLES

ARAS Sensorimotor and Neuromodulatory Neurons

Most of the classic reticular core neurons have very specific afferent inputs and highly organized outputs that underlie the multiple functions of the brainstem, such as sensory input, motor output, and autonomic control. These reticular neurons receive inputs from skin, muscle, bone, and joint receptors in the periphery, which they integrate and link to the vestibular and cerebellar circuits that determine posture and movement (see Chapter 29). Performing an entirely different function are small groups of neurons that send widely branching axons to distant parts of the brain where their neurotransmitters modulate brain function and play an essential role in behavioral state regulation including control of sleep/wake and REM/NREM cycles. These ARAS modulatory neurons differ from neighboring sensorimotor neurons in both morphology and characteristic firing patterns.

Sensorimotor neurons, approximately 50 to 75 microns in diameter, can fire continuously at high rates of up to 50 Hz and can generate bursts of up to 500 Hz. Their larger axons, especially those projecting to the spinal cord, have conduction velocities in excess of 100 m/s (Hobson & Steriade, 1986), making these neurons well suited to rapid posture adjustment and motor control. In contrast, modulatory neurons are smaller (10–25 microns in diameter), and even those with long axons conduct their signals very slowly (1 m/s). Modulatory neurons fire wider spikes (2 ms in duration) at much slower tonic frequencies (1–10 Hz) than sensorimotor neurons. In addition, they

often show a very regular, metronome-like firing pattern, a reflection of their pacemaker properties. As their leaky membranes spontaneously and slowly depolarize, they reach threshold, fire, and then self-inhibit, becoming refractory even to exogenous excitatory inputs (Ramirez, Tryba, & Peña, 2004). Because of their vast postsynaptic domain, they can help set behavioral and mental states.

ARAS Neuronal Groups Involved in Behavioral State Regulation Produce Specific Neuromodulators

Modulatory ARAS neuronal groups produce specific types of neuromodulators (Dahlstrom & Fuxe, 1964). Norepinephrine (NE) neurons are located in the pons and medulla in two major groups. The lateral tegmental group consists of scattered neurons in the ventral and lateral reticular formation and appear to be involved in hypothalamic regulation and motor control (Moore & Card, 1984). Neurons of the second and major NE cell group, the locus coeruleus (LC), are located in the rostral pontine reticular formation and central gray matter. One group of LC neurons projects caudally to sensory regions of the brainstem and spinal cord, and another projects widely to the cerebellar cortex, dorsal thalamus, and cerebral cortex (Moore & Card, 1984). Thus, LC neurons are likely to be involved in regulating sensory input and cortical activation. Serotonin (5-HT) neurons are located in the raphe nuclei that extend, in the ARAS midline, from caudal medulla to midbrain in the dorsal (DR) and median raphe nuclei. These neurons project rostrally and innervate nearly the entire forebrain, again suggesting a role in regulation of behavioral state. The other important set of brainstem reticular formation nuclei involved in behavioral state control produce acetylcholine (ACh) and include two pontine nuclei: the laterodorsal tegmental (LDT) and the pedunculopontine (PPT) nuclei. Cholinergic neurons in these nuclei project to the brainstem reticular formation, hypothalamus, thalamus, and basal forebrain. A second set of cholinergic neurons in the basal forebrain (described below) projects to the limbic forebrain and neocortex. In contrast to these modulatory (5-HT, NE, and ACh) neurons, neurons in brainstem reticular formation nuclei involved in sensorimotor integration typically produce the excitatory transmitter glutamate or the inhibitory amino acids gamma-aminobutyric acid (GABA) and/or glycine.

Waking Requires Active Maintenance

The reticular formation is necessary to maintain the waking conscious state (Moruzzi & Magoun, 1949). Lesions in the midbrain reticular formation result in a state that resembles NREM sleep. Maintenance of the waking state requires brain mechanisms that compete with other active mechanisms that promote sleep. Multiple neurochemical systems maintain cortical arousal, and this redundancy allows the waking state to persist in the face of deficiency or destruction of specific arousal-related neurons (Saper et al., 2010).

These nuclei and their respective neurotransmitters and targets (Fig. 40.4) include the basal forebrain (BF) nuclei (medial septum, nucleus of the diagonal band, substantia innominata–nucleus basalis) that send ACh projections to topographically specific cortical and subcortical limbic areas (Jones, 2008); hypothalamic neurons (i) producing the neuropeptide orexin (also called hypocretin) in the lateral (LH) and perifornical (PFH) hypothalamus that project to other arousal systems as well as the entire cerebral cortex (Ohno & Sakurai, 2008), and (ii) histamine (HA)-producing neurons from the tuberomammilary

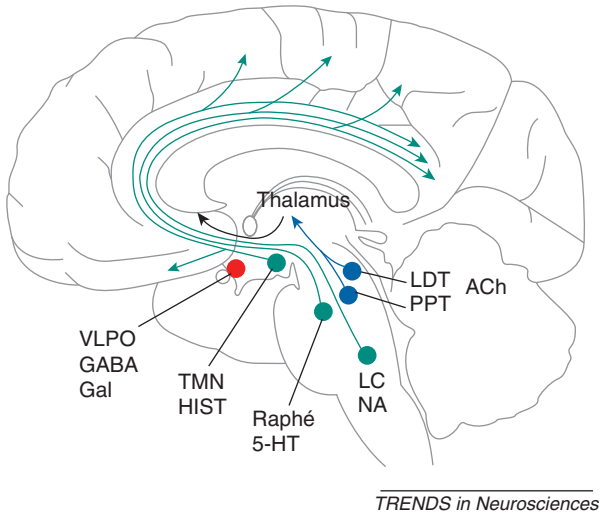


FIGURE 40.4 Ascending arousal systems of the brainstem and posterior hypothalamus and sleep-promoting areas of the anterior hypothalamus. Nuclei producing wake-promoting monoaminergic neuromodulators are shown in green. These include noradrenaline (NA)-producing neurons of the locus coeruleus (LC) and serotonin (5-HT)-producing neurons of the dorsal raphe (Raphe), both located in the mesopontine brainstem, as well as histamine (HIST)-producing neurons of the tuberomammilary nucleus (TMN), located in the posterior hypothalamus. These nuclei project to and activate widely distributed terminal fields throughout the forebrain. Nuclei shown in blue produce acetylcholine (ACh), which promotes forebrain activation in both waking and REM sleep. Cholinergic nuclei include the pedunculopontine (PPT) and laterodorsal (LDT) tegmental nuclei of the mesopontine brainstem as well as cholinergic nuclei of the basal forebrain (not shown). Cholinergic neurons of the PPT and LDT project to the thalamus and basal forebrain that then, in turn, send arousal-promoting projections to both distributed and regionally specific terminal fields in the forebrain. Shown in red are sleep-promoting neurons of the ventrolateral preoptic (VLPO) area of the anterior hypothalamus. VLPO neurons produce the inhibitory neuromodulator gamma-amino butyric acid (GABA) and the inhibitory neuropeptide galanin (Gal). VLPO neurons project to and inhibit the above wake-promoting neurons, thereby promoting and maintaining sleep. In turn, the wake-promoting neurons of the LC, DRN, and TMN reciprocally innervate and inhibit the neurons of the VLPO. *From Saper et al. (2001).*

nucleus (TMN) of the posterior hypothalamus (PH), which send widespread projections to diverse forebrain sites (Szymusiak & McGinty, 2008); midbrain neurons producing dopamine (DA) from specifically wake-active centers in the midbrain periaqueductal gray (PAG; Saper et al., 2010) that are distinct from midbrain substantia nigra pars compacta (SNpc) and ventral tegmental (VTA) area dopaminergic neurons (that, respectively, promote movement via projection to the basal ganglia, and appetitive behaviors via projection to the ventral striatum and prefrontal cortex); and mesopontine (junction of pons and midbrain) nuclei that include (i) ACh-producing PPT and LDT projecting to the diencephalon, basal forebrain, and restricted portions of the cortex; (ii) NE-producing LC neurons that send widespread projections to the forebrain; and (ii) 5-HT-producing DR neurons that also widely project to the forebrain (for reviews, see Pace-Schott & Hobson, 2002; Saper et al., 2010).

Certain neurochemical systems also promote cortical arousal indirectly. For example, cholinergic neurons of the LDT and PPT promote cortical activation and desynchronization of the EEG by exciting thalamo-cortical projection and, especially, inter-laminar neurons of the thalamus, as well as by inhibiting the inhibitory thalamic reticular neurons and exciting cholinergic neurons of the basal forebrain (Steriade, 2000). Similarly, orexinergic neurons stabilize the waking state by exciting other arousal systems in the hypothalamus, basal forebrain, and brainstem (Jones, 2008). Additionally, GABAergic neurons of the basal forebrain promote cortical activation by inhibiting inhibitory GABAergic cortical interneurons (Saper et al., 2010). Notably, at localized sites in the mesopontine brainstem, higher levels of GABA may actually promote wakefulness at the expense of REM and NREM sleep due to similar complex circuits of inhibition and disinhibition (Watson, Baghdoyan, & Lydic, 2011).

The Hypothalamus Controls the Sleep–Wake Transition

Lesions to anterior portions of the hypothalamus cause insomnia, whereas lesions of the posterior hypothalamus cause hypersomnolence (Saper, Chou, & Scammell, 2001). Neurons in the anterior hypothalamus increase firing during sleep, and their electrical stimulation promotes sleep, whereas neurons of posterior portions of the hypothalamus decrease firing during sleep, and their electrical stimulation promotes waking (Szymusiak & McGinty, 2008). Sherin, Shiromani, McCarley, and Saper (1996) demonstrated that neurons in the ventrolateral preoptic area (VLPO) of the anterior hypothalamus increase metabolic activity during NREM sleep in the rat. VLPO neurons produce both GABA and the inhibitory neuropeptide galanin and project to wake-promoting neurons in the TMN, LC, DR, LDT, and PPT (Saper et al., 2001). Activity in an adjacent region, the median preoptic area (MnPO), may respond to increased homeostatic sleep pressure (see next section) and contribute to subsequent activation of the VLPO that then persists to maintain sleep itself (Saper et al., 2010). Additionally, distinct subregions of the VLPO may be specialized for the maintenance of REM and NREM sleep (Saper et al., 2010). The LC, DRN, and TMN, in turn, innervate and inhibit the neurons of the VLPO (Saper et al., 2001).

Saper et al. (2001) suggested that this mutually inhibitory arrangement constitutes the biological analog of a bistable electrical "flip-flop" switch in which either the sleep (VLPO dominant) or wake (LC, DRN, TMN dominant) conditions are self-reinforcing stable states, whereas intermediate states are highly transient (Fig. 40.5). Orexin plays a key modulatory role in this flip-flop mechanism by providing excitatory drive on aminergic neurons, thereby further stabilizing the waking pole of the bipolar sleep–wake switch. In 1999, two research teams independently showed that deficiencies in orexinergic neurotransmission underlie the sleep disorder narcolepsy. Orexin-producing neurons are lost in human narcolepsy (Nishino, Ripley, Overeem, Lammers, & Mignot, 2000), likely due to an autoimmune mechanism, and, as a result, wake to sleep transitions can occur at inappropriate times (Saper et al., 2001). Orexin also opposes the atonia of REM, and, therefore, in narcolepsy, REM atonia can intrude into waking in the form of cataplexy (Alam, Szymusiak, & McGinty, 2011).

Homeostatic and Circadian Factors Interact to Control Sleep Onset and Offset

The timing of transitions between sleep and waking that are effected in the hypothalamus, however, depend upon input from extra-hypothalamic sources. Alexander Borbely's two-process model of sleep propensity (Fig. 40.6) suggests that homeostatic mechanisms (Process S) interact with circadian factors (Process C) to regulate behaviorally expressed sleep and waking (Borbely, 1982). Process C (Fig. 40.6A) constitutes a circadian rhythm (see Chapter 39) in the propensity to fall asleep that is controlled by an endogenous circadian clock in the suprachiasmatic nucleus (SCN) of the anterior hypothalamus (Dibner, Schibler, & Albrecht, 2010). Reliable output from the SCN, possessing a near–exact 24-hour periodicity in humans (Czeisler et al., 1999), results in a daily rhythm in sleep propensity that is maximal in the early morning, corresponding to the circadian nadir in body temperature and is minimal in the evening, corresponding to a "forbidden zone" for sleep (Lavie, 1986). Another smaller increase in circadian sleep propensity, the "post-prandial dip," may occur in the early afternoon around "siesta time"

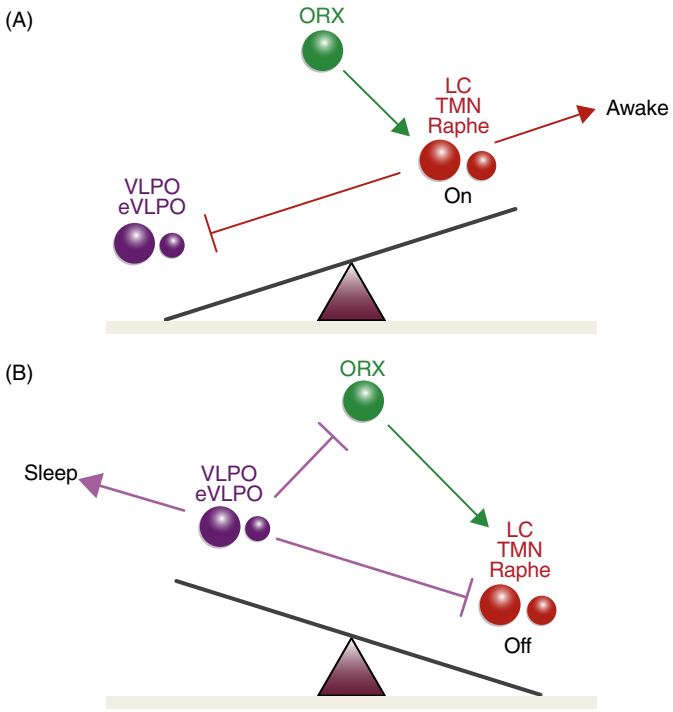

FIGURE 40.5 The flip-flop switch model of sleep–wake control proposed by Saper et al. (2001). (A) During waking, monoaminergic neurons (shown in red) of the locus coeruleus (LC), tuberomammillary (TMN), and dorsal raphe (Raphe) nuclei promote waking and inhibit the sleep-producing neurons of the ventrolateral preoptic area (VLPO) that are shown in purple. Orexinergic neurons (ORX) from the lateral hypothalamus (shown in green) excite and reinforce the wake-promoting activity of the monoaminergic neurons. (B) During sleep, neurons of the VLPO inhibit the wake-promoting monoaminergic neurons as well as the orexinergic neurons that help maintain their activity. By inhibiting the VLPO, monoaminergic neurons disinhibit their own wake-promoting activity, whereas, by inhibiting the monoaminergic nuclei, the VLPO disinhibits its own sleep-promoting activity. This mutually inhibitory interaction produces conditions analogous to an electrical flip-flop switch whereby the alternate states of sleep and waking are self-reinforcing but intermediate states are unstable and transient. This results in rapid transitions from waking to sleep and vice versa. Orexin serves to stabilize the waking state and prevent inappropriate transitions to sleep should the monoaminergic drive transiently weaken. In narcolepsy, orexinergic neurons are lost, thereby allowing such abrupt transitions from waking to sleep during the characteristic sleep attacks of this disorder. (*Modified from Saper, Scammel & Lu, 2005*).

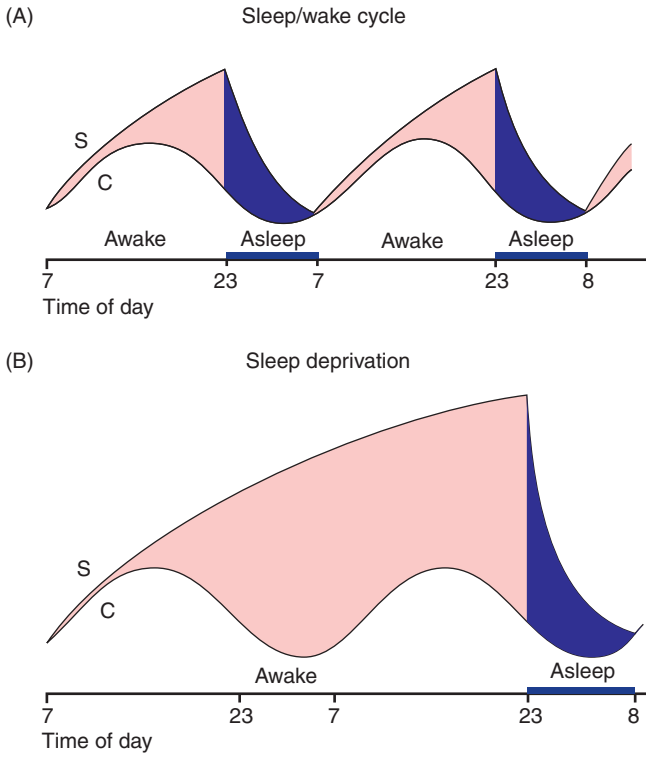

FIGURE 40.6 The Borbely and Daan model of sleep regulation. Sleep is assumed to result from the actions of process C and process S. Process C follows a circadian rhythm and is independent of sleeping and waking. Process S, on the other hand, depends on sleep–wake behavior; S declines during sleep and rises continuously during sleep deprivation. The period of recovery sleep that follows sleep deprivation is more intensive but only slightly longer than normal. If curve C represents the threshold for waking up, then at any time, "sleep pressure" is the (vertical) distance between the S and C curves. The greater the distance, the greater the pressure to fall asleep. *Reprinted with permission from Daan et al. (1984).*

(Bes, Jobert, & Schulz, 2009). If a research subject is deprived of sleep, sleepiness will continue to follow a circadian rhythm, indicating that sleepiness cycles can be independent of actual sleeping and waking.

Briefly, the molecular and cellular basis of Process C involves synchronized molecular clocks in each cell of the SCN that maintain 24-hour periodicity via interlocking positive and negative feedback control in the transcription and translation of circadian genes (see Chapter 39 and Dibner et al., 2010). This endogenous clock is entrained to the ambient photoperiod via nonvisual, photoreceptive pigments such as melanopsin in retinal ganglion cells (Peirson & Foster, 2006) that send glutamatergic signals to the SCN via the retinohypothalamic tract. The SCN conveys circadian information via the subparaventricular and dorsomedial nuclei of the hypothalamus to the VLPO to influence sleep–wake transitions (Saper, Chou, & Scammel, 2005). Secretion of the sleep hormone melatonin from the pineal gland is also indirectly controlled by the SCN, increases just prior to normal sleep onset, and provides an internal indicator of circadian time as well as feedback influence on the SCN, serving to further stabilize circadian rhythms via action at melatonin receptors on the SCN itself (Arendt, 2006).

Sleep homeostasis, or Process S, is a mechanism that increases sleep pressure as a function of the amount of time since the last sleep episode (Fig. 40.6B). Process S generates the powerfully increased drive to sleep that accompanies prolonged sleep deprivation and is believed to result from sleep-promoting substances, "endogenous somnogens," that accumulate during waking and dissipate during sleep. The purine nucleoside adenosine,

which accumulates in extracellular space as a product of metabolism, is currently the most likely candidate (Porkka-Heiskanen & Kalinchuk, 2011). Evidence also exists for endogenous somnogenic actions of interleukin-1B, prostaglandin D2, and growth hormone–releasing hormone (Szymusiak & McGinty, 2008). A primary mechanism for the sleep-promoting effects of adenosine is believed to be activation of inhibitory adenosine A1 receptors on wake-promoting cholinergic cells in the basal forebrain that project to and activate the cortex and desynchronize the EEG. However, recent findings suggest that adenosine may also produce somnogenic effects elsewhere in the brain, such as at excitatory A2A receptors in the hypothalamus and ventral striatal areas. Interestingly, the most commonly employed drug to counteract high homeostatic sleep pressure, the nonspecific adenosine receptor agonist caffeine, acts not at the basal forebrain but at postsynaptic A2A receptors in the basal ganglia (Lazarus et al., 2011). Adenosine may also mediate localized sleeplike electrophysiology in restricted areas of the cortex reflecting a prior-use dependent, restorative function (Krueger et al., 2008). Astrocytic release of adenosine, which inhibits local neurons by binding to A1 receptors, may allow localized emergence of sleeplike activity such as the slow (<1 Hz) oscillation (Halassa, 2011).

By acting in concert, processes C and S promote a single, daily consolidated nocturnal sleep bout in healthy adult humans (Dijk & Czeisler, 1994; Fig. 40.6). Specifically, in the evening, when sleep homeostatic pressure is maximal following a day's waking, the circadian "forbidden zone" maintains wakefulness until the normal time of sleep onset. In the early morning at the circadian nadir, when homeostatic sleep pressure has largely dissipated, Process C maintains the drive to sleep until the normal time of awakening.

NREM Sleep Rhythms Require Thalamo-Cortical Interaction

Following the transition from waking to NREM, neuronal firing rates in all wake-active nuclei decline with deepening NREM. This decline allows the emergence of intrinsic oscillations in reciprocally interconnected thalamic and cortical circuits that appear in the human EEG as the characteristic wave forms of N2 and N3 sleep: spindles, K-complexes, delta waves, and the (<1 Hz) slow oscillation (Steriade, 2006; Fig. 40.7). During waking, ascending arousal systems modulate thalamo-cortical circuits with the arousal-promoting neuromodulators (ACh, NE, 5-HT, and HA) and prevent the emergence of these oscillations. Similarly, during REM sleep, thalamo-cortical rhythms are prevented by cholinergic activation of the thalamus from the LDT and PPT.

The sleep spindles, K-complexes, and delta waves of NREM reflect the influence of the cortical slow oscillation on the thalamic reticular nucleus, a thin sheet of GABAergic neurons surrounding the thalamic periphery that inhibit other thalamic neurons (Steriade, 2000). The slow oscillation results from an alternation between a prolonged hyperpolarized ("down-state") phase and a shorter, rapidly

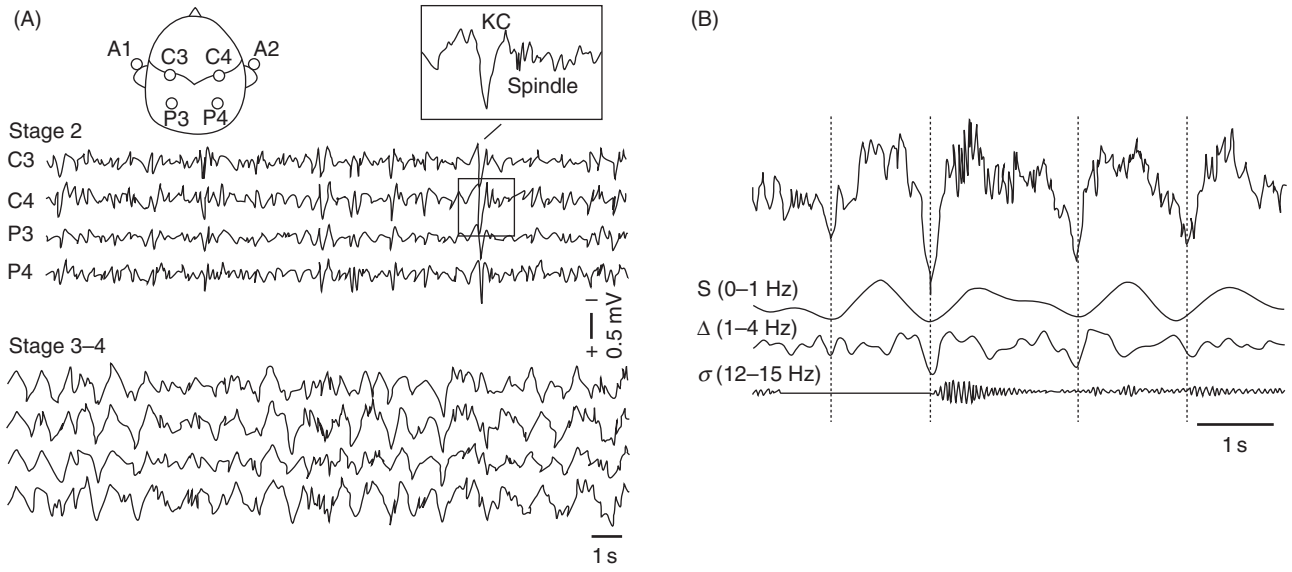

FIGURE 40.7 Characteristic NREM oscillations in the human EEG. (A) Recordings from central (C3, C4) and parietal (P3, P4) scalp sites referenced to the contralateral ears (A1, A2) during stage 2 NREM sleep (upper traces) and stages 3 and 4 NREM or slow wave sleep (lower traces). The insert shows the characteristic Stage 2 K-complex and sleep spindle wave forms. (B) Frequency composition of the NREM EEG showing the slow (0–1 Hz), delta (1–4 Hz), and 12–15 Hz sleep spindle (sigma frequency) oscillations. Note the organizing or grouping effect of the slow oscillation on the faster NREM oscillations. *From Amzica and Steriade (1996).*

spiking, depolarized ("up-state") phase that is synchronized among large assemblages of cortical neurons (Menicucci et al., 2009). The slow oscillation can be generated entirely within the cortex and may be an intrinsic property of cortical networks (Halassa, 2011), although the thalamus may also be crucial to its expression in vivo (Crunelli & Hughes, 2010). In human sleep, slow oscillations originate in frontal areas and travel posteriorly within the cortex (Massimini, Huber, Ferrarelli, Hill, & Tononi, 2004) but can also occur locally in the cortex (Nir et al., 2011). The slow oscillation exerts an organizing or grouping influence on other intrinsic NREM sleep rhythms (Fig. 40.6).

The cortical slow oscillation initiates sleep spindles when, during its depolarized up-phase, neurons projecting from the cortex to the thalamus excite neurons of the thalamic reticular nucleus that, in turn, inhibit thalamo-cortical neurons projecting from the thalamus to the cortex (Steriade, 2000). This periodic inhibition of thalamo-cortical neurons changes their firing pattern from a "transmission mode," in which firing frequency is proportional to the strength of a sensory input, to a "bursting mode," in which transmission of sensory information to the cortex is blocked (McCormick & Bal, 1997; Fig 40.8). This bursting mode is initiated when thalamo-cortical neurons are sufficiently hyperpolarized to activate a unique ion channel that opens only when their membrane potential falls well below its normal resting potential (McCormick & Bal, 1997). Opening of this channel begins a series of membrane events ("H" currents followed by "T" or "low-threshold calcium spike" currents) that culminates in thalamo-cortical neurons emitting a series of spikes that impinge on the cortex at spindle frequency.

Delta frequency EEG oscillations may have both thalamic and cortico-thalamic origins (Steriade, 2000). Delta-frequency oscillations can arise via thalamic neurons' intrinsic delta-frequency pacemaker property or, alternatively, when cortico-thalamic neurons excite thalamic reticular neurons that, in turn, hyperpolarize the thalamo-cortical neurons, causing them to stimulate the cortex at delta frequency. Both of these mechanisms also result from H and T currents. Because spectral power in the delta (Ferrara et al., 2002) as well as the slow oscillation (Bersagliere & Achermann, 2010) frequencies increase in response to the duration of prior waking, both are indicative of increased sleep pressure.

REM Sleep Is Initiated in the Brainstem

In the transition from NREM to REM sleep, firing rates of LC, DR, and TMN neurons and respective levels of NE, 5-HT, and HA at their terminal fields decline to their minimum levels. In contrast, firing rates of PPT/LDT neurons return to levels comparable to waking (reviewed in Pace-Schott & Hobson, 2002). Like aminergic neurons, orexin neurons of the LH/PFH decline in activity at sleep onset and remain quiescent in REM (Ohno & Sakurai, 2008). In the transition from NREM to REM, activation of the thalamus by brainstem cholinergic (LDT and PPT) neurons blocks the intrinsic oscillations of NREM and results in cortical EEG desynchronization (Steriade, 2000). The PPT and LDT also activate cortically projecting BF cholinergic neurons, resulting in further desynchronization of the cortex (Jones, 2008).

The cellular and molecular events that produce the regular alternation of REM and NREM sleep emerge under brainstem control once sleep has been achieved (reviewed in Steriade & McCarley, 2005 and Datta & Maclean, 2007). The cardinal neural features of REM are initiated by specific brainstem cell groups, illustrated in Figure 40.9, and include: (i) EEG desynchronization resulting from ARAS activation of the thalamus and basal forebrain; (ii) PGO waves in the cat, or P-waves in the rat, originating from different distinct pontine generators. PGO waves result from tonic disinhibition and phasic excitation of bursting cells in the peribrachial region of the mesopontine tegmentum and, like REM sleep, they can be triggered and augmented by cholinergic stimulation see below; (iii) rapid eye movements brought about by pre-motor neurons in proximity to oculomotor (abducens) nuclei; (iv) a change in hippocampal EEG from irregular rhythms to a regular theta rhythm (Vertes & Kocsis, 1997); and (v) skeletal muscle atonia resulting when pontine REM-active glutamatergic neurons transmit signals from pontine REM-control regions to inhibitory glycinergic and GABAergic cells of the medulla that, in turn, suppress somatic motorneurons to produce REM atonia (Chase, 2008). Other peripheral signs triggered by activity in specific brainstem nuclei include penile and clitoral tumescence, fluctuations of autonomic functions such as heart rate and blood pressure, and skeletal muscle twitches.

The earliest cellular model of the brainstem REM sleep generator, the Reciprocal Interaction (RI) Model (Hobson, McCarley, & Wyzinski, 1975), suggested that regular alternation of REM and NREM sleep results from the interaction of aminergic REM-off and cholinergic REM-on neuronal populations in the pontine brainstem as illustrated in Figures 40.10A and B. This hypothesis was supported by extensive experimental and clinical findings showing, for example, that micro-injection of cholinergic agonists (or drugs like neostigmine that block the enzymatic degradation of naturally produced ACh) into the pontine ARAS of cats produced a state indistinguishable from naturally occurring REM sleep. In addition, REM sleep was reduced or blocked by micro-injection of noradrenergic or serotonergic agonists into similar sites. Moreover, in humans, REM is suppressed by systemic administration of drugs that block the synaptic re-uptake or enzymatic

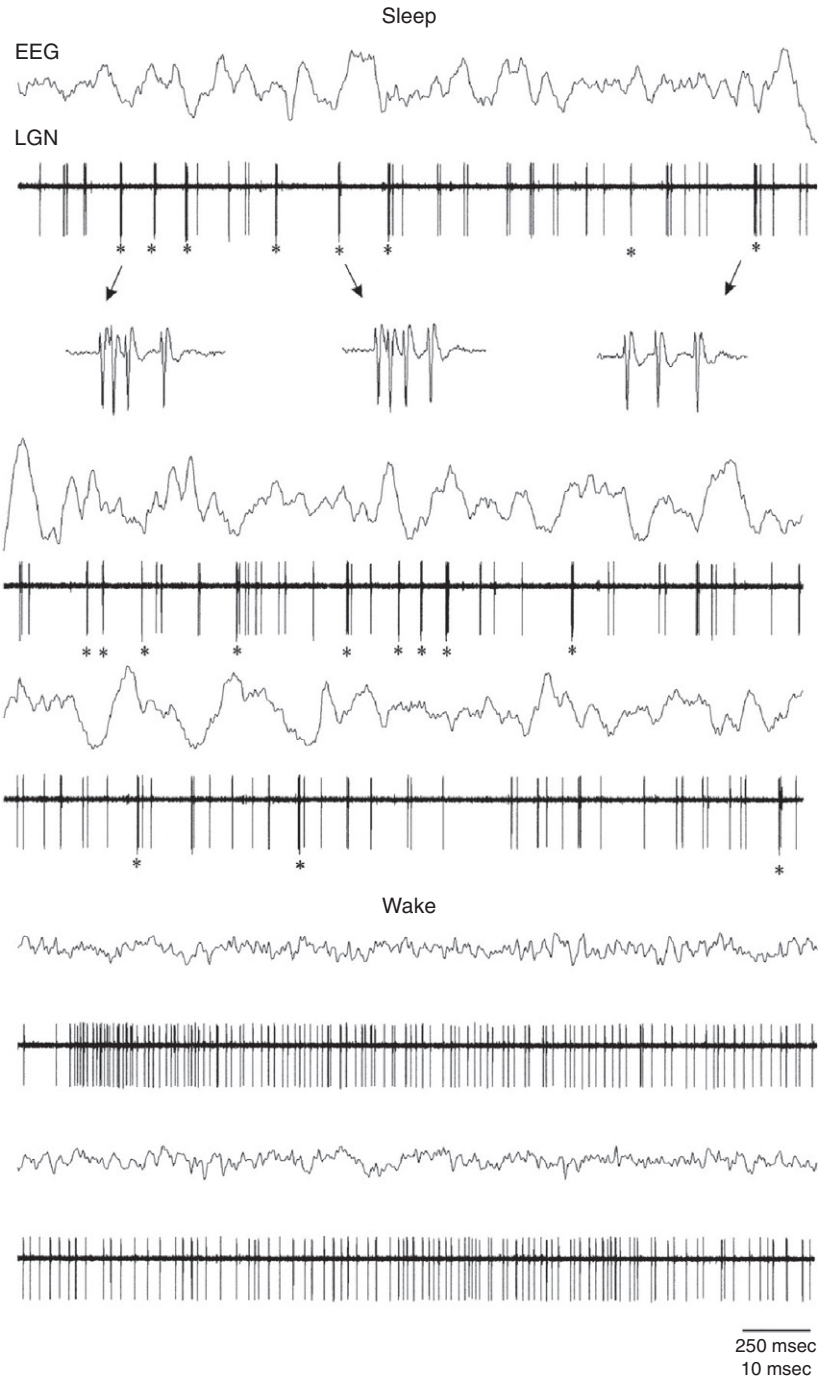

FIGURE 40.8 Two alternate firing modes of thalamic relay neurons: the bursting mode that is typical of slow wave sleep and the tonic (transmission) mode typical of waking. Traces show recordings in the thalamic lateral geniculate nucleus (LGN) of the cat along with simultaneous EEG from the occipital cortex. The top 7 traces show burst firing during sleep and the resultant synchronized low-frequency, high amplitude occipital EEG. The bottom 4 traces show recordings from these same sites during waking along with the resultant desynchronized, high-frequency EEG. Asterisks indicate bursting periods and the third trace shows an enlargement of the LGN channel during bursts. In the tonic mode during waking, firing frequency is proportional to the strength of a sensory input whereas during the bursting mode in sleep, transmission of sensory information to the cortex via the thalamus is blocked. For additional details on these modes of firing in thalamic relay neurons, as well as the membrane currents that underlie the rhythmic bursting mode, please see Chapter 5, Figure 5.14. *From Weyand et al. (2001),* J. Neurophysiology 85*:1107–18).*

degradation of naturally produced monoamines, such as many antidepressants.

Based upon subsequent reports, revision of the RI model added intermediate synaptic steps for both the activation of REM-on neurons and the suppression of REM-off aminergic nuclei (reviewed in Hobson et al., 2000). For example, mutually excitatory interactions between cholinergic and glutamatergic neurons may underlie the rapidly escalating

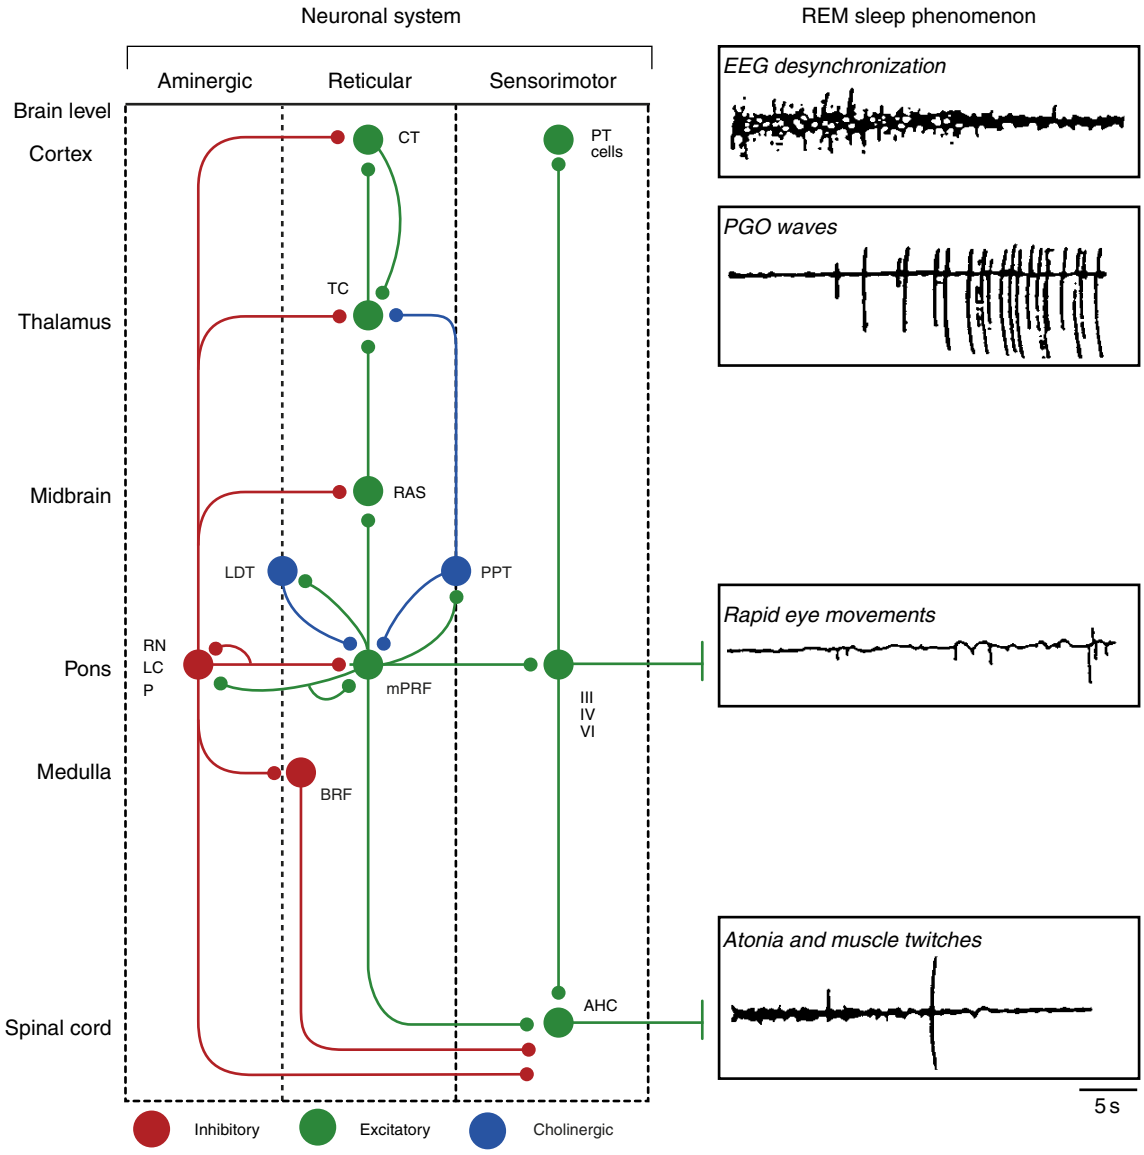

FIGURE 40.9 Schematic representation of the REM sleep generation process. A distributed network involves cells at brain levels from the spinal cord to the cortex (listed on the left). The network is represented as a diagram of three neuronal systems (aminergic, reticular, and sensorimotor) that mediate REM sleep phenomena (depicted in tracings on the right). Postulated inhibitory connections are shown as red circles; postulated excitatory connections as green circles; and cholinergic pontine nuclei are shown as blue circles. It should be noted that the actual synaptic signs of many of the aminergic and reticular pathways remain to be demonstrated, and, in many cases, the neuronal architecture is known to be far more complex than indicated here (e.g., the thalamus and cortex). During REM, additive facilitatory effects on pontine REM-on cells are postulated to occur via disinhibition (resulting from the marked reduction in firing rate by aminergic neurons at REM sleep onset) and through excitation (resulting from mutually excitatory cholinergic–noncholinergic cell interactions within the pontine tegmentum). The net result is strong tonic and phasic activation of reticular and sensorimotor neurons in REM sleep. REM sleep phenomena are postulated to be mediated as follows: EEG desynchronization results from a net tonic increase in reticular, thalamocortical, and cortical neuronal firing rates. PGO waves are the result of tonic disinhibition and phasic excitation of burst cells in the lateral pontomesencephalic tegmentum. Rapid eye movements are the consequence of phasic firing by reticular and vestibular cells; the latter (not shown) excite oculomotor neurons directly (see Chapter 32). Muscular atonia is the consequence of tonic postsynaptic inhibition of spinal anterior horn cells by the pontomedullary reticular formation. Muscle twitches occur when excitation by reticular and pyramidal tract motorneurons phasically overcomes the tonic inhibition of the anterior horn cells. RN, raphe nuclei; LC, locus coeruleus; P, peribrachial region; PPT, pedunculopontine tegmental nucleus; LDT, laterodorsal tegmental nucleus; mPRF, meso- and mediopontine tegmentum (e.g., gigantocellular tegmental field, parvocellular tegmental field); RAS, midbrain reticular activating system; BIRF, bulbospinal inhibitory reticular formation (e.g., gigantocellular tegmental field, parvocellular tegmental field, magnocellular tegmental field); TC, thalamocortical; CT, cortical; PT cell, pyramidal cell; III, oculomotor; IV, trochlear; V, trigmenial motor nuclei; AHC, anterior horn cell. *From Hobson et al. (2000).*

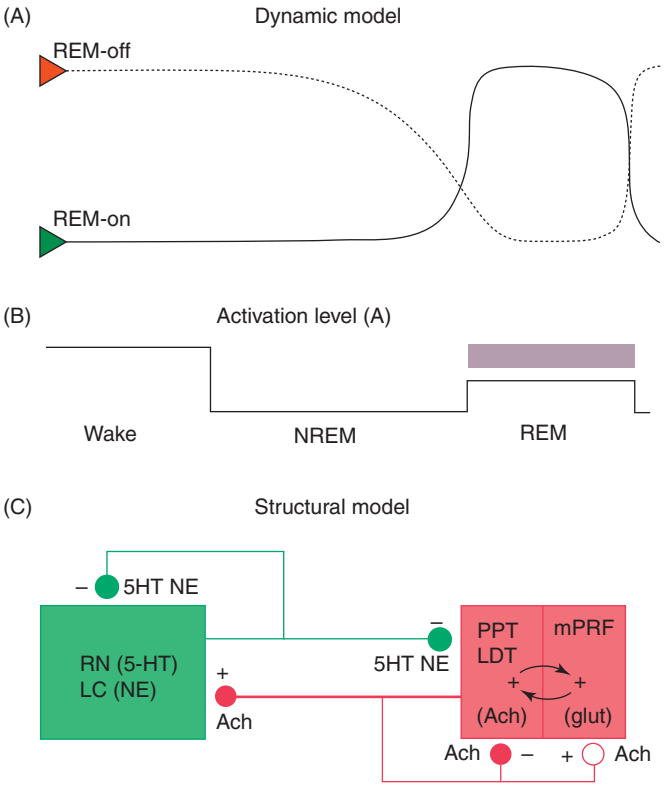

FIGURE 40.10 The Reciprocal Interaction (RI) Model (A) In the original RI model (Hobson et al., 1975; McCarley & Hobson, 1975), REM-on cholinergic neurons (Green triangle, solid line) both self-excite and excite aminergic REM-off neurons (Red triangle, dashed line). Aminergic REM-off neurons both inhibit cholinergic REM-on neurons and self-inhibit. This interaction leads to the alternation of behavioral states, depicted in (B), as follows: During waking, the REM-off aminergic system is active continuously and inhibits the pontine cholinergic system. During NREM sleep, aminergic activity decreases, allowing cholinergic activity to rise. The number of activated cholinergic REM-on neurons then exponentially increases due to self-excitation until sufficient numbers of aminergic REM-off neurons are also excited and begin to suppress the cholinergic REM-on population. However, these aminergic REM-off neurons then self-suppress, allowing the emergence of the next REM period. (C) In a subsequent revision of the RI hypothesis, mutually excitatory interactions between cholinergic and glutamatergic neurons underlie the rapidly escalating firing of pontine reticular REM-on neurons during REM sleep and cholinergic REM-on cells both self-excite and self-inhibit via cholinergic autoreceptors. *From Hobson et al. (2000).*

firing of pontine reticular REM-on neurons during REM sleep (Fig. 40.10C). Similarly, GABAergic inhibition by midbrain or local mesopontine interneurons may be responsible for inhibiting REM-off serotonergic and noradrenergic cells thereby allowing REM (Luppi et al., 2006). GABAergic inhibition of cholinergic cells in the PPT may prevent REM during SWS, while glutamatergic activation of a certain percentage of these cholinergic cells may trigger REM with further increase in percentage activated leading to waking (Datta & Maclean, 2007).

Other models on the control of REM onset and offset have emphasized interactions between brainstem GABAergic cell populations in which GABAergic inhibition plays both REM facilitatory and REM inhibitory roles. For example, Luppi et al. (2006) have suggested that the onset of REM in the rat is triggered by the release of noncholinergic, possibly glutamatergic, neurons of the pontine sublaterodorsal (SLD) nucleus from tonic GABAergic inhibition by midbrain reticular neurons that is present during NREM and wake. Most recently, Saper et al. (2010) have proposed that a GABAergic flip-flop switch, analogous to the above hypothalamic flip-flop switch, controls the alternation of REM and NREM sleep states in the rat. GABAergic REM-off regions in the ventrolateral periaqueductal gray and lateral pontine tegmentum project to and are mutually inhibitory with REM-on regions in the mesopontine SLD, precoeruleus, and periventricular gray areas. In this model, aminergic and cholinergic influences are modulatory, but a mutually inhibitory GABAergic flip-flop circuit is the final common pathway of REM-NREM switching. Aminergic inputs from the LC and DR excite the REM-off GABAergic regions and inhibit the REM-on ones, whereas cholinergic input from the LDT/PPT displays the opposite pattern. Similarly, orexinergic neurons excite the REM-off GABAergic regions, thereby inhibiting REM, whereas GABAergic projections from REM-promoting regions of the VLPO inhibit this same region. Discrepancies between models may result from species differences. For example, Datta and Maclean (2007) hypothesize different anatomical origins of pontine (PGO and P) waves in predator versus prey species.

Other Neurotransmitter Systems Participating in Behavioral State Control

Many additional neurotransmitter systems participate in the modulation of sleep states. Such modulatory neurochemicals may exert their effects on behavioral state by interacting with aminergic, cholinergic, GABAergic, and glutaminergic neurons that exert a more direct "executive" control over sleep and waking states, or they may mediate only specific physiological signs of REM and NREM sleep. Little attention was initially paid to dopamine (DA) in behavioral state control because, unlike the other monoamines, firing rates of dopaminergic cells in the SNpc and VTA did not appear to vary with behavioral state. However, synaptic levels of DA increase in REM when VTA neurons shift from tonic to burst firing modes (Dahan et al., 2007) and recently discovered wake-active dopaminergic neurons in the ventral PAG may constitute a dopaminergic component of ascending arousal analogous to serotonergic, noradrenergic, and histaminergic systems (Saper et al., 2010). In addition to the roles of galanin, orexin, and the cytokine peptides

described above, other neuropeptides implicated in the REM–NREM and sleep–wake cycles include vasoactive intestinal polypeptide, as well as numerous hormones, such as corticotropin releasing hormone (reviewed in Prospéro-García, Méndez-Díaz, Ruiz-Contreras, & Pérez-Morales, 2011). Nitric oxide (NO), an intercellularly diffusible gaseous neurotransmitter, is co-produced by cholinergic mesopontine neurons and may play a role in maintaining the cholinergically mediated REM sleep state in both the pons and the thalamus (Leonard & Lydic, 1999).

Molecular Biology of Behavioral State Control

Research on behavioral state control now extends inquiry beyond neurotransmitters and their receptors to intracellular second messenger cascades and gene transcription. The cyclic AMP-protein kinase A (cAMP-PKA) intracellular signaling pathway has been identified as the target of glutamatergic activation as well as GABAergic inhibition of PPT cholinergic cells generating physiological signs of REM (Datta & Maclean, 2007). For example, Bandyopadhya, Datta, and Saha (2006) have shown that intracellular concentrations of the catalytic subunit of PKA that enter the nucleus to phosphorylate CRE-binding protein vary with the prior amount of REM sleep. The specific profile of genes selectively activated in different sleep–wake states is also a current area of intense investigation (Cirelli, 2009), as is the genetic basis for variability in normal and disordered human sleep patterns (Landolt & Dijk, 2011). For example, genetic variation in adenosine deaminase, the degratory enzyme of adenosine, affects inter-individual variation in response to increased sleep pressure (Landolt & Dijk, 2011).

SYSTEMS NEUROSCIENCE OF SLEEP AND DREAMING

Electromagnetic Physiology

As described above, slow oscillatory rhythms produced in reentrant thalamo-cortical and cortico-cortico circuits predominate in human slow wave sleep (SWS). High-density EEG shows that the slow oscillation can originate in frontal regions of the brain and then travel posteriorly across the cortex (Massimini et al., 2004), as well as occur as a local cortical phenomenon (Nir et al., 2011). Frontal areas are also the first regions of the brain to show EEG slowing at sleep onset, as well as those that most reflect the increase in slow wave activity following sleep deprivation (Ferrara et al., 2002).

In contrast to NREM, wakelike electromagnetic brain activity in REM contains fast, gamma range (low gamma = 30–80 Hz, high gamma = 80–150 Hz) oscillations (Ferri et al., 2001). Gamma oscillations are associated with effortful waking cognitive activity such as working memory or attention to perceptual stimuli. Long-range synchronization of gamma oscillations across different brain regions has been proposed as one way in which the brain generates the coherent experience of a percept or memory across different sensory modalities ("binding"), and such binding may also create coherent hallucinatory percepts during REM-sleep dreams (Kahn, Pace-Schott, & Hobson, 1997). Interestingly, another difference in REM compared to waking, the loss of coherence (a quantitative measure of EEG synchrony) at gamma frequencies between frontal executive-control areas and posterior perceptual areas of the cortex, may be one mechanism by which dream bizarreness could arise (Corsi-Cabrera, Guevara, & Del Rio-Portilla, 2008).

Functional Neuroimaging of Sleep

Early positron emission tomography (PET) studies showed decreasing brain activation with sleep onset. As NREM deepens to SWS, global brain activity can decline by as much as 40% below waking (Maquet, 2000). Deactivation of the thalamus may occur at an early stage in this process and contribute to subsequent deactivation of widespread cortical, limbic, and striatal areas (Dang-Vu et al., 2010). fMRI has further demonstrated decreases in perfusion initially of frontal cortical areas and, as NREM deepens, also in the hypothalamus, striatum, thalamus, hippocampal formation, and posterior cortex (Kaufmann et al., 2006).

Recent studies have examined the effect of NREM sleep on activity in the brain's default network, a group of (mostly) midline brain areas that characteristically show a *decrease* in regional cerebral blood flow signal in response to a wide variety of goal-directed tasks, especially those requiring attention to exteroceptive (i.e., outside the body), perceptual stimuli (Buckner, Andrews-Hanna, & Schacter, 2008). In the absence of exteroceptive attention, these regions are believed to carry out adaptive, homeostatic, interoceptive (directed toward the internal milieu), and self-related functions, including imaginal simulation of future needs and desires, retrieval of autobiographical episodic memory, and self-regulation. In the blood oxygen level dependent (BOLD) signal of fMRI, the default network manifests as temporal synchrony of low-frequency (0.01–0.1 Hz) oscillations among its different regions (Buckner et al., 2008). This signature synchrony of BOLD fluctuations that defines the default mode during task-free waking persists into early stages of NREM sleep (N1, N2) but is lost during SWS (Samann et al., 2011).

With transition from NREM to REM, most lateral portions of the cortex remain less active than in waking, whereas activation, sometimes to levels exceeding that of

waking, occurs in the pons, midbrain, thalamus, amygdala, hypothalamus, and basal ganglia, as well as limbic-related cortices (reviewed in Pace-Schott, 2011b). These regions comprise what Nofzinger et al. (2004) call the "anterior paralimbic REM activation area," and these findings have led to an important expansion of theories on the neural origin of REM dreams, as described in the next section.

A Neurobiological Model of Dreaming

From evidence such as the above, we can suggest a neurobiological model of REM-sleep dreaming—the major conscious state that humans experience during sleep. Although REM dreams—being the most vivid, motoric, emotional, and bizarre—are modeled, dreaming also occurs at lower intensity and rate of recall during NREM (Hobson et al., 2000). (More detailed presentations of this model, shown in Fig. 40.11, can be found in Pace-Schott, 2011b.) Table 40.1 lists the phenomenological features of dreams that this neurobiological model seeks to explain.

In REM, the forebrain is activated, as in waking, by ARAS cholinergic nuclei and their brainstem targets that, by activating the thalamus and basal forebrain, allow these forebrain structures to, in turn, activate the limbic system and cortex via glutamatergic and cholinergic mechanisms, respectively. As originally hypothesized in the Activation-Synthesis Hypothesis (Hobson & McCarley, 1977), such forebrain activation results in a markedly different sort of conscious experience owing to the almost complete lack

of noradrenergic, serotonergic, and histaminergic neuromodulation of the cortex. Notably, as detailed in Chapter 46 and 50, aminergic modulation facilitates higher cognitive functions such as attention and working memory.

Activity in the "anterior paralimbic REM activation area" may generate the emotionally salient features of dreaming. For example, activity in the amygdala, related basal forebrain areas (e.g., bed nucleus of the stria terminalis) and medial prefrontal (e.g., subgenual) areas, which are components of fear-processing circuits, may result in anxious or fearful dreams (Levin & Nielsen, 2007). On the other hand, activity in the midbrain, ventral striatum, and pallidum (components of reward circuits) may produce appetitive dreams (Solms, 1997). Similarly, activity in the hypothalamus and brainstem (e.g., periaqueductal gray) may trigger instinctual programs resulting in sexual, panic, or rage experiences (Jouvet, 1999). In addition, the richly social and interpersonally salient nature of dreams may result from activation of medial prefrontal areas involved in social cognition, such as the capacity for forming a "theory of mind," empathizing, or moralizing.

Veridical replay of actual episodic experiences is quite rare in dreams (Stickgold, Hobson, Fosse, & Fosse, 2001), but recognition memory can sometimes be bizarrely enhanced, such as when we "just know" who a dream character is despite marked differences from the real-life counterpart (Kahn, Stickgold, Pace-Schott, & Hobson, 2000). Such credulity in dreams may be one manifestation of how low activity in lateral prefrontal areas results in dream bizarreness. Ventromedial frontal areas active in REM are involved in rapid, feelings-based appraisal of memory accuracy and may accept dream events without the verification provided by lateral and polar prefrontal areas that are needed for critical thinking and strategic search of memory. In a similar manner, other forms of dream bizarreness, such as incongruous juxtapositions, sudden discontinuities of plot, or bizarre uncertainty (see Hobson, 1988), may be uncritically accepted due to deactivation of lateral and polar prefrontal cortex. Interestingly, damage to lateral frontal areas has little effect on dreaming (Solms, 1997).

Although dreams abound with hallucinatory motion, REM atonia prevents contraction of skeletal muscles for the enactment of motor commands except in the case of REM behavior disorder (see below). However, REM-related activity in basal ganglia may produce the sense of initiated motion, while activity in the cerebellum may produce vestibular sensations such as flying, falling, or moving.

The Activation-Synthesis Hypothesis suggested that the striking visual hallucinations of dreams arise when phasic signals from the brainstem during REM, such as PGO waves, arrive at the cortex through a dedicated visual pathway and are interpreted by the visual cortex as true sensory input (Hobson & McCarley, 1977). Activation of visual association areas during REM by such ascending signals may allow emergence of complex hallucinations of actual objects and persons (Hobson et al., 2000). For example, regions of the ventral stream of visual processing (see Chapter 44), such as the fusiform face area or the parahippocampal place area, increase their activity during REM (Braun et al., 1998). Interestingly, damage to such ventral stream areas can result in nonvisual dreams (Solms, 1997).

Much, however, remains unexplained. For example, why are dream hallucinations integrated into elaborate plots in the absence of higher-order functions that, in waking, would be needed to create a coherent story? Similarly, why should damage to the inferior parietal cortex result in dream cessation when this area is among those that remain deactivated during REM? And, of course, how are dreams generated in NREM sleep?

DEVELOPMENT AND PHYLOGENY OF SLEEP

Changes in Sleep over the Human Lifespan

Human sleep shows striking developmental changes across the lifespan (Fig. 40.12). Newborns spend 17 to 18 hours per day sleeping in 3- to 4-hour bouts that, by approximately age 6, have consolidated into a single 10- to 12-hour nocturnal sleep period (Scher, 2008). An important transition during this period involves consolidation of diurnal sleep, first into a single daytime nap, that is then abandoned for solely nocturnal sleep (Davis, Parker, & Montgomery, 2004). SWS is absent at birth and develops during the first year of life, as do sleep spindles. In contrast, REM makes up around 50% of sleep in newborns, who also display incomplete atonia with a poorly differentiated EEG. By age 4, however, REM has declined to approximately adult levels of 20 to 25%. As the preadolescent enters adolescence, there is an endogenous circadian

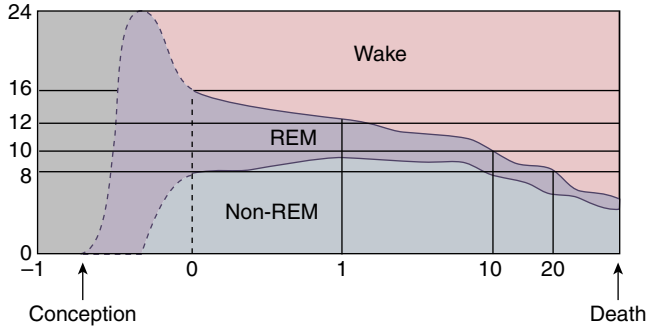

FIGURE 40.12 Portions of a 24-hour day that are devoted to waking, REM sleep, and non-REM (NREM) sleep change over a lifetime. Although the timing of these changes *in utero* is not known with certainty (dotted lines), data from premature infants are consistent with REM sleep occupying most of life at a gestational age of 26 weeks. After 26 weeks, the time spent in waking increases until death.

phase delay resulting in later sleep onset and rising time (Carskadon, 2011) as well as a decline in SWS. In young adults, on average, total sleep time is around 6 to 8 hours, of which about 5% is N1, 50 to 60% N2, 15 to 20% SWS, and 20 to 25% REM (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004). Healthy aging is characterized by a diminished quality and duration of sleep, with increased time awake after sleep onset (Pace-Schott & Spencer, 2011). Older adults awaken more frequently and show a dramatic decline in SWS along with less marked decreases in numbers of sleep spindles and K-complexes. Opposite to changes entering adolescence, circadian rhythms of temperature, melatonin, and cortisol become phase advanced (earlier sleep and rising) in older adults.

Phylogeny of Sleep

All mammals display REM and NREM sleep, but the duration and architecture of sleep vary widely. In general terms, smaller mammal species sleep more than larger ones, brain weight positively correlates with length of the REM-NREM cycle, and those born less mature have more REM (Hobson, 1989). In some marine mammals and birds, sleep occurs in one hemisphere at a time which, in the case of cetaceans, allows continued breathing (Rattenborg, Amlaner, & Lima, 2000). Birds have very short sleep and REM/NREM cycles, with minimal REM lacking atonia. Reptiles, amphibia, fish, and invertebrates have periods of quiescence with both circadian and seasonal periodicities, but the equivalence of these states to the sleep of homeotherms is just now being elucidated (Allada & Siegel, 2008). As noted in Chapter 39, the genetic basis of circadian rhythms is remarkably conserved from the most primitive to the most advanced phyla. Table 40.2 shows what is currently believed true about sleep states in the various phyla.

SLEEP DISORDERS

Disrupted Control of Behavioral State Can Lead to Insomnia and Hypersomnia

When brain aminergic activity is excessive due to stress, disease, or genetic predisposition, behavioral state is shifted in the direction of hyperarousal, and insomnia can result. Behavioral and pharmacologic interventions can be used to reduce this hyperarousal (Ellenbogen & Pace-Schott, 2012). Among pharmacological treatments, the most common are drugs such as zolpidem that target the benzodiazepine binding site on $GABA_A$ receptors. Binding to the benzodiazepine receptor site increases the ability of GABA to trigger chloride influx through the ionotropic $GABA_A$ receptor. The resulting hyperpolarization of the membrane then leads to neuronal inhibition and behavioral sedation. As described in Chapter 8, the $GABA_A$ receptor is a pentameric structure whose subunits exist in various isoforms. By targeting specific isoforms, hypnotic drugs have been developed that promote sleep with a lesser tendency to be addictive or to cause cognitive problems compared to "traditional benzodiazepines" like valium.

Abnormal decreases in CNS aminergic activity have the opposite effect on cognitive and behavioral systems. In the case of narcolepsy, the reduced orexinergic drive on aminergic systems allows sleep attacks. In such conditions, the REM generator is disinhibited, as can be seen in REM sleep attacks of narcoleptics. These symptoms can be decreased by aminergic agonists, such as antidepressants and psychostimulants, that block amine reuptake. The drug now most commonly used to treat hypersomnolence, modafinil (and its R-enantiomer armodafinil), shows weak reuptake blockade of norepinephrine and dopamine but may also augment electrical coupling among cells of the ARAS (Ellenbogen & Pace-Schott, 2012).

Respiratory Dysfunction Is Common in Sleep

One of the more dramatic problems associated with sleep is an exaggeration of the normal decline in drive from brainstem respiratory centers that occurs during sleep, a condition known as central sleep apnea (Fig. 40.13). A much more common condition, obstructive or peripheral sleep apnea (OSA), results from mechanical collapse or compression of the airway, a condition especially common in obese people (see Kryger et al., 2011, for extensive reviews; Fig. 40.13). In OSA, central respiratory drive causes continued respiratory effort. Eventually, the increase of CO_2 in the brain leads to an arousal that in turn produces increased muscle tone in the oropharynx, and the airway opens. As the person

TABLE 40.2 Physiological Basis of Changes That Occur during Dreaming

Function	Change (Compared with Waking)	Hypothesized Cause
Sensory input	Blocked	Presynaptic inhibition
Perception (external)	Diminished	Blockade of sensory input
Perception (internal)	Enhanced	Removal of inhibition from networks that store sensory representations
Attention	Lost	Aminergic modulation decreases, causing a decrease in the ratio of signal to noise
Memory (recent)	Diminished	Because of a decrease in aminergic activity, activated representations are not stored in memory
Memory (remote)	Enhanced	Removal of inhibition from networks that store memory representations
Orientation	Unstable	Internally inconsistent signals are generated by cholinergic systems
Thought	Poor reasoning, processing hyper-associative	Loss of attention, memory, and volition leads to failure of sequencing and rule inconstancy; analogy replaces analysis
Insight	Self-reflection lost	Failures of attention, logic, and memory weaken second- (and third-) order representations
Language (internal)	Confabulatory	Aminergic demodulation frees the use of language from the restraint of logic
Emotion	Episodically strong	Cholinergic hyperstimulation of the amygdala and related structures of the temporal lobe triggers emotional storms, which are not modulated by aminergic activity
Instinct	Episodically strong	Cholinergic hyperstimulation of the hypothalamus and limbic forebrain triggers fixed motor programs, which are experienced fictively but not enacted
Volition	Weak	Cortical motor control cannot compete with disinhibited subcortical networks
Output	Blocked	Postsynaptic inhibition

falls into deeper sleep again, the oropharynx relaxes and the airway can become obstructed again until arousal recurs. In severe cases, arousals every one to two minutes all night are common.

People with sleep apnea usually feel excessively sleepy during the daytime because frequent arousal prevents deep, sustained sleep. They are often unaware of their sleep-dependent breathing pattern because they are never fully aroused from sleep. Instead, observant friends or family often describe seeing these signs of respiratory dysfunction. In a sleep laboratory, EEG, respiratory effort, and cardiovascular parameters (e.g., heart rate, blood pressure, and oxygen saturation) are measured to quantify the problem. OSA can be treated by having the person wear a continuous positive airway (CPAP) mask through which air is forced gently, helping to keep the airways open. The pressure of the air fluctuates to allow regular exhalation. People with OSA are treated not only to alleviate their constant drowsiness but to prevent long-term effects of sleep apnea, such as cardiopulmonary complications and cognitive impairment.

Motor Disturbances Can Occur during Sleep

Parasomnias that affect the skeletal motor system can occur in either REM or NREM sleep. In NREM sleep, these parasomnias (e.g., sleep walking, sleep talking, tooth grinding, and night terrors) are mainly seen in young people, and reflect motor responses to the outputs of central motor pattern generators. Normally, responses to these generators are disinhibited at sleep onset and inhibited during REM sleep (by the REM atonia previously described). Excessive motor output during REM, termed REM sleep behavior disorder (RBD), can be an early sign of degenerative brain disease in the elderly when the brainstem neural circuits controlling REM atonia have become damaged. Because of a failure to inhibit the expression of motor acts in REM, people with this disorder may literally enact their dream scenarios in their bedrooms. A syndrome strikingly similar to RBD can be induced experimentally by bilateral lesions of the pontine tegmentum in cats. When in REM sleep, these animals perform stereotyped behavior sequences, such as hissing, piloerection, pouncing, and jumping. Jouvet called these

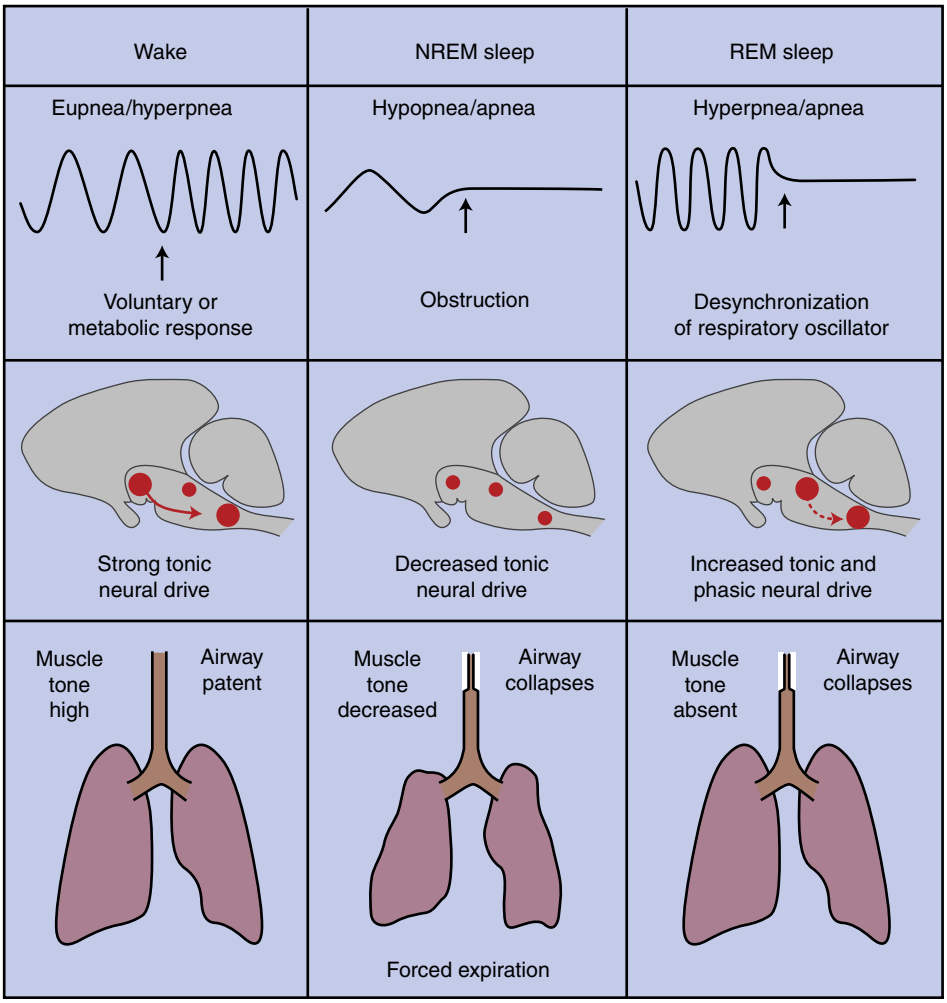

FIGURE 40.13 Central and obstructive sleep apnea. During waking, the respiratory oscillator of the medulla receives tonic drive from other neural structures and can respond to voluntary and metabolic signals to change breathing pattern. Muscle tone keeps the oropharynx open to the flow of air. In NREM sleep, central drive decreases, and the rate and depth of ventilation fall. If the decrease is excessive, central sleep apnea results, including a complete, albeit temporary, cessation of breathing. If the airway collapses, obstructive sleep apnea may result, with a similar cessation of breathing. During REM sleep, activation of pontine generator neurons drives the respiratory oscillator, and desynchronization may lead to breathing efforts that are too frequent or strong (hyperpnea) or that stop. During REM sleep the oscillator also becomes unresponsive to metabolic signals.

"hallucinatory behaviors," and Morrison called the phenomenon "REM sleep without atonia" (see Jouvet, 1999). Because the ability of a cat to inhibit motor pattern commands during REM sleep is impaired by the lesions, they act out commands that are normally initiated during REM sleep. The instinctual aspect of these released behaviors is relevant to the psychophysiology of dreaming as described above.

Other Sensorimotor Disturbances

Among the most interesting of sleep disorders is restless leg syndrome (RLS), a disorder that is often accompanied by another sleep disorder, periodic limb movement disorder (PLM). In RLS, while trying to go to sleep, the patient experiences a highly unpleasant burning or crawling sensation in the legs that can be relieved only by movement, often by arising and pacing. RLS is treated with dopaminergic agents that compensate for deficient output from dopaminergic neurons of the A11 region of the posterior hypothalamus that is the sole source of spinal cord dopamine (Paulus & Schomburg, 2006). Dopamine regulates sensory input to the dorsal horn of the spinal cord as well as the transmission of this input to the brain. In RLS, dopamine deficiency may allow excessive transmission of the normal low-level activity entering the spinal cord from peripheral receptors that, when transmitted to the brain, then produces abnormal sensations. Similarly, dopaminergic medications treat PLM by boosting dopaminergic inhibition of spinal early flexor reflexes that, when such inhibition is deficient, can be abnormally triggered by such baseline sensory inputs.

Disorders of Circadian Misalignment

Misalignment of waking activities with endogenous circadian rhythms is a common source of disordered sleep. As has been discussed, abnormal delay of sleep onset and offset (delayed sleep phase syndrome) is more common in adolescents and young adults, whereas abnormally early sleep onset and offset (advanced sleep phase syndrome) is more common in the elderly. In addition, overnight shift work or travel across time zones can lead to a desired sleep bout becoming misaligned with one's

endogenous circadian propensity for sleep and waking. Because light can entrain the circadian oscillator in the SCN, precisely timed treatment with bright light is the most commonly employed strategy for treating those circadian disorders. Melatonin and its agonists are also used to promote sleep onset in disorders of circadian misalignment.

THE PURPOSE OF SLEEP

Sleep Appears to Have Multiple Functions

As a quiescent and ecologically protected behavior, sleep fosters conservation of energy, defense from predation, and an opportunity for repair of injury. The anabolic character of NREM sleep (e.g., brain and body inactivity and hormone release) suggests a rest and restoration function. For example, Benington and Heller (1995) propose that an important function of NREM sleep is to restore brain glycogen stores. In contrast, the high proportion of REM sleep in the developing brain (Fig. 40.12) suggests a role of REM sleep in brain development and plasticity (Marks, Shaffery, Oksenberg, Speciale, & Roffwarg, 1995).

The crucial anabolic and conservative role of sleep is illustrated by studies showing that prolonged sleep deprivation results in the disruption of metabolic and caloric homeostasis and eventually death (Rechtschaffen & Bergmann, 2002). In rats, sleep deprivation was fatal when it persisted for 4 to 6 weeks. Early in the deprivation period, the rats began to eat more but could not maintain their body weight. Later, they lost their ability to maintain body temperature, developed strong heat-seeking behavior, and finally died. It is suspected their death resulted from overwhelming sepsis because of immunodeficiency. The linkage between sleep and immune function is further emphasized by their numerous interactions (Imeri & Opp, 2009). For example, NREM sleep is enhanced by the cytokines interleukin-1 and interleukin-2, both of which are released during NREM sleep (Krueger, Rector, & Churchill, 2007).

Sleep also plays a key role in hormonal regulation. Growth and development are enhanced by the release of growth hormone and gonadotropins during SWS (Leproult & Van Cauter, 2010). Such hormone release declines, along with SWS, after growth and sexual maturation are complete (Van Cauter, Leproult, & Plat, 2000). In addition, sleep loss has been linked to dysregulation of glucose metabolism and increased risk of the metabolic syndrome diabetes and obesity (Van Cauter et al., 2007).

Several recent theories extend the role of sleep to the cellular and molecular levels. The synaptic homeostasis theory (Tononi & Cirelli, 2006) suggests that sleep, especially SWS, may serve to reduce or "downscale" excessive synaptic potentiation produced during prior waking, eliminating the more weakly potentiated synaptic connections and leaving only those associated with the most salient waking events. A particularly intriguing idea is that sleep is necessary to optimize correct folding of proteins in the endoplasmic reticulum (ER), as evidenced by the fact that sleep deprivation increases production of chaperone proteins involved in the ER stress (or "unfolded protein") response (Naidoo, 2009). As further detailed in the next section, sleep and memory consolidation are closely interconnected, and the cAMP-PKA-CREB, second messenger cascade, important to memory formation in wake, also appears to be important in sleep-related memory consolidation (Hernandez & Abel, 2011).

Sleep and Memory Are Interdependent

Perhaps the clearest evidence of a function for sleep is its role in consolidating recently formed memories (for recent reviews, see Diekelmann & Born, 2010; Walker & Stickgold, 2006). One of the most notable examples is the discovery, in rats, by Carlyle Smith, of "REM windows"

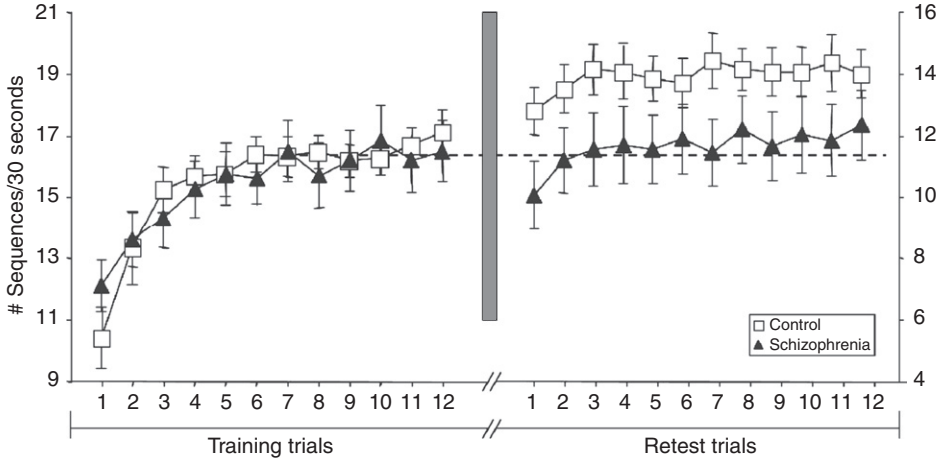

FIGURE 40.14 Sleep-dependent memory consolidation. Subjects were asked to type the sequence "41324" as quickly and accurately as they could for 30 seconds and then rest for 30 seconds before doing it again. Twelve trials were performed on each of two successive days. While the control subjects showed a 16% increase in speed overnight, the schizophrenia patients showed none.

(see Smith, 1995), which are time periods after an animal is trained on specific tasks when the animal shows enhanced quantities of REM sleep and when retention of learning could be decreased by selective REM sleep deprivation. Thus, not only does REM sleep appear to be critical for the maintenance of this learning, but animals also increase their REM sleep after training, presumably by a homeostatic mechanism that regulates the amounts of different sleep stages based on the needs of the organism. Subsequent studies in humans have led to the theory that REM sleep is especially important for the consolidation of procedural memories, which are defined as memories of how to do things in the absence of explicit rules, such as how to ride a bicycle or read a map (Walker & Stickgold, 2006). In contrast, SWS has been implicated in the consolidation of explicit or declarative memory, which includes autobiographical memories as well as general knowledge of facts (Diekelmann & Born, 2010). However, studies on a procedural visual discrimination task have shown a requirement for both REM and SWS on the night following training in order for next-day improvement on the task to be observed (Stickgold, Whidbee, Schirmer, Patel, & Hobson, 2000b). This finding supports an earlier theory based on animal studies in which a two-step process involving both REM and SWS was hypothesized. In humans, the requirement for sleep immediately following learning was shown when subjects who were sleep deprived the night following training, but who then were allowed two nights of unrestricted recovery sleep before testing, showed no significant task improvement (Stickgold, James, & Hobson, 2000a). In addition to procedural learning tasks, REM effects have been reported in humans on learning of complex logic games, foreign language acquisition, intensive studying in general, and both REM and SWS effects have been reported for the consolidation and processing of emotional memories. In contrast, sleep-dependent consolidation of simple motor skill learning, such as for a sequential finger tapping task, correlates with Stage II NREM sleep (Walker, Brakefield, Morgan, Hobson, & Stickgold, 2002).

The Functions of Dreaming, If Any, Are Poorly Understood

Does dreaming also serve a function? Answering this question is not yet possible, because we do not know how to separate possible functions of the experience of dreaming from functions of the neurobiological processes that produce it. But REM sleep dream content can predict who will become clinically depressed following marital divorce or separation (Cartwright, Young, Mercer, & Bears, 1998), suggesting that dreaming may serve to modulate emotional states during waking.

Dreaming may also play a role in modifying associative memory networks. Subjects awakened from REM sleep show preferential activation of more distantly related associated than seen either during waking or following NREM sleep (Stickgold et al., 1999). Such preferential activation of weak associations might explain the bizarre content of dreams during REM sleep and may permit the brain to discover creative solutions to problems during sleep. Indeed, sleep has been shown to increase the likelihood of such discoveries (Fig. 40.15; Wagner, Gais, Haider, Verleger, & Born, 2004). Most recently, it has been demonstrated that individuals who dream about a cognitive task following practice perform better on that task when they awaken (Wamsley, Tucker, Payne, Benavides, & Stickgold, 2010). But whether the conscious experience of dreaming is crucial for any of these sleep-dependent processes remains unknown.

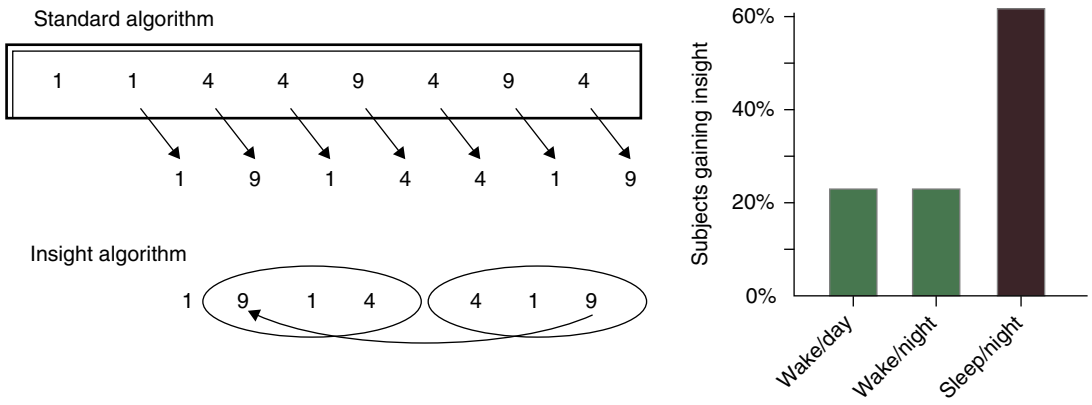

FIGURE 40.15 Sleep facilitates mathematical insight. Subjects are taught to reduce an 8-digit sequence to a single digit (9 at the right), through six intermediate calculations (in italics) with a standard algorithm. Unknown to the subjects, the task is designed so that the last three calculations form a mirror image of the preceding three, and thus the second intermediate calculation matches the final answer. Right: Subjects who slept between training and testing were more than twice as likely to discover the insight algorithm than those not allowed to sleep.

Dreaming may be viewed as evidence for a state of primary consciousness whose function is to provide the brain with an updatable virtual reality model of the brain that it uses in waking consciousness (Hobson, 2009). This view is surprisingly compatible with thermodynamic hypotheses about the brain (Friston, 2010).

CHAPTER

41

Reward, Motivation, and Addiction

REWARD AND MOTIVATION

Motivation is the process that mediates goal-directed responses to changes in the external or internal environment. Early explanations of motivated behavior focused on reductions of drives or needs, such as for sodium (salt) or water. Such purely homeostatic frameworks for motivation could plausibly account for ingestive and thermoregulatory behaviors and possibly even the drug-seeking behavior generated by the state of drug-withdrawal. Many behaviors, however, are triggered by external incentives which are perceived as appetizing, rewarding, or aversive. Thus, motivated behavior is determined both by biological needs and by learned associations between environmental cues and the value associated with the outcome of particular actions.

Behavioral goals, such as food or a sexual partner, are often not immediately available but must be searched for. Motivated behavior thus comprises both appetitive behavior and consummatory behaviors. *Appetitive behavior*, such as foraging for food or seeking a mate, tends to be adaptive, flexible, and learned through experience. In contrast, *consummatory behavior*, such as ingestion and copulation, tends to be reflexive or stereotyped and acquired early in development. Appetitive behavior occurs in conjunction with endocrine and autonomic responses, such as salivation and insulin secretion (see Chapter 34), which prepare the animal for efficient consummatory behavior.

The complexity of motivated behavior (Fig. 41.1), from the selection of learned voluntary actions to reflexive control of consummatory behavior, involves the coordination of several levels of neural control, including the prefrontal and cingulate cortices, the amygdala, the basal ganglia, the hypothalamus, and neuromodulatory nuclei in the brainstem.

Conditioning and Learning

In the absence of immediate goals, such as food or sex, animals typically use what they have learned from past experiences to predict the outcome of particular actions. Two predominant forms of learning are critical for motivated behavior: *classical conditioning* (i.e., Pavlovian conditioning) and *operant conditioning* (the learned association between goal-directed, instrumental behaviors and their outcomes).

In operant conditioning, outcomes are used to strengthen preceding behaviors via either positive or negative reinforcement. Positive reinforcement increases the likelihood of a particular behavior by having an attractive stimulus, termed a *positive reinforcer*, follow a given behavior. Conversely, negative reinforcement strengthens a behavior by removing an aversive stimulus, or a negative reinforcer, after that behavior is performed. The addition of a positive reinforcer is thought to be rewarding for an animal, whereas the removal of a negative reinforcer is believed to be relieving. (Negative reinforcers are not to be confused with punishers, which serve to decrease, rather than increase, the probability of a response). Reinforcers can be stimuli such as food or drugs which are valuable or aversive in themselves (primary reinforcers), or stimuli that become valuable or aversive by association with primary reinforcers (conditioned reinforcers).

Because motivation depends on the contingency between a particular behavior and a reinforcer, as well as the strength of the reinforcer, researchers can employ operant conditioning paradigms to study an animal's level of motivation. In the self-administration paradigm, animals learn arbitrary instrumental actions, such as a lever press, to gain access to positive reinforcers such as food and drugs (Fig. 41.2). Depending on the value of the reinforcer

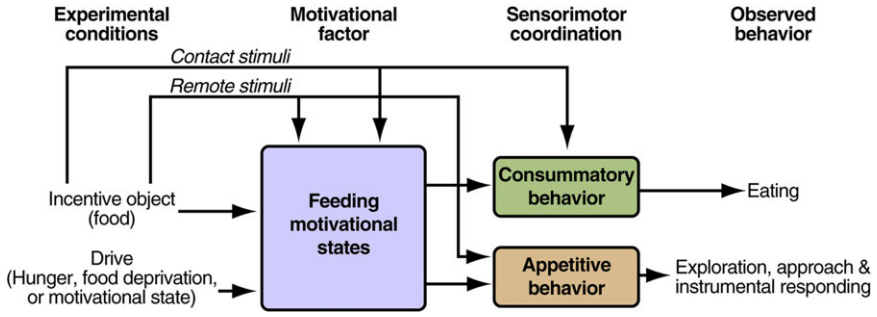

FIGURE 41.1 Theory of incentive-motivation, as applied to feeding. Note that drive (internal stimuli) and food (external stimuli) separately affect central motivation to feed. Also, incentive (i.e., food) and discriminative (i.e., sensorimotor) influences exert their effects separately to control consummatory behavior (when food is contacted) and appetitive behavior (when food remains remote). *Modified with permission from Robbins (1986).*

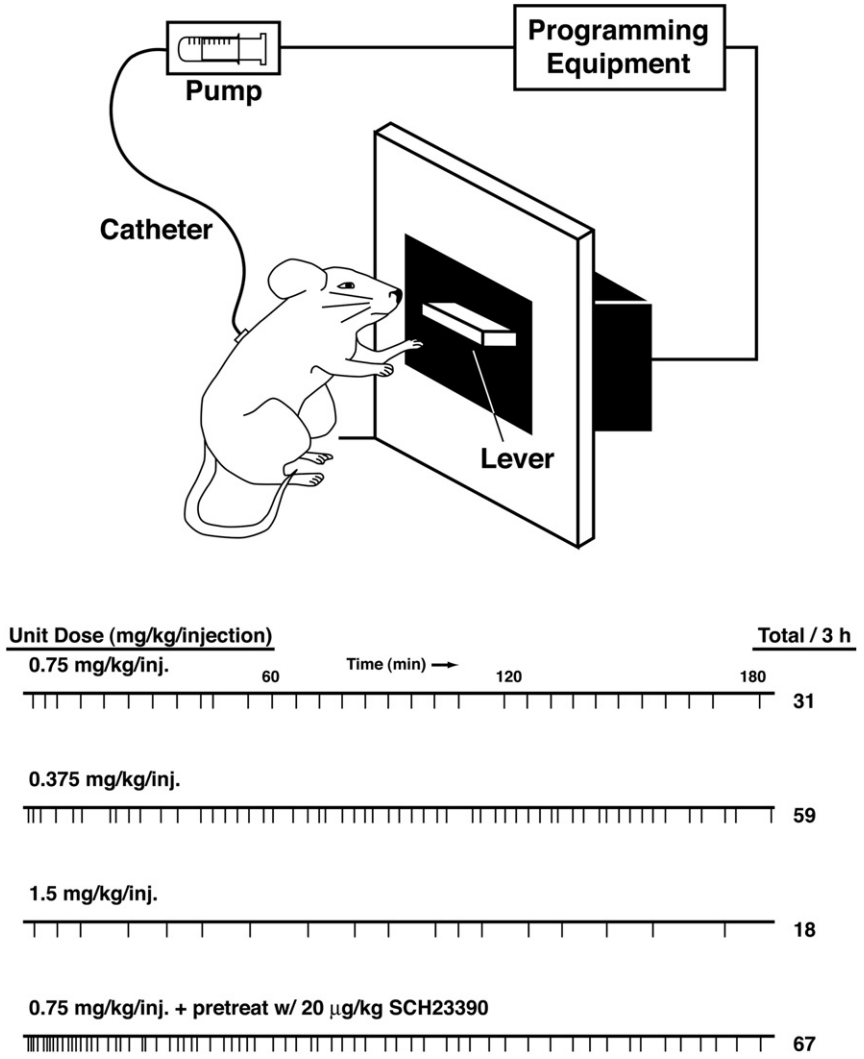

FIGURE 41.2 Intravenous self-administration by rats. (Top) Drawing illustrating the setup for intravenous self-administration of cocaine by rats. (Bottom) Event records for different unit doses of cocaine show a dose-response relationship relating dose of cocaine to number of infusions. Rats implanted with intravenous catheters and trained to self-administer cocaine with limited access (3 h per day) show stable and regular drug intake over each daily session. No obvious tolerance or dependence develops. Rats generally are maintained on a fixed-ratio (FR) schedule of drug infusion, such as FR-1 or FR-5. In an FR-1 schedule, one lever press is required to deliver an intravenous infusion of cocaine; in an FR-5 schedule, five lever presses are required to deliver an infusion of cocaine, and so on. With an FR schedule, rats appear to regulate the amount of drug self-administered. Lowering the dose from the training level of 0.75 mg/kg per injection increases the number of self-administered infusions. Raising the unit dose decreases the number of infusions. Pretreatment with the dopamine receptor antagonist SCH 23390 also increases the number of self-administered infusions. *Reprinted with permission from Caine et al. (1993).*

and the likelihood that their behavior will result in the reinforcer, animals will vary their level of activity (e.g., the amount they lever press). Thus, self-administration is a behavioral paradigm that measures an animal's degree of motivation by assessing its capacity to work for a goal.

Another measure of motivation involves assessing whether animals choose to execute particular behaviors when confronted with alternative choices. A commonly used experimental paradigm is conditioned place preference, in which a choice is made between two locations, only one of which is linked to a positive reinforcer (such as food or a drug). Following several learning trials, a test trial is conducted in the absence of the goal itself. In the test, the preference for that place (as measured by the time spent there) relative to another place without that association is taken as an index of the attractiveness, or incentive properties, of the goal.

The Hypothalamus Plays a Role in Motivation

Inspired by the discovery of brainstem centers for fundamental processes such as respiration, early investigators searched for a motivation center, conceptualized as a neural locus that could integrate internal and external stimuli and thereby coordinate neural circuits to produce adaptive behavioral, endocrine, and autonomic responses. The hypothalamus (Chapter 33) was thought to be ideal for such integrative functions, given its rich blood supply and exposure to cerebrospinal fluid (and thus access to a variety of chemical signals and the capacity also to deliver them), its control over the pituitary, and its neural connections (through brainstem and spinal centers) with visceral afferent information, autonomic and somatic motor outflow.

The hypothalamus is critical for a diverse range of motivated behaviors, including drinking, thermoregulation, aggression, and sex (see Chapter 33). For example, thermoregulatory behavior, such as reflexive shivering, panting, and grooming, is impaired by lesions of the preoptic region of the hypothalamus and is elicited by cooling or warming of this region (Satinoff, 1982). Defensive (affective) aggression and accompanying autonomic changes, such as piloerection, are produced by electrical stimulation of the ventromedial hypothalamus, whereas predatory ("quiet") aggression is produced by electrical stimulation of the lateral hypothalamus (Flynn, Vanegas, Foote, & Edwards, 1970).

The role of the hypothalamus in sexual motivation has been particularly well studied. Some hypothalamic nuclei contain high concentrations of steroid receptors (e.g., for estradiol and testosterone), especially the medial preoptic area and ventromedial hypothalamic nucleus. In male rats, copulatory behavior is abolished by medial preoptic area lesions (Heimer & Larsson, 1966–1967), whereas electrical stimulation of this region elicits copulation. In female rats, lordosis is blocked (and aggression toward males increased) by lesions of the ventromedial hypothalamic nucleus. Lordosis is also induced by electrical stimulation of this region (see Pfaff, 1982). Most of these responses depend on hormones. In ovariectomized females, proceptive ("ear wiggling," hopping, and darting) and receptive (lordosis) behaviors can be elicited by implanting estradiol into the ventromedial hypothalamic nucleus. Similarly, the sexual behavior of castrated males can be restored by implanting testosterone into the medial preoptic area. This hormone dependence underlines the interaction between external (environmental) and internal (plasma steroids) states in inducing motivated responses. Hormones influence the organization of sexually dimorphic brain development (e.g., development of the sexually dimorphic nuclei in the preoptic region), as well as sexually dimorphic behavior. Maternal behavior also is dependent on hormones and is impaired by lesions of the medial preoptic area.

Studies of the role of the hypothalamus in motivation that focus on consummatory, rather than learned instrumental, behavior can yield misleading conclusions. For example, when challenged with thermal stress, rats with preoptic lesions do not exhibit adaptive responses such as reflexive shivering, adjustments in food intake, nest building, or alterations in locomotion. They can, however, achieve thermoregulation by learning to press a lever for hot or cool air and remain motivated to do so (Carlisle, 1969). Similarly, male rats with preoptic area lesions exhibit locomotor excitement in the presence of a receptive female and will press levers to gain access to the female but cannot perform the consummatory behavior of copulation. Male monkeys with preoptic lesions continue to show motivated behavior (e.g., they will masturbate in the presence of females) but are unable to mount and intromit.

This dissociation between consummatory and instrumental behaviors is important because damage to the amygdala is known to produce the opposite pattern of effects—unimpaired mounting but reduced instrumental behavior (Everitt, 1990). These examples show that hypothalamic circuits predominantly control consummatory behaviors rather than learned, goal-directed instrumental behaviors. Behavioral flexibility, which requires learning, depends on the recruitment of additional neural systems, including the amygdala and prefrontal cortex, as described later (see Box 41.1).

Lesions of the Lateral Hypothalamus Disrupt Motivated Behavior and Dopaminergic Axons

Electrolytic lesions of the lateral hypothalamus cause dramatic deficits in food intake which were originally interpreted as a deficit in motivation. However, such lesions destroy far more than the lateral hypothalamic region itself,

BOX 41.1

LOGIC OF METHODOLOGY USED IN BEHAVIORAL NEUROSCIENCE

Theorists (e.g., Hoebel, 1974) have defined principles for identifying the involvement of particular brain regions in motivational (and other behavioral) functions. For example, electrophysiological, neurochemical, or metabolic activity may be observed in a structure, correlated with a behavioral response of interest, which suggests an involvement of that structure with the function under study. However, this correlative relationship does not establish whether the functioning of that region is causally important for the behavior. This issue may be addressed by an intervention that disrupts (impairs or improves) the function under study. For example, if the function is lost following selective lesioning, this suggests that the brain structure is implicated in that function. Similarly, if the function is enhanced following a boosting of neurotransmission in that region (e.g., via mild levels of electrical or chemical stimulation through implanted electrodes or cannulae), this is similarly converging evidence of a causative role. However, it is important to realize that the use of these techniques is each associated with interpretative problems, and their effects must be critically appraised. For example, the designation of the lateral hypothalamic region as a "feeding center" was based on the following: (1) electrolytic lesions produced profound aphagia (abstention from eating); (2) electrical stimulation of the brain through electrodes implanted in the lateral hypothalamus induced eating in sated rats (Hoebel, 1974); (3) infusions of the neurotransmitter norepinephrine into the hypothalamus also induced eating in sated rats (Leibowitz, 1980); and (4) electrophysiological recording showed that when monkeys were deprived of food, individual neurons in the lateral hypothalamus were sensitive to the sight and taste of food (Rolls, 1985). While many of these experimental observations have remained valid, subsequent evidence has suggested that the lateral hypothalamus has a much more specific role in feeding motivation, as a result of using improved techniques (see main text). Moreover, many of the effects associated with diminishing and increasing activity within the lateral hypothalamus have been shown subsequently to depend upon coincidental influences on axons within the medial forebrain bundle which merely pass through the lateral hypothalamus (e.g., between midbrain and striatum or between prefrontal cortex and brainstem) and had little to do functionally with the lateral hypothalamus itself. Only through the use of several neurobiological techniques providing converging evidence can the relationships between brain and behavior become more certain.

since they also interrupt ascending and descending fibers in the medial forebrain bundle, including dopaminergic axons (Fig. 41.3). Four major systems that are responsible for conveying dopamine to specific regions of the forebrain have been identified. The diencephalic incertohypothalamic dopamine system provides dopaminergic terminals to the hypothalamus, including the medial preoptic area responsible for sexual behavior (Pfaus, 2009). The tuberoinfundibular dopamine system controls hormone release from the anterior pituitary gland. The mesolimbic dopamine system conveys dopamine from neurons in the midbrain ventral tegmental area (VTA) to "limbic" regions of the forebrain, including the nucleus accumbens of the ventral striatum, amygdala, and medial prefrontal cortex. The nigrostriatal dopamine system originates in the substantia nigra and provides dopaminergic innervation to the caudate and putamen of the dorsal striatum.

Consistent with a critical role for dopamine in motivated behavior, injections of the catecholamine-selective neurotoxin 6-hydroxydopamine (6-OHDA) into the vicinity of the lateral hypothalamus reproduced many of the effects of electrolytic lesions (Ungerstedt, 1971a). The injected rats suffered large depletions (>90%) of dopamine from the striatum. They were cataleptic and had difficulty initiating head, limb, axial, and oral movements. Further experiments showed that the syndrome could be produced by injection of 6-OHDA at any of several points along the nigrostriatal dopamine pathway. Thus, dopamine depletion at sites far from the lateral hypothalamus reproduced much of the lateral hypothalamic syndrome. 6-OHDA-induced lesions of the mesolimbic pathway minimally affected ingestion but did disrupt other behaviors that can accompany feeding, including locomotion and exploration (Koob, Riley, Smith, & Robbins, 1978). These findings demonstrate that dopamine depletion impairs both consummatory and appetitive behaviors. Direct axonal projections from orexin neurons in the hypothalamus to dopamine neurons in the VTA provide a functional link between the homeostatic and incentive motivational components of ingestive behavior.

Dopamine Is Critical for Motivated Behavior

What is the nature of the contribution by dopaminergic neurons to motivation? Clues to answering this question were originally provided by experiments in which rats received unilateral 6-OHDA lesions of the nigrostriatal

dopamine circuit. The rats rotated toward the side of the lesion following treatment with a dopamine-releasing drug, such as D-amphetamine (Ungerstedt, 1971b). Presumably, this rotation occurred because more dopamine is released on the intact side than on the lesioned side of the brain and because any output pathway from the striatum influences movements in the opposite side of the body. Of even greater interest, the direct dopamine receptor agonist apomorphine caused the rats to turn away from the side of the lesion, an effect explained by actions at supersensative dopamine receptors on the lesioned side.

Unilateral lesions of either the lateral hypothalamus or the nigrostriatal dopamine pathway produce polymodal sensorimotor neglect, measured by responses to contralateral somatic, auditory, and olfactory stimuli (Marshall & Teitelbaum, 1977). Although this neglect was originally attributed to sensory inattention, further analysis suggests that the fundamental deficit is a failure in initiating responses rather than in attention (see Box 41.2). Animals with lesions of the nigrostriatal dopamine system retain the capacity for movement but have great difficulty in initiating movement. Similarly, patients suffering from Parkinson's disease have severe deficits in nigrostriatal dopamine with concommitant impairments in initiating movement. These considerations suggest that nigrostriatal dopamine is critical for activating or invigorating behavioral responses.

Studies with molecular and genetic techniques have also implicated dopamine in behavioral activation (Palmiter, 2009). Dopamine production relies on the synthetic

BOX 41.2

SEPARATION OF SENSORY AND RESPONSE FACTORS IN THE DOPAMINERGIC SYNDROME OF NEGLECT

Sensory and motor aspects of the neglect syndrome were separated in the following way (Carli et al., 1985). Rats were trained to detect brief flashes of light presented to either side of the head. In one case, they were trained to respond where the light was. In the alternate case, rats were trained to respond in a location away from the side of the light. Rats with dopamine depleted from one side of the striatum could not respond properly toward the contralateral side, whether or not the stimulus was presented on that side. Measurement of reaction time showed that the problem was in the initiation, rather than completion, of the movement. Consistent with these data, dopamine-depleted rats could detect a contralateral stimulus and respond to it with an unlateralized response. Thus, their deficit was in the initiation of movement in response to stimuli rather than in the detection of the stimuli.

enzyme tyrosine hydroxylase, which is also critical for the production of norepinephrine. Genetic deletion of tyrosine hydroxylase specifically in dopaminergic neurons produces severe impairments in mice; they become hypoactive and aphagic, and they starve by 4 weeks of age. Daily treatment with L-DOPA restores activity and feeding, demonstrating the critical role of dopamine for goal-directed behaviors necessary for survival. Restoration of dopamine synthesis specifically to the dorsal striatum via stereotactic injections of a recombinant virus is sufficient to rescue deficits in feeding and the initiation of locomotory behavior, underscoring the critical role of dopaminergic innervation of striatal neurons for motivated behaviors.

Dopaminergic Neuron Firing Is Related to Incentive and Reward

Electrophysiological recordings from midbrain dopaminergic neurons in animals have provided a framework for understanding the role of dopamine in motivated behavior (Bromberg-Martin & Hikosaka, 2010; Schultz, Dayan, & Montague, 1997). Midbrain dopaminergic neurons fire tonically at low rates of about 5 Hz in awake animals. The resulting tonic release of dopamine is critical for the ongoing operation of downstream circuits. Stimuli that are either directly rewarding (such as juice) or predict rewards (such as a cue which has been paired with a subsequent reward) evoke phasic increases in firing which elevate dopamine concentration at synaptic terminals for a period of several seconds.

A critical insight into the function of dopamine neurons was revealed by the pioneering studies of Wolfram Schultz and colleagues (Schultz et al., 1997). Dopaminergic neurons in the VTA originally fire in response to the presentation of a reward, but if a sensory cue is provided which predicts the reward, dopamine neurons fire in response to the cue instead of the reward (Fig. 41.4). Remarkably, if a fully predicted reward fails to occur, dopamine neurons decrease rather than increase their firing rate. These and other findings have led to the hypothesis that dopamine neuronal firing encodes "reward prediction errors." The dynamic changes in dopamine neuron firing as learning proceeds match quantitative predictions from reinforcement learning and have inspired researchers to borrow principles from economics to guide neuroscientific studies (Glimcher, 2011).

Motivated behaviors can be directed toward rewarding stimuli and some dopamine neurons appear to encode the motivational salience of stimuli, responding to stimuli that are either rewarding or aversive (Matsumoto & Hikosaka, 2009). Signals encoding aversive stimuli (or the lack of rewarding stimuli) are thought to be conveyed to dopamine neurons indirectly from a nucleus in the diencephalon called the habenula (Hikosaka et al., 2010). Neurons in the habenula decrease their firing rate in response to rewarding stimuli and increase their firing rates in response to aversive stimuli and when expected rewards are absent. Dopaminergic neurons in the substantia nigra which fire in response to both rewarding and aversive stimuli are hypothesized to convey motivational signals to the superior colliculus and frontal cortex, brain regions responsible for orienting attention toward and evaluating potentially salient stimuli, as well as to the striatum.

Electrical Stimulation of the Brain Can Be a Positive Reinforcer

Olds and Milner (1954) discovered that rats learned new responses when their learning was positively reinforced by electrical stimulation of the brain, and the sites that supported robust electrical brain self-stimulation followed the trajectory of the medial forebrain bundle. That finding affirmed the importance of incentive factors in instrumental behavior. The best natural parallel appeared to be behavior in response to large incentives by animals in low states of drive (e.g., chocolate milk in nondeprived

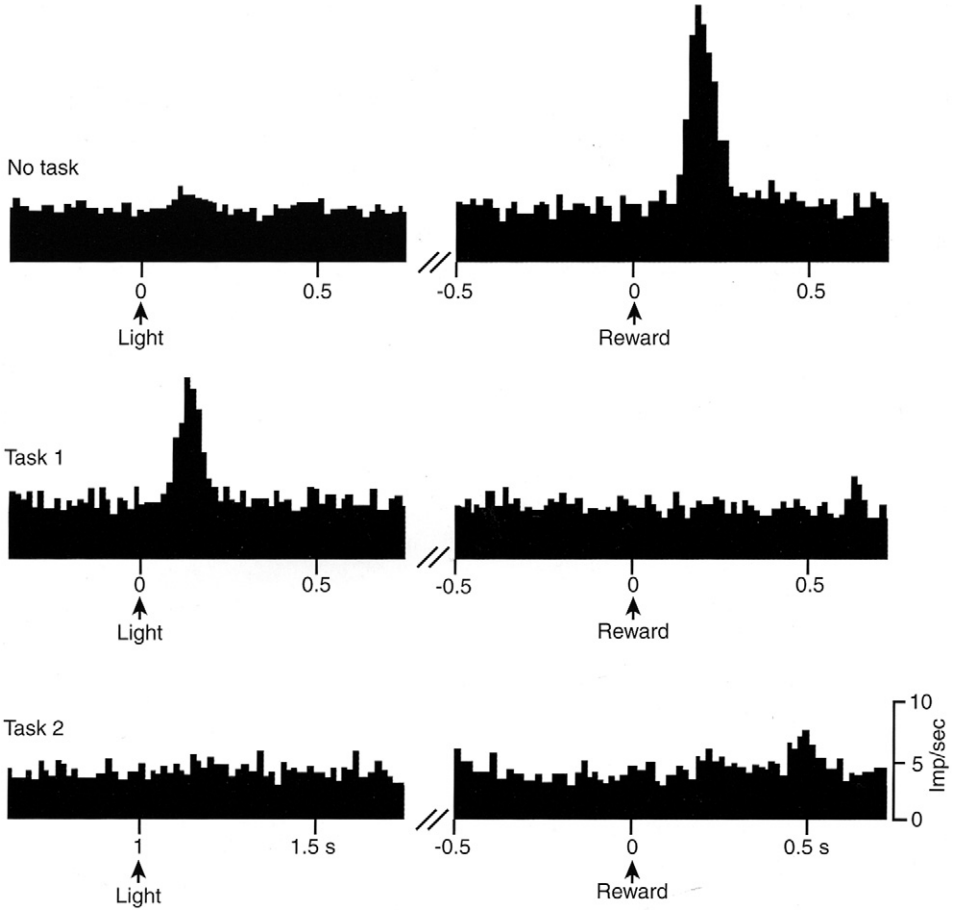

FIGURE 41.4 Responses of a dopamine neuron to unpredicted primary reward (top) and the transfer of this response to progressively earlier reward-predicting conditioned stimuli with training (middle). The bottom record shows a control baseline task when the reward is predicted by an earlier stimulus and not the light. *From Schultz et al. (1995), with permission.*

rats). Indeed, measurement of the strength of reinforcers in microamperes (Box 41.3 and Fig. 41.5) promised a pragmatic, as well as objective, new approach to the psychophysics of an operational hedonism. However, perhaps its greatest contribution was to enable the anatomical mapping of the central reward or reinforcement mechanisms of the brain (Phillips, 1984).

Catecholamine Hypothesis of Rewarding Brain Stimulation

Subsequent experiments indicated that animals can learn to engage in intracranial self-stimulation (ICSS) in several other brain regions (e.g., the locus coeruleus, midbrain central gray, cerebellum, trigeminal motor nucleus, substantia nigra, caudate nucleus, and nucleus accumbens) (Phillips, 1984). Although the diversity of these sites has not been fully elucidated, many of them are known to contain catecholamine-containing neurons, and while such neurons can express either norepinephrine or dopamine, most pharmacologic data can be interpreted in terms of dopaminergic mechanisms (Box 41.3 and Fig. 41.5). In particular, very high rates of ICSS were found in the ventral tegmental area, ventral striatum (including the nucleus accumbens to which dopamine neurons project), all key structures of the medial forebrain bundle. However, of several neural circuits that may subserve rewarding brain stimulation, only some are influenced directly by dopamine. The difficulty in interpreting the role of striatal dopamine in ICSS lies in distinguishing motor from reward effects (Box 41.3). The phenomenon of human drug dependence and the discovery in the early 1960s of drug self-administration in animals opened the way to more precisely analyze the neurochemical basis of reinforcement.

The Mesolimbic Dopamine System Plays a Key Role in Incentive Motivation

Wise (1982) proposed that natural reinforcers are perceived as rewards because they increase activity of the mesolimbic dopamine system. If this is correct, then the mesolimbic dopamine system should be important for behavioral responses to natural rewards, such as food and sex. In fact, depletion of dopamine in the nucleus accumbens does not impair consummatory behavior in rats (unlike dopamine depletion from the caudate-putamen), but it does reduce incentive-motivational responses. For example, proceptive behaviors (such as "ear wiggling,"

BOX 41.3

PSYCHOPHYSICS OF HEDONISM AS MEASURED BY BRAIN STIMULATION REWARD

Electrical stimulation of the brain can be used as positive reinforcement of learned behaviors. An apparatus is set up so that when an animal presses a lever, its brain is stimulated. Alternatively, a threshold procedure can be used where a lever or wheel response is required. An advantage of using electrical stimulation to measure motivation is that the strength of the reward can be titrated easily by adjusting the amount of current delivered for each response. If the current is adjusted too low (i.e., below the threshold for reinforcement), then the animals will not press the lever. As current is increased, the relationship between the rate of lever pressing and the strength of current typically follows a sigmoidal curve called rate-intensity function. In the threshold procedure, a series of discrete trials are presented at different current intensities, and the responses within a certain cutoff period are recorded. Current levels are lowered and raised to capture the threshold current (Fig. 41.2). Pharmacologic manipulation of catecholamine neurotransmitter systems can lower thresholds (e.g., treatment with amphetamines or cocaine) or raise thresholds (e.g., treatment with the dopamine receptor antagonist pimozide). Such changes mean the amount of electrical current required to support lever presses varies, while the latency to respond is unchanged. Thus, these drugs affect reward processes, rather than motor function. The threshold of reinforcement also can be measured by allowing rats to adjust the strength of the current. In this setup, a process is employed in which rats press lever one to produce ICSS, but each lever-one press also reduces the intensity of the current. To reset current intensity, rats must press lever two. Such "self-titration" experiments yield conclusions similar to those based on threshold and rate-intensity functions.

Threshold = 163.75 μA

FIGURE 41.5 Intracranial self-stimulation threshold procedure. Panels I, II, and III illustrate the timing of events during three hypothetical discrete trials. Panel I shows a trial during which the rat responded within the 7.5 s following the delivery of the noncontingent stimulus (positive response). Panel II shows a trial during which the animal did not respond (negative response). Panel III shows a trial during which the animal responded during the intertrial interval (negative response). For demonstration purposes, the intertrial interval was set at 10 s. In reality, the interresponse interval had an average duration of 10 s and ranged from 7.5 to 12.5 s. The table depicts a hypothetical session and demonstrates how thresholds were defined for the four individual series. The threshold of the session is the mean of the four series' thresholds. *Taken with permission from Markou and Koob (1992).*

hopping, and darting, all of which serve to solicit the attention of the male) are reduced in female rats with dopamine depletions. In addition, depletion of dopamine from the nucleus accumbens decreases locomotor excitement of hungry rats in the presence of food (Koob, Riley, Smith, & Robbins, 1978). Intriguingly, consummatory behavior, including eating of high incentive foods, appears to be mediated by distinct mechanisms within the nucleus accumbens that depend on opioid receptors (Hnasko, Sotak, & Palmiter, 2005; Kelley and Berridge, 2002).

Mesolimbic dopamine also may control behavior motivated by reward. For example, it was shown in studies by Robbins and Taylor that when a previously neutral light became a predictor of the occurrence of a primary reinforcer (water), rats learned a new behavior to turn on the light. Injection of amphetamine into the nucleus accumbens (but not the caudate) increased the frequency of the behavior, suggesting that amphetamine enhanced the motivational properties of this reward-related stimulus (i.e., the light, which was related to the reward, water). Amphetamine itself was well known to suppress eating and drinking; thus, the increased frequency of behavior was not due to increased thirst, for example. Furthermore, amphetamine did not increase the frequency of responding to a randomly paired stimulus. Finally, amphetamine-induced facilitation was completely blocked by dopamine depletion in the nucleus accumbens (but not by dopamine depletion in the caudate). These results indicated that the mesolimbic dopamine system enhances the motivational properties of stimuli predictive of natural rewards (Robbins, Taylor, Cador, & Everitt, 1989). Another way of describing this activational role of the dopamine system is that it confers "incentive salience" (Berridge & Robinson, 1998).

The Amygdala Also Has a Role in Appetitive Conditioning and Motivation

Growing evidence implicates the amygdala in evaluating both positive and negative stimuli (Morrison & Salzman, 2010). Excitotoxic, axon-sparing lesions of the amygdala diminish the capacity of stimuli associated with reward to motivate behavior. Such lesions also impair responses that are rewarded with access to female rats. However, mating *per se* is unaffected, in contrast with the effect of medial preoptic area lesions, (see above and Everitt, Cardinal, Hall, Parkinson, Robbins, 2000). This separation of control of consummatory and learned aspects of sexual behavior indicates that motivated sequences of behavior are constructed through the coordination of neural systems that are at least partly independent. Lesions of the basolateral amygdala also impair conditioned place preferences. In contrast, selective lesions of the central nucleus of the amygdala impair the learning of Pavlovian conditioned approach responses.

Motivated Behavior Translated to Habits

The ventral striatum, including the nucleus accumbens, receives afferents from the basolateral amygdala, hippocampal formation, and prefrontal cortex, and projects to the lateral hypothalamus and ventral pallidum (Fig. 41.6). Output from the ventral pallidum is routed in several different ways, including to brainstem motor regions and back to the prefrontal cortex through the mediodorsal thalamus. This circuit (prefrontal cortex-ventral striatum-ventral pallidum) appears to fit the requirements for "a neural mechanism by which motivation gets translated into action" (Mogenson, Jones, & Yim, 1980).

As described earlier, the basal and lateral amygdala convey associative information about stimuli that predict the occurrence of reinforcers. A link between the amygdala and ventral striatum is important in the translation of emotion (and motivational effects of stimuli) to behavioral output (Everitt et al., 2000). Glutamatergic inputs from the amgydala to ventral striatum work together with the ascending dopamine system to determine the output of ventral striatal γ-aminobutyric acid (GABA)-ergic medium spiny neurons that project to the globus pallidus (ventral pallidum) (see Chapter 30).

The nucleus accumbens is a heterogeneous structure. Its "shell" region is considered by some to be part of an "extended amygdala" encompassing the central nucleus of the amygdala and bed nucleus of the stria terminalis. The basolateral amygdala projects predominantly to the nucleus accumbens core subregion and specific parts of the dorsal striatum. These connections are paralleled by other cortico-striatal "loops" (see Chapter 30) (e.g., between different parts of the neocortex that project topographically to different sectors of the dorsal striatum). Moreover, there appears to be the possibility of cross-talk between these systems, arising from anatomical connections that potentially allow communication from the amygdala-ventral striatal circuitry to the cortico-dorsal striatal loops (Haber, Fudge, & McFarland, 2000). The ventral striatum has been linked to the initial acquisition of drug-seeking and drug-taking behavior and the subsequent cascade of loop circuitry involving the dorsal striatum to the gradual acquisition of stimulus-response habits that help to give the habits their "compulsive" quality (Belin, Jonkman, Dickinson, Robbins, & Everitt 2009; Everitt and Robbins, 2005).

ADDICTION

Epidemiology of Drug Abuse

Drug abuse is one of the world's major public health problems. For example, statistics from the 2009 *National*

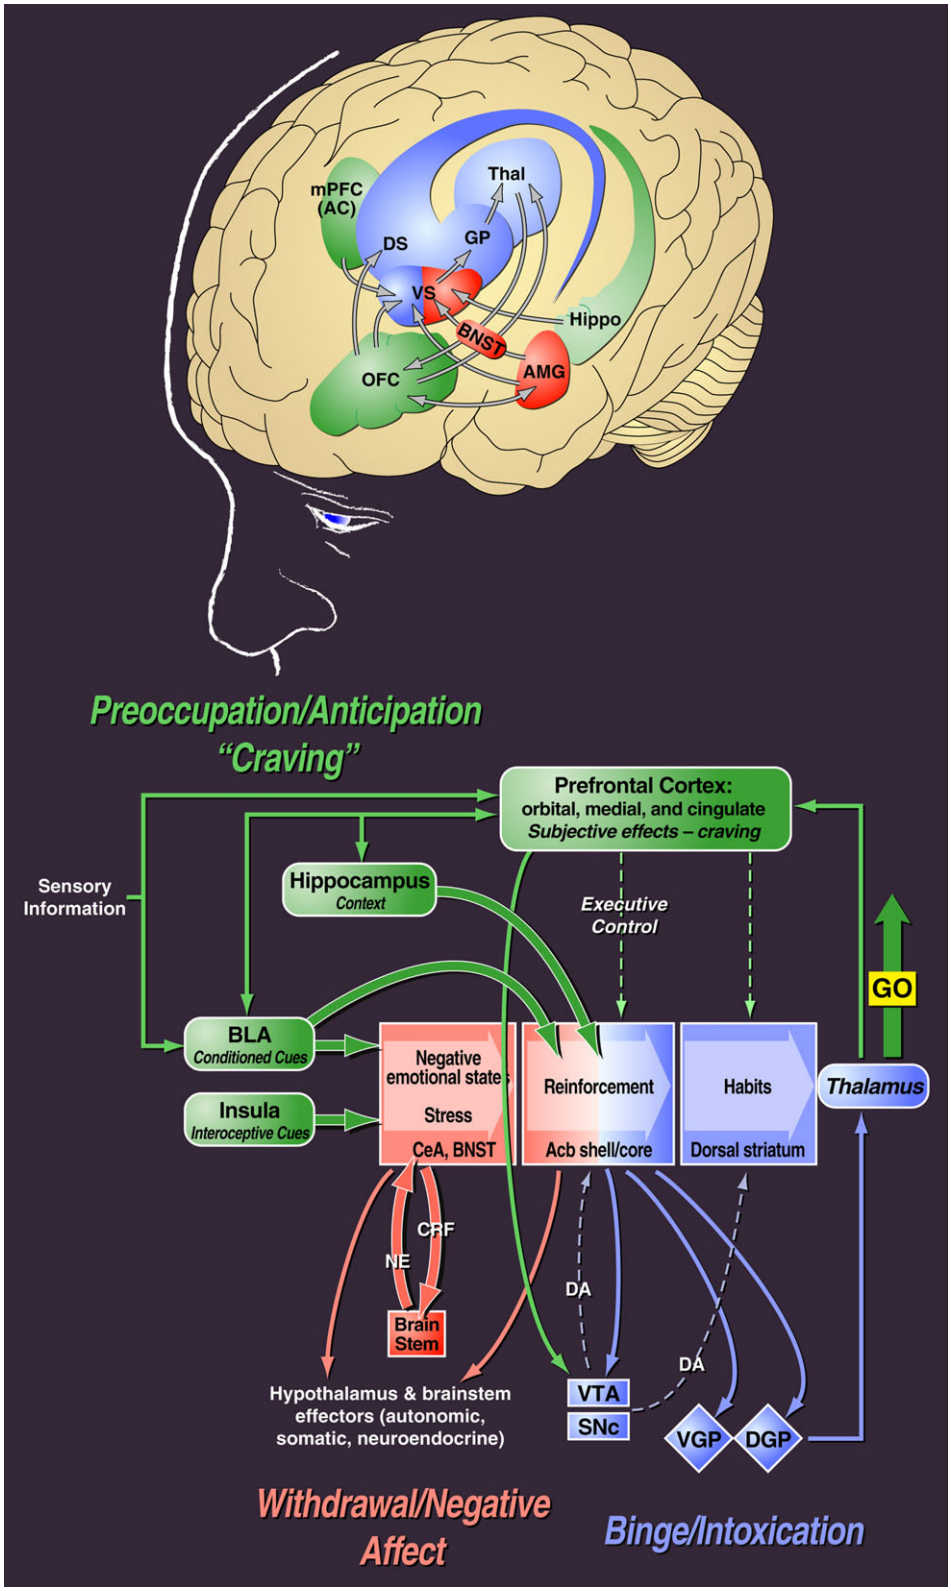

FIGURE 41.6 Neurocircuitry schematic illustrating the combination of neuroadaptations in the brain circuitry for the three stages of the addiction cycle that drive drug-seeking behavior in the addicted state. Note the activation of the ventral striatum/dorsal striatum/extended amygdala driven by cues via hippocampal and basolateral amygdala and stress via the insula. The frontal cortex system is compromised, producing deficits in executive function and contributing to the incentive salience of drugs compared to natural reinforcers. Dopamine systems are compromised, and brain stress systems such as corticotropin-releasing factor (CRF) are activated to reset further the salience of drugs and drug-related stimuli in the context of an aversive dysphoric state. *Modified with permission from Koob and Volkow (2010) and based on Everitt and Robbins (1995).*

Household Survey on Drug Abuse of the National Institute on Drug Abuse of the United States reveal that approximately 21.8 million Americans aged 12 and older were past-month users of illicit drugs, and 22.5 million could be classified with substance dependence or abuse. In addition, 15.4 million individuals were dependent on or abused alcohol, and 69.7 million were current smokers (Substance Abuse and Mental Health Services Administration, 2010). The cost of drug abuse to society is staggering. Total economic costs of alcohol abuse per year in the United States is listed as $166.5 billion dollars, smoking $157 billion dollars (Centers for Disease Control and Prevention, 2004), and illicit drugs $193 billion dollars (National Drug Intelligence Center, 2011). This totals over $500 billion dollars in lost productivity due to illness or death, health care expenditures, motor vehicle crashes, and social welfare, among others (Stein, 2001).

Addiction Cycle

Drug addiction, also known as substance dependence, is a chronically relapsing disorder characterized by (1) compulsion to seek and take the drug, (2) loss of control in limiting intake, and (3) emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) when access to the drug is prevented (Koob & Le Moal, 1997). *Addiction* and *substance dependence* (as currently defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition; American Psychiatric Association, 1994) will be used interchangeably throughout this text and refer to a final stage of a usage process that moves from drug use to addiction. Clinically, the occasional but limited use of a drug with the *potential* for abuse or dependence is distinct from escalated drug use and the emergence of a chronic drug-dependent state (Table 41.1). An important goal of current neurobiological research is to understand

TABLE 41.1 DSM-IV and ICD-10 Diagnostic Criteria for Alcohol and Drug Dependence

	DSM-IV	ICD-10
Clustering criterion	A. A maladaptive pattern of substance use, leading to clinically significant impairment or distress as manifested by three or more of the following occurring at any time in the same 12-month period:	A. Three or more of the following have been experienced or exhibited at some time during the previous year:
Tolerance	1. Need for markedly increased amounts of a substance to achieve intoxication or desired effect; or markedly diminished effect with continued use of the same amount of the substance.	1. Evidence of tolerance, such that increased doses are required in order to achieve effects originally produced by lower doses.
Withdrawal	2. The characteristic withdrawal syndrome for a substance or use of a substance (or a closely related substance) to relieve or avoid withdrawal symptoms.	2. A physiological withdrawal state when substance use has ceased or been reduced as evidenced by: the characteristic substance withdrawal syndrome, or use of substance (or a closely related substance) to relieve or avoid withdrawal symptoms.
Impaired control	3. Persistent desire or one or more unsuccessful efforts to cut down or control substance use. 4. Substance used in larger amounts or over a longer period than the person intended.	3. Difficulties in controlling substance use in terms of onset, termination, or levels of use.
Neglect of activities	5. Important social, occupational, or recreational activities given up or reduced because of substance use.	4. Progressive neglect of alternative pleasures or interests in favor of substance use; or
Time spent	6. A great deal of time spent in activities necessary to obtain, to use, or to recover from the effects of substance used.	a great deal of time spent in activities necessary to obtain, to use, or to recover from the effects of substance use.
Inability to fulfill roles	None	None
Hazardous use	None	None
Continued use despite problems	7. Continued substance use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to be caused or exacerbated by use.	5. Continued substance use despite clear evidence of overtly harmful physical or psychological consequences.
Compulsive use	None	6. A strong desire or sense of compulsion to use substance.
Duration criterion	B. No duration criterion separately specified. However, several dependence criteria must occur repeatedly as specified by duration qualifiers associated with criteria (e.g., "often," "persistent," "continued").	B. No duration criterion separately specified.
Criterion for subtyping dependence	*With physiological dependence*: Evidence of tolerance or withdrawal (i.e., any of items A-1 or A-2 above are present). *Without physiological dependence*: No evidence of tolerance or withdrawal (i.e., none of items A-1 or A-2 above are present).	None

the neuropharmacological and plastic mechanisms within specific neural circuits that mediate the transition from occasional, controlled drug use to the loss of behavioral control over drug-seeking and drug-taking that defines chronic addiction.

Addiction has been conceptualized as a chronic relapsing disorder with roots both in impulsivity and compulsivity and neurobiological mechanisms that change as an individual moves from one domain to the other (Hyman, Malenka, & Nestler, 2006). Subjects with impulse control disorders experience an increasing sense of tension or arousal before committing an impulsive act; pleasure, gratification, or relief at the time of committing the act; and finally, regret, self-reproach, or guilt following the act. In contrast, individuals with compulsive disorders experience anxiety and stress before committing a compulsive repetitive behavior and then relief from the stress by performing the compulsive behavior. In addiction, drug-taking behavior progresses from impulsivity to compulsivity in a three-stage cycle: *binge/intoxication*, *withdrawal/negative affect*, and *preoccupation/anticipation*. As individuals move from an impulsive to a compulsive disorder, the drive for the drug-taking behavior shifts from positive to negative reinforcement (Fig. 41.7). Impulsivity persists, but compulsivity develops (Box 41.4). Impulsivity in general is an aberration of reward anticipation processes, mainly in the ventral striatum (plus possibly response preparation processes in the dorsal striatum), whereas compulsivity is in part the product of habit structures mediated by the dorsal striatum (plus possibly ventral striatal Pavlovian overmotivation; Everitt & Robbins, 2005). Compulsivity also involves the additional negative reinforcement recruited from sensitization of the brain stress systems (Koob & Le Moal, 2005).

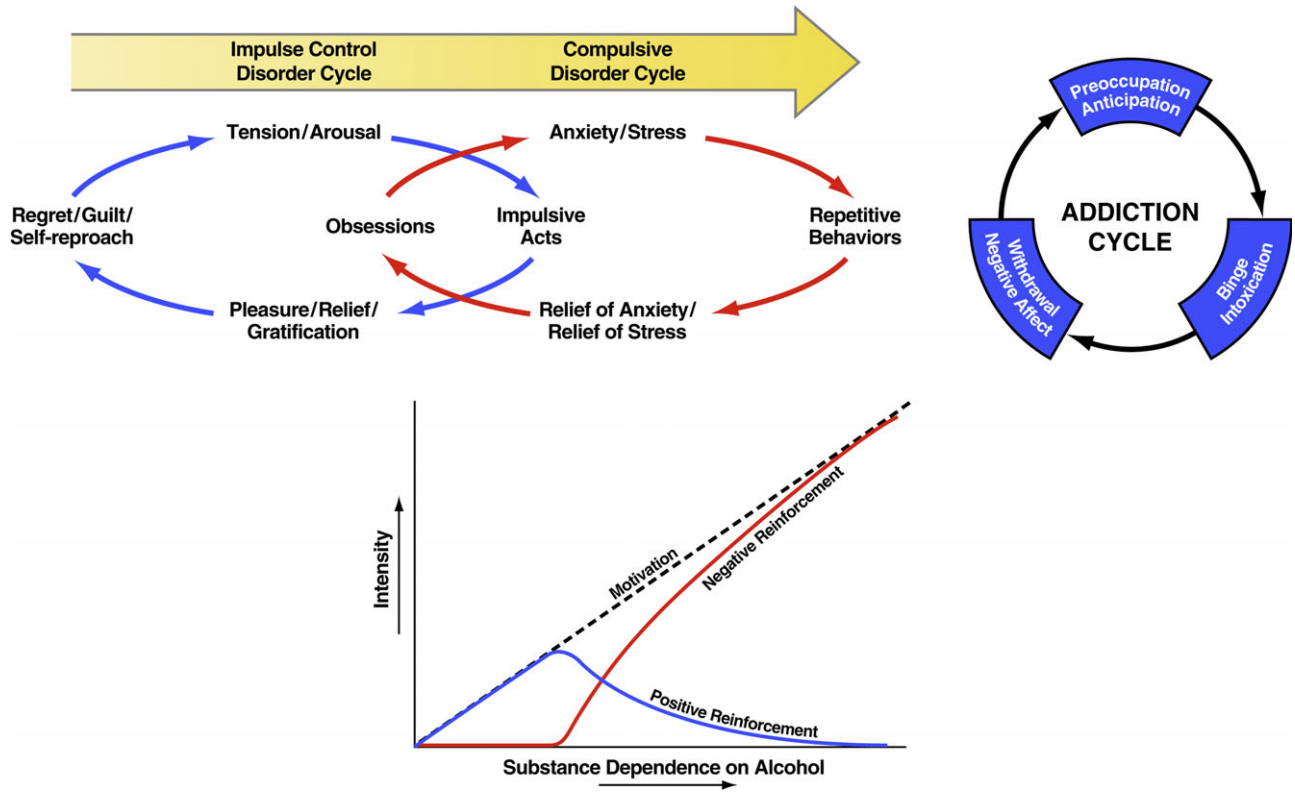

FIGURE 41.7 (Top) Diagram showing the stages of impulse control disorder and compulsive disorder cycles related to the sources of reinforcement. In impulse control disorders, an increasing tension and arousal occurs before the impulsive act, with pleasure, gratification, or relief during the act. Following the act, there may or may not be regret or guilt. In compulsive disorders, there are recurrent and persistent thoughts (obsessions) that cause marked anxiety and stress, followed by repetitive behaviors (compulsions) that are aimed at preventing or reducing distress (American Psychiatric Association, 1994). Positive reinforcement (pleasure/gratification) is more closely associated with impulse control disorders. Negative reinforcement (relief of anxiety or relief of stress) is more closely associated with compulsive disorders. (Bottom) Change in the relative contribution of positive and negative reinforcement constructs during the development of substance dependence on alcohol. *Taken with permission from Koob, (2011).* (Top right) Collapsing the cycles of impulsivity and compulsivity results in the addiction cycle, conceptualized as three major components: *preoccupation/anticipation*, *binge/intoxication*, and *withdrawal/negative affect. BOX 41.4

IMPULSIVITY AND COMPULSIVITY

Impulsivity can be defined behaviorally as "actions which are poorly conceived, prematurely expressed, unduly risky, or inappropriate to the situation and that often result in undesirable consequences" (Durana and Barnes, 1993). However, *compulsivity* can be captured by a modification of the definition of impulsivity: actions inappropriate to the situation which persist, have no obvious relationship to the overall goal, and which often result in undesirable consequences (e.g., operationally defined as responding for a drug or alcohol in the face of adverse consequences (Wolffgramm & Heyne, 1995), responding in the face of punishment (Vanderschuren & Everitt, 2004), perseveration in reversal learning (Walker, Robbins, & Roberts, 2009), or responding for a drug or alcohol on a progressive-ratio schedule of reinforcement (Walker, Rasmussen, Raskind, Koob, 2008)).

Much of the recent progress in understanding the neurobiology of addiction has derived from the study of animal models of addiction on specific drugs such as opioids, stimulants, and alcohol. While no animal model of addiction fully emulates the human condition, animal models do permit the investigation of specific elements of the process of drug addiction. Such elements can be defined by psychological constructs such as positive and negative reinforcement and different stages of the addiction cycle.

Neurobiological Substrates of Drug Reward

Positive Reinforcing Effects of Drugs Are Mediated by Multiple Systems Converging on Common Targets in the Basal Forebrain

As noted above, the medial forebrain bundle is involved in brain stimulation reward and natural rewards, and work in the neurobiology of addiction has led to an understanding of the neurochemical and neuroanatomical components of this system. The principal components of this system include the ventral tegmental area, basal forebrain (nucleus accumbens, olfactory tubercle, frontal cortex, and amygdala), and dopamine connection between the VTA and basal forebrain, called the mesolimbic dopamine system. Additional components are the opioid peptide, GABA, serotonin (5-hydroxytryptamine; 5-HT), and endocannabinoid systems that interact with the ventral tegmental area and the basal forebrain (Koob, 1992) (Fig. 41.8). The functional role of each component of the basal forebrain reward system is discussed in the following sections. The actions of several groups of drugs with respect to this system, including indirect sympathomimetics (cocaine and amphetamine), opioids (heroin), nicotine, sedative hypnotics (alcohol, barbiturates, and benzodiazepines), and Δ^9-tetrahydrocannabinol (THC) also will be discussed.

The Positive Reinforcing Effects of Cocaine and Other Indirect Sympathomimetics Depend Critically on the Mesolimbic Dopamine System

Amphetamine and cocaine are psychomotor stimulants that, in humans, have behavioral effects such as suppressing hunger and fatigue and inducing euphoria. In animals, these drugs increase locomotor activity, decrease food intake, stimulate operant behavior, enhance conditioned responding, and produce place preferences. Psychomotor stimulants also decrease thresholds for reinforcing brain stimulation and act as reinforcers for drug self-administration (Koob, 1992) (Fig. 41.8).

Psychomotor stimulants with a high potential for abuse have effects that lead to increases in the availability of monoamine neurotransmitters at synapses. By blocking reuptake or enhancing release, cocaine and amphetamine increase the synaptic availability of dopamine, norepinephrine, and serotonin. However, the acute reinforcing effects of these drugs depend critically on dopamine. Studies of intravenous self-administration have provided the most direct evidence implicating dopamine and, more specifically, the mesolimbic dopamine system in the reinforcing actions of cocaine and amphetamines. Low doses of dopamine receptor antagonists injected either systemically or centrally into the nucleus accumbens, amygdala, or bed nucleus of the stria terminalis block cocaine and amphetamine self-administration in rats. A specific role for the mesolimbic dopamine system in the reinforcing properties of cocaine and amphetamine was deduced from the observation that neurotoxin-induced lesions of the terminal regions of the mesolimbic dopamine system in the nucleus accumbens produce a significant and long-lasting decrease in self-administration of cocaine and amphetamine over days (Koob, 1992). 6-OHDA-induced lesions of the dopamine terminals in the nucleus accumbens even decrease the amount of work an animal will perform for cocaine without affecting work for many other reinforcers, such as food.

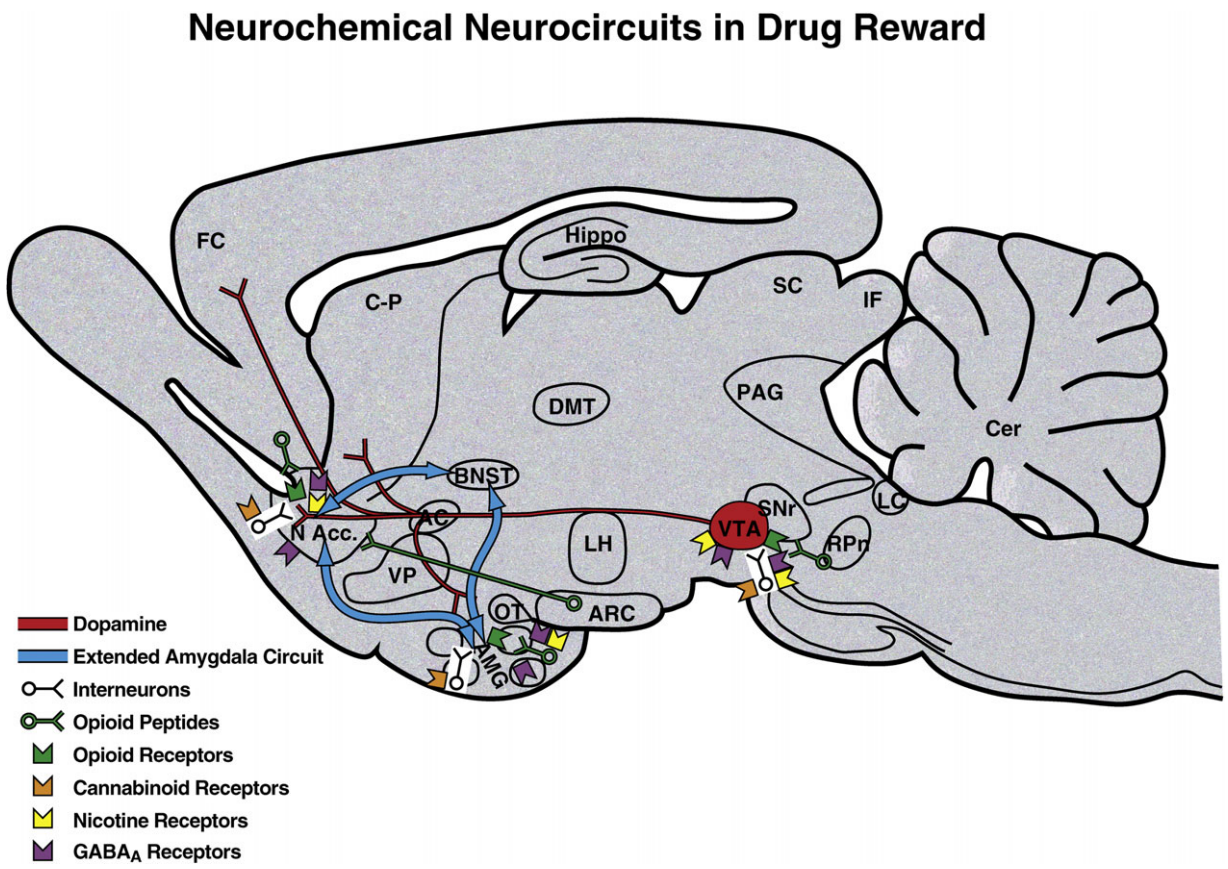

FIGURE 41.8 Sagittal section through a representative rodent brain illustrating the pathways and receptor systems implicated in the acute reinforcing actions of drugs of abuse. Cocaine and amphetamines activate the release of dopamine in the nucleus accumbens and amygdala via direct actions on dopamine terminals. Opioids activate opioid receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Opioids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens (but also are hypothesized to activate elements independent of the dopamine system). Alcohol activates γ-aminobutyric acid-A ($GABA_A$) receptors in the ventral tegmental area, nucleus accumbens, and amygdala via either direct actions at the $GABA_A$ receptor or through indirect release of GABA. Alcohol is hypothesized to facilitate the release of opioid peptides in the ventral tegmental area, nucleus accumbens, and central nucleus of the amygdala. Alcohol facilitates the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens. Nicotine activates nicotinic acetylcholine receptors in the ventral tegmental area, nucleus accumbens, and amygdala, either directly or indirectly, via actions on interneurons. Nicotine also may activate opioid peptide release in the nucleus accumbens or amygdala independent of the dopamine system. Cannabinoids activate CB_1 receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Cannabinoids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens, but also are hypothesized to activate elements independent of the dopamine system. Endogenous cannabinoids may interact with postsynaptic elements in the nucleus accumbens involving dopamine and/or opioid peptide systems. The blue arrows represent the interactions within the extended amygdala system hypothesized to have a key role in drug reinforcement. AC, anterior commissure; AMG, amygdala; ARC, arcuate nucleus; BNST, bed nucleus of the stria terminalis; Cer, cerebellum; C-P, caudate-putamen; DMT, dorsomedial thalamus; FC, frontal cortex; Hippo, hippocampus; IF, inferior colliculus; LC, locus coeruleus; LH, lateral hypothalamus; N Acc., nucleus accumbens; OT, olfactory tract; PAG, periaqueductal gray; RPn, reticular pontine nucleus; SC, superior colliculus; SNr, substantia nigra pars reticulata; VP, ventral pallidum; VTA, ventral tegmental area. *Taken with permission from Koob (2005).*

Neural Substrates of Sensitization Involve Changes in the Mesolimbic and Nigrostriatal Dopamine Systems

Under certain circumstances, repeated administration of stimulants and opioids results in increasingly strong motor activation, and these effects have been hypothesized to contribute to the development of the neuroadaptations associated with addiction, particularly those involving initial use and/or reinstatement of drug-taking following abstinence. This sensitization to the activating effects of stimulants involves activation of the mesolimbic and nigrostriatal dopamine system (Robinson & Berridge, 1993). Repeated microinjections of amphetamine into the somatodendritic region of the ventral tegmental dopamine cells, at doses that do not cause behavioral activation, are sufficient to sensitize the dopamine cells to later systemic injections of amphetamine. This sensitization can be manifested as increased locomotor activation or

increased stereotyped-like behavior (see above). Thus, changes in the activity of these dopamine cells are sufficient to produce sensitization.

Multiple mechanisms for sensitization have been proposed, and a common theme is a time-dependent chain of adaptations that ultimately leads to long-lasting changes in the function of the mesolimbic dopamine system (Robinson & Berridge, 1993). For example, repeated administration of cocaine produces a decrease in the sensitivity of impulse-regulating somatodendritic dopamine D_2 receptors on dopamine neurons (termed *autoreceptors* because the neuron is itself responding to the transmitter it releases). Because these autoreceptors normally exert an inhibitory influence on the activity of dopaminergic neurons, this change in sensitivity could translate into enhanced dopamine availability with subsequent injections of cocaine (Robinson & Berridge, 1993). However, the decrease in D_2 receptor sensitivity lasts only 4–8 days, and behavioral sensitization can last for weeks; thus, other mechanisms also must be involved. *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonists selectively block the development of sensitization to psychomotor stimulants, suggesting a role for brain glutamate systems and specific glutamate receptors in sensitization (Robinson & Berridge, 1993). In addition, an increased surface-to-intracellular ratio of glutamate-1 receptors (GluR1) has been observed 21 days after the last injection of cocaine, suggesting a slowly developing redistribution of AMPA receptors to the surface of nucleus accumbens neurons, particularly in those lacking GluR2 subunits (Boudreau & Wolf, 2005).

Stressors can cause sensitization to stimulant drugs, and both the stress axis and the extrahypothalamic corticotropin-releasing factor (CRF) system appear to be important in stress-induced sensitization (Koob, 1999). The hypothalamic-pituitary-adrenal stress axis (see Chapter 33) also may play an important role in sensitization. Sensitization may be hypothesized to play a key role in initial sensitivity to drugs and contribute to the high incentive salience attributed to drugs during the course of addiction. However, sensitization of the reward systems is not readily observed in individuals meeting the criteria for addiction, rather a profound tolerance and negative emotional state during withdrawal are the clinical norm.

Neurobiological Substrates for the Acute Reinforcing Effects of Opioids Involve Opioid Peptide Systems

Much like psychostimulants, opioid drugs such as heroin are readily self-administered intravenously by animals, and with limited access opioids do not produce dependence (Schuster & Thompson, 1969). Advances in opioid pharmacology, such as the identification of high specific binding for opioids in the brain and discovery of endogenous opioid peptides, provided insight into the brain systems responsible for the reinforcing effects of these drugs (Koob, 1992) (Box 41.5 and Figs. 41.7 and 41.10). The reinforcing actions of heroin and morphine appear to be mediated largely by the μ opioid receptor subtype. Antagonists at the μ receptor produce dose-dependent decreases in heroin reinforcement, and μ receptor knockout mice show loss of morphine-induced reward and loss of morphine-induced analgesia. Intracerebral opioid receptor antagonists block heroin self-administration in nondependent rats when these drugs are injected into the VTA or the region of the nucleus accumbens. Microinjections of opioids into the VTA also lower thresholds for ICSS and produce robust place preferences, and these effects appear to be dependent on mesolimbic dopamine function (Di Chiara & North, 1992). Rats will self-administer opioid peptides in the region of the nucleus accumbens. However, heroin self-administration is not blocked by dopamine receptor antagonists administered at doses that block cocaine self-administration or by large neurotoxin-induced lesions of the mesolimbic dopamine system. These

BOX 41.5

OPIOID RECEPTORS

In 1978, Professors Solomon H. Snyder, John Hughes, and Hans W. Kosterlitz were awarded the Lasker award for their combined discovery of opioid receptors in the brain and for the even more amazing discovery of the existence of endogenous ligands for opioid receptors. The endogenous brain compounds were peptides, called enkephalins and endorphins, which shared all the physiologic properties of opioids. These observations opened a rich field of inquiry into the mechanism of action of opioid drugs, and these findings began a new outlook on neuropeptide neurotransmitters, an area of intense research. First, many new neuropeptides have been discovered with brain receptors potentially amenable to nonpeptidergic agonists and antagonists. Second, because neuropeptides are contained within neurons that also are more conventional amino acid or amine transmitters, the possibility of multiple mediators for any specific synapse had to be considered.

results demonstrate that neural elements in the regions of the VTA and nucleus accumbens are responsible for the reinforcing properties of opioids, suggesting both dopamine-dependent and dopamine-independent opiate actions.

Nicotine Activates Mesolimbic Dopamine

Nicotine has anti-fatigue, stimulant-like, and anti-anxiety effects and appears to improve cognitive performance in animals and humans. It has direct reinforcing actions, as measured by intravenous self-administration in animals and humans. Nicotine is a direct agonist at nicotinic acetylcholine receptors (see Chapter 8) and appears to activate nicotinic acetylcholine receptors in the mesolimbic dopamine system both at the level of the VTA and nucleus accumbens (Figs. 41.7 and 41.10). Knockout of the $\alpha 4$ and $\beta 2$ nicotinic acetylcholine receptor subunit blocks nicotine self-administration (Picciotto et al., 1998). Blockade of dopaminergic systems with antagonists or lesions to the mesolimbic dopamine system can also block nicotine self-administration, suggesting a key role for dopamine in the acute reinforcing actions of nicotine.

Alcohol Has Multiple Neurochemical Substrates within Brain Reinforcement Systems

Alcohol (i.e., ethanol), barbiturates, and benzodiazepines all have measurable sedative–hypnotic actions, including euphoria, disinhibition, anxiety reduction, sedation, and hypnosis. All of these drugs also have anxiolytic (or antianxiety) effects, reflected in conflict situations as a reduction of behavior suppressed by punishment. The neurobiological basis of the anxiolytic properties of these sedative–hypnotic drugs has provided clues to their reinforcing properties and their abuse potential. For example, GABAergic receptor antagonists reverse many of the behavioral effects of alcohol, an observation that has led to the hypothesis that GABA has a role in alcohol's intoxicating effects. Further support for a role of brain GABA in alcohol reinforcement is the observation that potent antagonists of GABA receptor function decrease alcohol reinforcement, and one particularly affected brain site is the central nucleus of the amygdala (Koob, 1992). Activation of opioid peptide systems has been implicated in alcohol reinforcement by numerous reports that the opiate antagonists naloxone and naltrexone reduce alcohol self-administration in several animal models (Tabakoff & Hoffman, 1992). The brain site most sensitive to opioid receptor antagonists are the VTA and central nucleus of the amygdala (Figs. 41.7 and 41.10).

Dopamine receptor antagonists also reduce lever pressing for alcohol in nondeprived rats (Koob, 1992), and extracellular dopamine levels increase in nondependent rats orally self-administering low doses of alcohol (Koob & Le Moal, 2001). Low doses of acetaldehyde are also self-administered by animals, and increasing evidence suggests that acetaldehyde may mediate some of ethanol's effects on the mesolimbic dopamine system (Rodd et al., 2005). However, virtually complete destruction of dopamine terminals in the nucleus accumbens by 6-OHDA failed to alter voluntary responding for alcohol (Tabakoff & Hoffman, 1992). Combined with the pharmacologic data discussed earlier, these results suggest that although mesolimbic dopamine transmission may be associated with important aspects of alcohol reinforcement, it is not critical for the reinforcing properties of alcohol, and multiple neurotransmitters combine to orchestrate the reward profile of this drug (Engel, et al. 1987). For example, alcohol in a physiologic dose range may antagonize the actions of glutamate. In addition, increases and decreases in synaptic availability of serotonin (e.g., via blockade of serotonin reuptake or via administration of selective serotonin receptor antagonists) reduce the voluntary intake of alcohol.

Δ^9-Tetrahydrocannabinol Has Effects Similar to Other Drugs of Abuse

THC shares effects in animal models of drug reinforcement similar to those of other drugs of abuse. Upon acute administration, THC decreases ICSS reward thresholds and produces a place preference in rats. It maintains self-administration behavior in squirrel monkeys, and a synthetic THC analog is self-administered intravenously in mice. THC binds to the cannabinoid CB_1 receptor that is distributed widely throughout the brain, particularly in the striatum, and is thought to mediate some of the actions of the endogenous endocannabinoids. THC self-administration is blocked by both CB_1 and opioid receptor antagonists (Justinova, Tanda, Munzar, & Goldberg, 2004; Justinova, Solinas, Tanda, Redhi, & Goldberg, 2005) (Figs. 41.7 and 41.10).

Neurobiological Substrates for the Withdrawal/Negative Affect State of Drug Dependence

Substance dependence is defined as compulsive, uncontrollable drug use; however, the etiology of that compulsive use is multidimensional. Although positive reinforcement is clearly necessary for the development of drug use, it may fall short in explaining the development of compulsive use. For example, tolerance or apparent tolerance develops to drug reward during chronic use, with positive reinforcement either being absent or subsumed by negative reinforcement. Indeed, this issue raises the question of what factors distinguish drug *use* from *abuse* and *dependence* or addiction.

Negative Affect Is a Common Result of Withdrawal from Chronic Administration of Drugs of Abuse

Withdrawal signs associated with the cessation of chronic drug administration usually are characterized by responses that are opposite to the initial effects of the drug. The physical signs (or somatic signs) of withdrawal are typically drug-specific. However, all drugs of abuse produce rewarding effects, and withdrawal commonly is associated with subjective symptoms of dysphoria, negative affect, and anxiety (Koob & Le Moal, 2001). In the case of opioid withdrawal, subjective symptoms such as dysphoria, anxiety, craving for drugs, and malaise are accompanied by both physical symptoms of extreme discomfort, including pupillary dilation, hot and cold flashes, goose bumps, and a flu-like state. In the case of alcohol withdrawal, humans show tremor and increases in heartbeat rate, blood pressure, and body temperature, as well as subjective signs, including dysphoria, anxiety, insomnia, and malaise. Indeed, whereas few physical signs of withdrawal usually are observed during cocaine withdrawal in humans, cessation of cocaine use often is characterized by severe depressive symptoms combined with irritability, anxiety, and anhedonia lasting several hours to several days (i.e., the "crash") and may be a motivating factor in the maintenance of the cocaine dependence cycle. Withdrawal from nicotine is characterized by anxiety, negative affect, fatigue, irritability, sleep disturbances, and an intense craving for cigarettes. Withdrawal from THC resembles a combination of sedative–hypnotic or opioid withdrawal, with irritability, restlessness, hot flashes, sweating, disturbances in appetite and sleep, and low-level dysphoria. Withdrawal from benzodiazepines resembles that of alcohol withdrawal but generally is more prolonged in onset and less intense.

Chronic Drug Administration Compromises the Brain Reward Systems

In animal studies, withdrawal from chronic administration of stimulants has been studied using ICSS after repeated administration of cocaine or amphetamine over several weeks or 12–48 h of cocaine self-administration. Withdrawal from prolonged self-administration of cocaine in rats increases ICSS reward thresholds. Here, an increase in reward thresholds has been hypothesized to reflect a dysphoric-like state observed in humans. The increase in threshold dose is time-dependent and is an effect opposite to that of acute cocaine (Koob & Le Moal, 2001). Similar effects have been observed during withdrawal from chronic amphetamine and methamphetamine administration. Withdrawal from chronic alcohol, opioids, nicotine, and THC also produces pronounced increases in ICSS reward thresholds, suggesting that brain reward dysregulation is a common element of acute withdrawal from drugs of abuse (Table 41.2).

TABLE 41.2 Drug Effects on Thresholds of Rewarding Brain Stimulation

Drug Class	Acute Administration	Withdrawal from Chronic Treatment
Psychostimulants (cocaine, amphetamines)	↓	↑
Opioids (morphine, heroin)	↓	↑
Nicotine	↓	↑
Sedative–hypnotics (ethanol)	↓	↑
Cannainoids	↓	↑

Neural Circuitry Mediating Withdrawal/Negative Reinforcement

A brain system that mediates aversion was identified early on by a combination of anatomical and behavioral experiments. For example, mapping studies identified sites eliciting escape from brain stimulation, sites at which electrical brain stimulation elicits defensive responses, and sites at which fear or pain naturally evokes aggressive responses. One component of the neural circuitry that mediates aversion includes connections from the medial habenula to interpeduncular nucleus, which in turn projects to brainstem serotonergic neurons as well as projections from the lateral habenula to the rostral tegmental nucleus, which provides inhibitory inputs to dopaminergic neurons in the VTA and substantia nigra.

Aversion May Be Mediated by Opponent Motivational Processes

Animal learning theory has led to the concept of opponent motivational processes (one appetitive, one aversive). An influential model proposed which reinforcers produce affective and hedonic effects (*a-processes*) which are opposed by *b-processes* of opposite affective sign in a simple, dynamic control system for affect (Fig. 41.9) (Solomon & Corbit, 1974). The *a-process* follows the reinforcing event with short latency and then decays. Its size decreases with repeated presentation of the reinforcer. The *b-process* has a longer latency of onset, reaches its maximum only after repeated trials, and decays very slowly. These components of emotional responses are exhibited in response to many reinforcers, including not only drugs such as heroin, but also natural rewards that also may lead to different forms of "dependence," such as attachment of offspring to a mother. So, for example, either heroin or the mother elicits a hedonic *a-process*, which is followed by a rebound negative or aversive *b-process* when the heroin wears off (or the mother leaves). These effects may

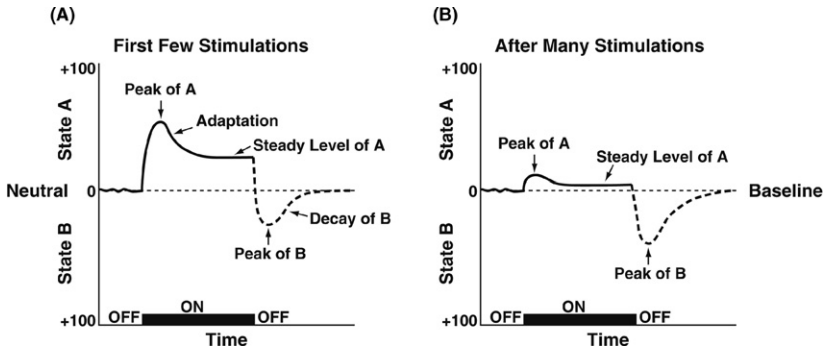

FIGURE 41.9 (A) The standard pattern of affective dynamics produced by a relatively novel unconditioned stimulus (nondependent drug intake). (B) The standard pattern of affective dynamics produced by a familiar, frequently repeated unconditioned stimulus (dependent drug intake). First, an unconditional arousing stimulus triggers a primary affective process, termed the *a-process*. An unconditional reaction that translates the intensity, quality, and duration of the stimulus (for example, the first injection of a drug). Second, as a consequence of the *a-process*, the *b-process* is evoked after a short delay, an opponent process. The two responses are consequently and temporarily linked (*a* triggers *b*) but are hypothesized to depend on different neurobiological mechanisms. The *b-process* has a longer latency but more inertia, slower recruitment, and more sluggish decay. At a given moment, the pattern of affect will be the algebraic sum of these opposite influences and the dynamics reveal, with the passage of time, the net product of the opponent process. *Taken with permission from Solomon (1980).*

get stronger with repeated experiences of heroin (or the mother at a critical period of development), leading to a form of dependence in each case. The opponent process also can work in reverse. For example, if tolerance develops for an initially aversive experience, then a rebound hedonic response can occur when this experience stops. Indeed, this has been suggested partly to explain the "pleasure" of jogging.

How might these opponent processes be mediated? The neuroadaptive mechanisms that reflect changes in reward function have been hypothesized to be alterations of the same neurotransmitters implicated in the acute reinforcing effects of drugs (Koob & Bloom, 1988). Examples of such homeostatic, "within-system" adaptations include decreases in dopaminergic and serotonergic transmission in the nucleus accumbens during drug withdrawal as measured by *in vivo* microdialysis (Parsons, Koob, & Weiss, 1995; Weiss, Markou, Lorang, & Koob, 1992), increased sensitivity of opioid receptor transduction mechanisms in the nucleus accumbens during opioid withdrawal (Shaw-Lutchman et al., 2002), and decreased GABAergic and increased NMDA glutamatergic transmission during ethanol withdrawal (Fitzgerald & Nestler, 1995; Roberts, Cole, & Koob, 1996; Weiss et al., 1996). However, recruitment of other neurotransmitter systems in the adaptive responses to drugs of abuse may involve neurotransmitter systems not linked to the acute reinforcing effects of the drug, or a "between-system" neuroadaptation (Koob & Bloom, 1988). An example of a between-system neuroadaptation is the activation of brain stress systems such as CRF and dysregulation of other stress-mediating neurotransmitter systems, such as dynorphin, during withdrawal (Koob & Le Moal, 2005) (see below).

Neurochemical Adaptation in Reward Neurotransmitters

Dopamine and Serotonin Systems Show Neuroadaptive Changes with Substance Dependence

Monoamines, including dopamine and serotonin, have been implicated in the reinforcing actions of each of the drugs discussed: psychostimulants, opioids, nicotine, alcohol, and THC. One way of assessing the prolonged effects of drug self-administration is to measure extracellular levels of a neurotransmitter during ongoing behaviors, such as intravenous self-administration of a drug or withdrawal from the drug after a period of chronic self-administration. Such measurements can be made by using the technique of *in vivo* microdialysis, which involves implanting into a specific site in the brain a guide cannula through which a probe with a semipermeable membrane at the tip perfuses and collects the neurotransmitter in extracellular fluid. Several studies using this technique have shown that extracellular dopamine and serotonin levels in the nucleus accumbens decrease during acute withdrawal from cocaine, opioids, and alcohol, an effect opposite to that of acute drug administration. Consistent with these results, many studies have shown that acute withdrawal from all drugs of abuse results in decreased firing of VTA dopamine neurons (Melis, Spiga, & Diana, 2005).

Brain Stress Systems: Corticotropin-Releasing Factor, Noradrenergic, and Dynorphin-κ Opioid Systems Show Neuroadaptive Changes with Substance Dependence

Anxiety, stress, and dysphoria are common elements of substance dependence and acute withdrawal from drugs

of abuse in humans, and withdrawal from drugs of abuse produces stress-like behavior in animals (Sarnyai, Shaham, & Heinrichs, 2001). Stress can be defined simply as *any challenge to or alteration in psychological homeostatic processes*. Animal studies exploring the role of brain stress systems in the actions of alcohol, opioids, cocaine, nicotine, and THC have provided evidence of a neurochemical basis for the stress associated with abstinence following chronic drug administration. One major player is CRF. Not only is CRF a major hypothalamic releasing factor controlling the classic glucocorticoid stress response, but it also appears to have a neurotropic role in the central nervous system, modulating behavioral responses to stress. CRF itself produces stress-related behaviors, and CRF antagonists reverse a number of behavioral responses to stress. Rats treated repeatedly with drugs such as alcohol, opioids, and cocaine show significant stress-like responses in behavioral tests that follow the cessation of drug administration, and these responses are reversed by administration of a CRF antagonist directly into the brain. For example, injection of a CRF antagonist into the central nucleus of the amygdala reverses the stress-like effects of withdrawal from alcohol, cocaine, nicotine, opioid, and THC in rats. Withdrawal from alcohol, cocaine, nicotine, opioids, and THC is associated with an increase in the release of CRF into the amygdala, suggesting that drug withdrawal can activate CRF systems previously implicated in behavioral responses to stress (Fig. 41.10). Also, stress-induced reinstatement of drug self-administration following extinction can be reversed by CRF antagonists (Shalev et al., 2002).

Norepinephrine in the limbic forebrain also has been associated with the physical and motivational signs of opioid withdrawal. Projections to the bed nucleus of the stria terminalis—a critical part of the extended amygdala—may have a role in the motivational effects of opioid withdrawal (Delfs, Zhu, Druhan, & Aston-Jones, 2000). In addition, the bed nucleus of the stria terminalis is rich in CRF neurons and has been implicated in a feed-forward norepinephrine-CRF-norepinephrine system that may be involved in stress and drug dependence. In this hypothesized feed-forward system, CRF activates brainstem noradrenergic activity, which in turn activates forebrain CRF activity, effectively closing the loop. This mechanism could explain the potentiation of stress responses with repeated exposure that could lead to psychopathology.

Intriguingly, activation of the dynorphin-κ opioid system has long been associated with the development of psychostimulant addiction. Activation of dopamine receptors in the nucleus accumbens shell stimulates a cascade of events that ultimately leads to cyclic adenosine monophosphate response element binding protein (CREB) phosphorylation and subsequent alterations in gene expression, notably the increased expression of protachykinin and prodynorphin mRNA. Subsequent activation of dynorphin systems has been hypothesized to result in decreased dopamine release, thereby contributing to the dysphoric syndrome associated with cocaine dependence (Nestler, 2001). Dynorphins produce aversive dysphoric-like effects in animals and humans and have been hypothesized to mediate negative emotional states by decreasing the functional activity of the mesolimbic dopamine system. However, such enhanced dynorphin action may also activate brain stress responses, such as CRF, or CRF in turn may activate dynorphin (McLaughlin, Marton-Poovici, & Chavkin, 2003; Land et al., 2008). Thus, activation of dynorphin systems by excessive drug use may drive both within-system (decreased reward) and between-system neuroadapatations (increased stress).

Addiction theories such as the opponent process theory postulate that the processes of tolerance to the positive affective state (hedonic tolerance) and subsequent development of the negative affective state (affective withdrawal) play important roles in the transition from drug use to drug dependence (Solomon, 1977). Whereas initial drug use may be motivated by the positive affective state produced by a drug and potentiated by sensitization, continued drug use leads to neuroadaptation to the presence of the drug, the development of a negative affective state, and ultimately self-medication of that affective state. Some theorists have gone so far as to argue that the presence of a negative affective state is the defining feature of addiction and that dysregulation of the residual reward system represents a state of allostasis, the process of obtaining stability through change (Box 41.6). The *allostasis* hypothesis suggests that *both* sensitization and opponent process mechanisms may contribute to changes in incentive motivation (or incentive salience) that convey the vulnerability to relapse for drug addiction.

Neuroadaptation, Prolonged Abstinence, and Relapse

An explanation for the chronic relapsing nature of drug addiction is that reinforcement can be derived from secondary sources that motivate continued drug use. Both positive and negative affective states can become associated with stimuli in the drug-taking environment through classical conditioning processes. When the drug taker is reexposed to these conditioned stimuli, compulsive drug use is reestablished (Box 41.7).

Conditioning to the positive affective states induced by drugs has been demonstrated in animals. Stimuli associated with drugs of abuse can maintain responding in rats and monkeys when presented without the drug. It is also possible to demonstrate conditioned withdrawal. For example, when previously neutral stimuli are paired with naloxone-induced withdrawal, the neutral stimuli themselves elicit signs of opioid withdrawal. Conditioned withdrawal has been observed in opioid-dependent animals and humans.

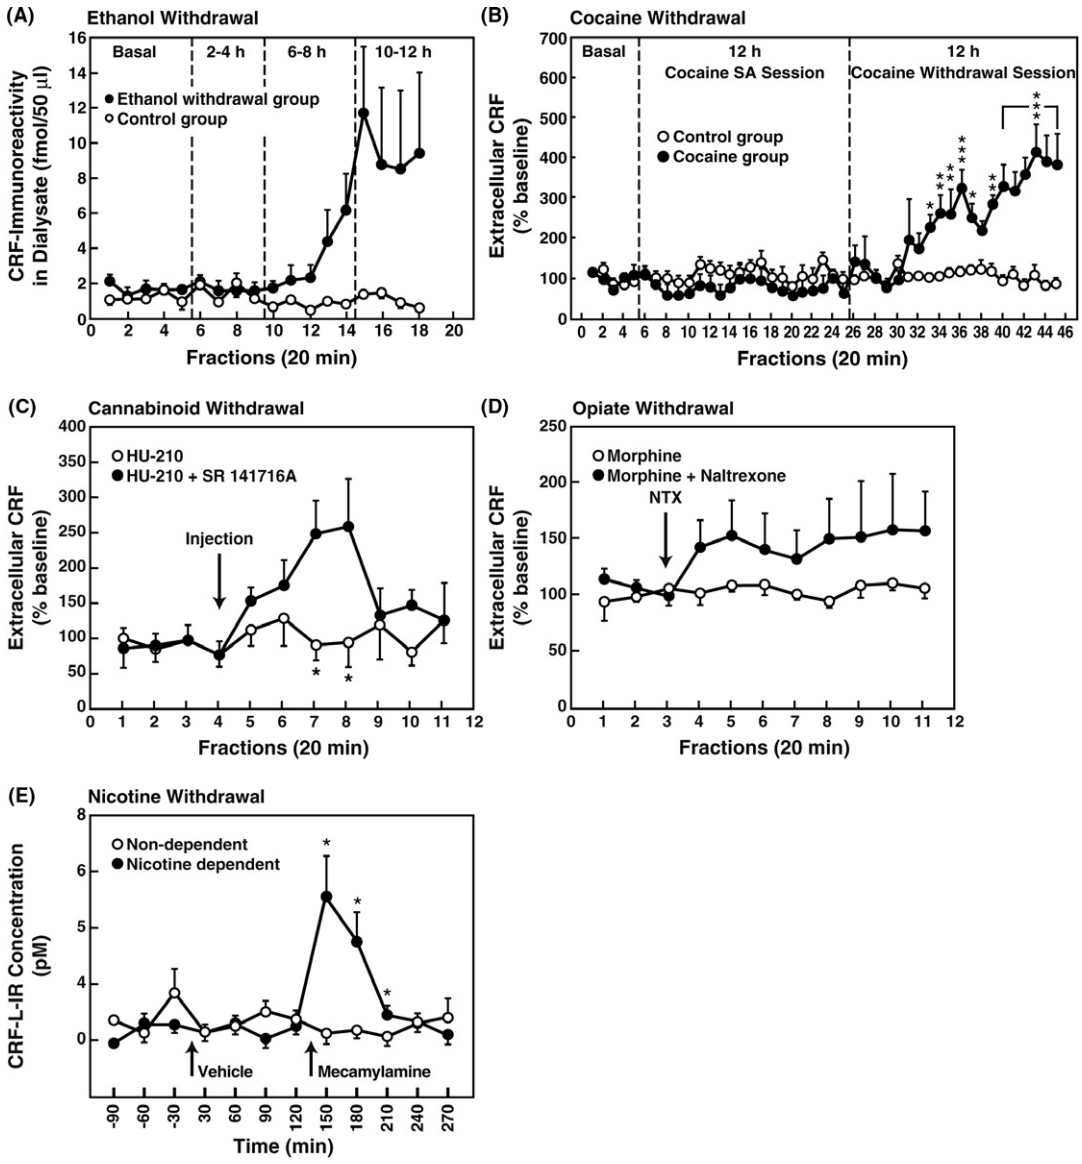

FIGURE 41.10 (A) Effects of ethanol withdrawal on CRF-like immunoreactivity (CRF-L-IR) in the rat amygdala determined by microdialysis. Dialysate was collected over four 2 h periods regularly alternated with nonsampling 2 h periods. The four sampling periods corresponded to the basal collection (before removal of ethanol), and 2–4 h, 6–8 h, and 10–12 h after withdrawal. Fractions were collected every 20 min. Data are expressed as mean ± SEM ($n = 5$ per group). Analysis of variance confirmed significant differences between the two groups over time ($p < 0.05$). *Taken with permission from Merlo-Pich et al. (1995).* (B) Mean (± SEM) dialysate CRF concentrations collected from the central nucleus of the amygdala of rats during baseline, 12 h cocaine self-administration, and a subsequent 12 h withdrawal period (cocaine group, $n = 5$). The control group consisted of rats with the same history of cocaine self-administration training and drug exposure but not given access to cocaine on the test day ($n = 6$). Data are expressed as percentages of basal CRF concentrations. Dialysates were collected over 2 h periods alternating with 1 h nonsampling periods shown by the timeline at the top. During cocaine self-administration, dialysate CRF concentrations in the cocaine group were decreased by about 25% compared with control animals. In contrast, termination of access to cocaine significantly increased CRF efflux that began approximately 5 h post-cocaine and reached about 400% of presession baseline levels at the end of the withdrawal session. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, simple main effects after overall mixed-factorial analysis of variance. *Taken with permission from Richter and Weiss (1999).* (C) Effects of cannabinoid CB_1 receptor antagonist SR 141716A (3 mg/kg) on CRF release from the central nucleus of the amygdala in rats pretreated for 14 days with the CB_1 receptor agonist HU-210 (100 mg/kg). Cannabinoid withdrawal induced by SR 141716A was associated with increased CRF release ($^{*}p < 0.005$, $n = 5$–8). Vehicle injections did not alter CRF efflux ($n = 5$–7). Data were standardized by transforming dialysate CRF concentrations into percentages of baseline values based on averages of the first four fractions. *Taken with permission from Rodriguez de Fonseca, Carrera, Navarao, Koob, & Weiss, (1997).* (D) Effects of morphine withdrawal on extracellular CRF in the central nucleus of the amygdala. Withdrawal was precipitated by administration of naltrexone (0.1 mg/kg) in rats prepared with chronic morphine pellet implants. *Taken with permission from Weiss et al. (2001).* (E) Effect of mecamylamine-precipitated (1.5 mg/kg, i.p.) nicotine withdrawal on extracellular levels of CRF-like immunoreactivity in the central nucleus of the amygdala measured by *in vivo* microdialysis in chronic nicotine pump-treated (nicotine-dependent, $n = 7$) and chronic saline pump-treated (nondependent, $n = 6$) rats. $^{*}p < 0.05$, compared with nondependent. *Taken with permission from George et al. (2007).*

BOX 41.6

ALLOSTASIS

Counteradaptive processes, such as opponent process, that are part of normal homeostatic limitations of reward function can fail to return within the normal range and are hypothesized to contribute to the allostatic state of addiction. Allostasis from the addiction perspective is defined as the process of maintaining apparent reward function stability by changes in brain reward mechanisms. The allostatic state is fueled not only by dysregulation of reward circuits *per se*, but also by the activation of brain and hormonal stress systems (Koob & Le Moal, 2001). The following definitions apply: (1) *allostasis*, the process of achieving stability through change; (2) *allostatic state*, a state of chronic deviation of the regulatory system from its normal, or homeostatic, operating level; and (3) *allostatic load*, the cost to the brain and body of the deviation, accumulating over time, and reflecting in many cases pathological states and accumulation of damage.

BOX 41.7

CRAVING

Craving is a hypothetical construct that can be defined as the memory of the rewarding effects of a drug, superimposed on a negative motivational state (Markou, Kosten, & Koob, 1998). Human studies of craving have been fraught with difficulty in linking it to relapse *per se* in humans with drug addiction, but it is a ubiquitous construct that pervades the fabric of the clinical setting (Tiffany, Carter, & Singleton, 2000). Two types of craving can be conceptualized and linked to animal models.

Craving Type 1: Craving is induced by stimuli that have been paired with drug self-administration such as environmental cues. Termed conditioned positive reinforcement in experimental psychology, an animal model of Craving Type 1 is cue-induced reinstatement where a cue previously paired with access to drug reinstates responding for a lever that has been extinguished. Another example is drug-induced reinstatement where a small dose of the drug elicits responding for a lever that has been extinguished.

Craving Type 2: Craving is conceptualized as a state change characterized by anxiety and dysphoria or a residual negative affective state that combines with Craving Type 1 situations to produce relapse to drug seeking. Animal models of Craving Type 2 include stress-induced reinstatement of drug seeking after extinction or increased drug taking in animals during or after a prolonged deprivation. Craving Type 2 can be conceptualized as a residual negative emotional state or an acute stress-like state, both of which can elicit drug-seeking behavior.

Neurobiological substrates for conditioned drug effects have been investigated in some detail (Cardinal, Parkinson, Hall, & Everitt, 2002; Everitt, Cardinal, Hall, Parkinson, & Robbins, 2000). The enhancement of conditioned reinforcement produced by psychomotor stimulants appears to involve the basolateral amygdala and its glutamatergic projection to the nucleus accumbens with dopaminergic modulation (Robbins et al., 1989). The neurobiological substrates for conditioned withdrawal also may depend on the basolateral amygdala. In contrast, drug-induced reinstatement of drug-seeking appears to be mediated via a prefrontal cortex glutamatergic projection to the nucleus accumbens with dopaminergic modulation (Kalivas & McFarland, 2003). Another powerful source of relapse in human subjects is exposure to a stressor or the state of stress. Both conditions may involve activation of CRF, dynorphin, and noradrenergic systems in the central nucleus of the amygdala and bed nucleus of the stria terminalis. Another powerful source of neurobiological changes that leads to relapse is the loss of frontal cortical function in subregions that control impulsivity and delay of gratification. Damage to such circuits can perpetuate the vulnerability to relapse occasioned by impulsive acts and choices.

Imaging Brain Circuits Involved in Addiction

Brain imaging studies using positron emission tomography with ligands for measuring oxygen utilization or glucose metabolism or using functional magnetic resonance imaging techniques have provided important insights into changes in human brain circuits associated with the development, maintenance, and even vulnerability to addiction. These imaging results, overall, are consistent with circuitry identified in animal studies. Acute intoxication with drugs such as cocaine,

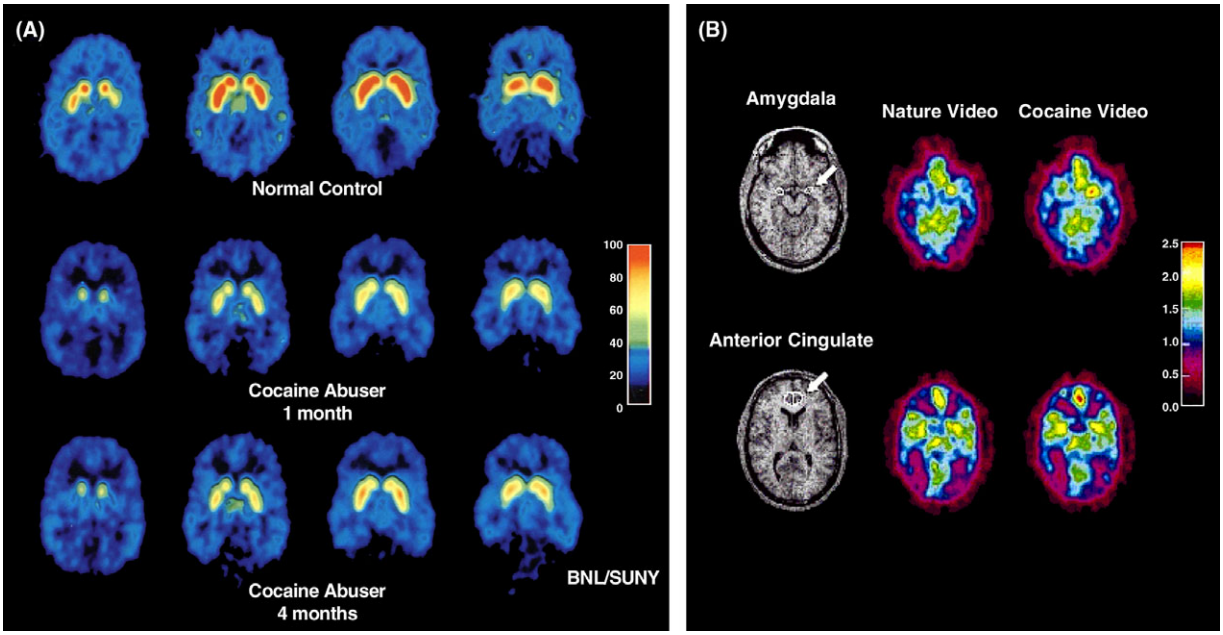

FIGURE 41.11 (A) [^{18}F]*N*-methylspiroperidol images in a normal control and in a cocaine abuser tested 1 month and 4 months after the last cocaine use. The images correspond to the four sequential planes where the basal ganglia are located. The color scale has been normalized to the injected dose. Notice the lower uptake of the tracer in the cocaine abuser compared to the normal control. Notice also the persistence of the decreased uptake even after 4 months of cocaine discontinuation. BNL, Brookhaven National Laboratory; SUNY, State University of New York. *Taken with permission from Volkow et al. (1993).* (B) Transaxial images illustrating the differential increase in relative regional cerebral blood flow (CBF) in the amygdala and anterior cingulate of a detoxified cocaine patient during a nondrug-related (nature) video and a cocaine-related video. Anatomical regions of interest first were localized on the patient's magnetic resonance image (the first image in each row). Region templates were subsequently superimposed on [^{15}O] positron emission tomography (PET) images, yielding radioactive count files for conversion to normalized (relative) regional CBF. The middle and final images in each row show relative regional CBF as measured by PET. The range on the arbitrary color scale is from 0.0 to 2.5 times background activity. Whole brain average regional CBF is 1.0 on the scale. Areas with greatest relative regional CBF are shown in red. Activity in the amygdala and in the anterior cingulate differentially increased during the cocaine video. *Taken with permission from Childress et al. (1999).*

methamphetamine, nicotine, alcohol, and THC produces changes in activation of the orbitofrontal cortex, prefrontal cortex, anterior cingulate cortex, amygdala, and ventral striatum. These changes are reflected both in functional magnetic resonance images and in oxygen utilization as measured by positron emission tomography. The changes evoked during acute intoxication often are accompanied by an increase in the availability of dopamine, particularly in striatal regions.

In contrast, acute and chronic withdrawal reverses these changes, resulting in decreases in metabolic activity in the orbitofrontal cortex, prefrontal cortex, and anterior cingulate cortex and decreases in basal dopamine activity in the striatum and prefrontal cortex as reflected in decreases in D_2 receptor binding (Fig. 41.11). The decreases in dopamine activity have also been validated by challenge studies where cocaine- and alcohol-dependent individuals show blunted dopamine responses to psychostimulant challenge (Volkow et al., 1997b; Martinez et al., 2005).

Craving elicited by presenting cues associated with cocaine, alcohol, nicotine, and THC appears to activate the same circuits as acute intoxication, but with the reactivation of the prefrontal cortex, orbitofrontal cortex, and anterior cingulate cortex and the additional recruitment of activation in the amygdala (Childress et al., 1999) (Fig. 41.11).

Signal Transduction Mechanisms Show Neuroadaptative Changes with Substance Dependence

Chronic drug use not only increases transmitter release via presynaptic effects but also produces long-lasting alterations in postsynaptic receptor activation, signal transduction, and gene expression (Robison & Nestler, 2011). For example, whereas chronic opioid use has minimal effects on the binding of opioid receptors by opioid peptides, it dramatically alters signal transduction in the terminal regions of the mesolimbic dopamine system, such as the nucleus accumbens (Nestler, 2001). This occurs at least in part by increasing adenylate cyclase activity and CREB. CREB is a transcription factor that increases or decreases the transcription of genes. These changes can result in the expression of novel proteins and, consequently, changes in neuronal function that could explain clinical phenomena, such as protracted abstinence and vulnerability to relapse, in people formerly addicted to drugs (Fig. 41.12).

The persistence of changes in drug reinforcement mechanisms that characterize drug addiction suggests that the underlying molecular mechanisms are long-lasting, and considerable attention has been given to the drug regulation of gene expression. Current research focuses on several types of transcription factors, including CREB and novel Fos-like proteins termed chronic Fos-related antigens. FosB, a member of the Fos family of transcription factors that dimerizes with a member of the Jun family to form activator protein-1 transcription factor complexes, has been implicated in the adaptation to chronic exposure to drugs of abuse. Activator protein-1 transcription factor complexes bind to sites in the regulatory regions of many genes. Acute administration of several drugs of abuse activates c-*fos* and Fos-related antigens, but chronic administration of drugs of abuse eliminates these activations and produces a gradual accumulation of FosB. This highly stable protein is hypothesized to function as a sustained molecular switch contributing to vulnerability to relapse after prolonged periods of abstinence (Nestler, 2001). These transcription factors may be possible mediators of chronic drug action. However, it has not yet been possible to relate regulation of a specific transcription factor to specific features of drug reinforcement or addiction.

Genetic and molecular genetic animal models have provided a convergence of data to provide hypotheses regarding vulnerability to addiction in some of the neuropharmacological substrates identified in neurocircuitry studies. High alcohol-preferring rats have been bred that show high voluntary consumption of alcohol, increased anxiety-like responses, and numerous neuropharmacological phenotypes such as decreased dopaminergic activity, increased CRF activity, and decreased neuropeptide Y activity, some of which have support from genetic studies of chromosomal linkage (Carr et al., 1998; McBride, Murphy, Lumeng, & Li, 1990; Murphy et al., 2002).

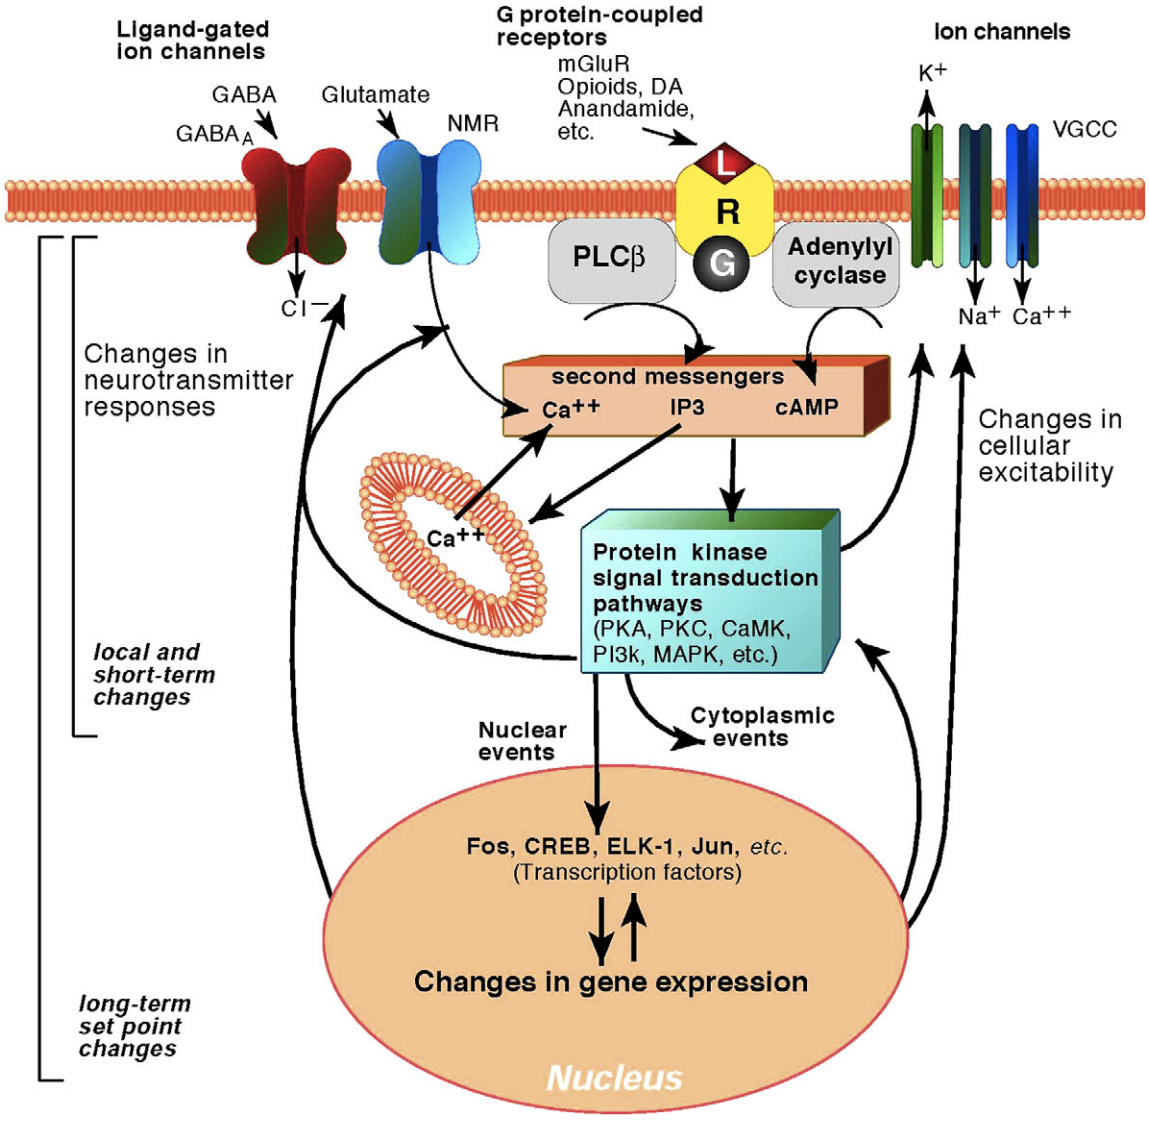

FIGURE 41.12 Molecular mechanisms of neuroadaptation. *Cocaine and amphetamines*, as indirect sympathomimetics, stimulate the release of dopamine which acts at G protein-coupled receptors, specifically D_1, D_2, D_3, D_4, and D_5. These receptors modulate the levels of second-messengers like cyclic adenosine monophosphate (cAMP) and Ca^{2+}, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and voltage-gated ion channels (VGCC). G_i and G_o proteins also can regulate K^+ and Ca^{2+} channels directly through their $\beta\gamma$ subunits. Protein kinase transduction pathways also affect the activities of transcription factors. Some of these factors, like cyclic adenosine monophosphate (cAMP) response element binding protein (CREB), are regulated posttranslationally by phosphorylation; others, like Fos, are regulated transcriptionally; still others, like Jun, are regulated both posttranslationally and/or transcriptionally. While membrane and cytoplasmic changes may be only local (e.g., dendritic domains or synaptic boutons), changes in the activity of transcription factors may result in long-term functional changes. These may include changes in gene expression of proteins involved in signal transduction and/or neurotransmission, resulting in altered neuronal responses. For example, chronic exposure to psychostimulants has been reported to increase levels of protein kinase A (PKA) and adenylyl cyclase in the nucleus accumbens and to decrease levels of $G_{\alpha i}$. Chronic exposure to psychostimulants also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens by chronic cocaine treatment. Chronic cocaine induces a transition from Fos induction to the induction of the much longer-lasting Fos-related antigens such as ΔFosB. *Opioids*, by acting on neurotransmitter systems, affect the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Shown are examples of ligand-gated ion channels such as the γ-aminobutyric acid-A ($GABA_A$) and glutamate *N*-methyl-D-aspartate (NMDA) receptor (NMR) and G protein-coupled receptors such as opioid, dopamine (DA), or cannabinoid CB_1 receptors, among others. These receptors modulate the levels of second messengers like cAMP and Ca^{2+}, which in turn regulate the activity of protein kinase transducers. Chronic exposure to opioids has been reported to increase levels of PKA and adenylyl cyclase in the nucleus accumbens and to decrease levels of $G_{\alpha i}$. Chronic exposure to opioids also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens and increased in the locus coeruleus by chronic morphine treatment, while chronic opioid exposure activates Fos-related antigens such as ΔFosB. *Alcohol*, by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Shown are examples of ligand-gated ion channels such as the $GABA_A$ and the NMDA receptor and G protein-coupled receptors such as opioid, dopamine, or cannabinoid CB_1 receptors, among others. The latter also are activated by endogenous cannabinoids such as anandamide. These receptors modulate the levels of second messengers such as cAMP and Ca^{2+}, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and VGCCs. Alcohol, for instance, has been proposed to affect the $GABA_A$ response via protein kinase C (PKC) phosphorylation. G_i and G_o proteins also can regulate K^+ and Ca^{2+} channels directly through their $\beta\gamma$ subunits. Chronic exposure to alcohol has been reported to increase levels of PKA and adenylyl cyclase in the nucleus accumbens and to decrease levels of $G_{i\alpha}$. Moreover, chronic ethanol induces differential changes in subunit composition in the $GABA_A$ and glutamate inotropic receptors and increases expression of VGCCs. Chronic exposure to alcohol also alters the expression of transcription factors themselves. CREB expression, for instance, is increased in the nucleus accumbens and decreased in the amygdala by chronic alcohol treatment. Chronic alcohol induces a transition from Fos induction to the induction of the longer-lasting Fos-related antigens. *Nicotine* acts directly on ligand-gated ion channels. These receptors modulate the levels of Ca^{2+}, which in turn regulate the activity of protein kinase transducers. Chronic exposure to nicotine has been reported to increase levels of PKA in the nucleus accumbens. Chronic exposure to nicotine also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the amygdala and prefrontal cortex and increased in the nucleus accumbens and ventral tegmental area. *Δ9-Tetrahydrocannabinol* (THC), by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Cannabinoids act on the cannabinoid CB_1 G protein-coupled receptor. The CB_1 receptor also is activated by endogenous cannabinoids such as anandamide. This receptor modulates (inhibits) the levels of second messengers like cAMP and Ca^{2+}, which in turn regulate the activity of protein kinase transducers. Chronic exposure to THC also alters the expression of transcription factors themselves. CaMK, Ca^{2+}/calmodulin-dependent protein kinase; ELK-1, E-26-like protein 1; PLCβ, phosphlipase C β; IP3, inositol triphosphate; MAPK, mitogen-activated protein kinase; PI3K, phosphoinositide 3-kinase; R, receptor. *Modified with permission from Koob, Sanna, and Bloom, (1998).*

BOX 41.8

MAJOR DEPRESSIVE DISORDERS

Feeling sad and blue are common and universal moods experienced in response to transient loss, stress, or disappointment. The clinical diagnosis of major depressive disorder (MDD) involves a persistent symptom complex that includes some combination of depressed mood, diminished interest or pleasure, changes in sleep and appetite, excessive guilt, agitation or retardation, loss of energy, diminished ability to think or concentrate, thoughts of death, and thoughts of suicide. These symptoms are recurrent and persistent and produce impairment.

Major depression is highly prevalent in all cultures and countries studied, and it is the most common psychiatric condition in medical patients. The community lifetime prevalence is approximately 12 to 15%, with the lowest rates in Asian countries and the highest in the Americas, Europe, and Australia. Even in countries with lower rates, it is not rare. The rates are two- to threefold higher in women than men. MDD is uncommon before puberty, with a marked increase in females during adolescence and following childbirth, and a decrease in first onset after menopause. Major depression with a first onset in the 60s or later is often associated with dementia or a medical condition.

Epidemiologic studies from the United States and elsewhere have documented higher lifetime rates of MDD in younger age groups. An analysis by birth cohort showed that rates of depression rose in cohorts born after World War II (the baby-boom generation). Numerous hypotheses noting the social changes that have occurred since that period have

BOX 41.8 (*cont'd*)

been considered, with no confirmed explanation. Follow-up epidemiologic studies carried out a decade or more later, in the 2000s, found the highest prevalence among the middle-age group (30–64 years), suggesting that the cohort born after WWII were carrying forth their high rates as they aged.

Different subtypes of major depression have been identified, including depression with psychotic features and a typical depression. Efforts to understand the heterogeneity of MDD by subtyping symptoms, however, are inherently difficult, as patients' symptoms may change with different episodes. Major depression in the context of a history of mania (bipolar disorder) has the most severe course and requires treatment that prevents both the depressive and the manic symptoms.

Depression is an extremely disabling disorder. About 75% of patients have recurrent episodes. Ten to 30% recover incompletely, with persistent residual symptoms. MDD also complicates the course of cardiovascular illness, diabetes, hypertension, and other chronic medical conditions. Suicide, accidents, and the risk of death from heart disease are highest among the depressed. Because onset is early, recurrence rates are high, and the years lived with disability are high, MDD is considered, according to the World Health Organization, to be among the most disabling medical conditions in the world, similar to ischemic heart disease.

Rates of MDD are highest in persons who are divorced, separated, or widowed, and lowest in unmarried or never-married persons. These differences vary by country and are confounded by the difficulty in determining the sequence of divorce, separation, and depression. The one clear finding is that the ending of marriage, when it occurs, is associated with an increase in MDD.

The increased risk of MDD in first-degree relatives of a depressed patient is approximately two- to sixfold, depending on the severity of the disorder. This pattern of transmission is found across cultures and countries. Early-onset recurrent MDD has the highest relative risk, with estimates as high as eightfold. The best replicated findings are the high rates of MDD, anxiety disorders, and conduct disorder found in the biological young offspring of depressed as compared to nondepressed parents. These studies have been carried out in three generations and show that grandchildren with two generations affected are at extremely high risk of developing MDD at a young age.

The high familial rate of MDD across generations is supported by twin studies showing higher rates of depression in monozygotic twins, and an estimated heritability of 37 to 43%. These estimates are similar to those described for Type 2 diabetes. Several large-scale molecular genetic studies of MDD have been undertaken; most have focused on early-onset (<30 years) recurrent MDD, since this subtype has the highest familial rate. DNA and deidentified clinical information from these studies are stored in the National Institute of Mental Health (NIMH)'s national repositories for use by qualified scientists. As of 2012, a large Genome-Wide Association (GWA) study with participation by numerous investigators across the globe is underway. Many sequence variations in several genes have been reported, but no consistently replicated findings are yet available.

Availability of families at high risk for MDD (by virtue of having a FDR with the disorder) and the numerous positive clinical trials of drugs for MDD have led to a search for biomarkers or "endophenotypes" for MDD. By identifying subjects at risk for depression but not yet ill, this approach allows the disentangling of processes that present *prior* to the illness and are therefore more likely to be true risk factors. One study using magnetic resonance imaging (MRI) found 30% cortical thinning in the second and third generations of high-risk, as compared to low-risk, families that was independent of presence of MDD in the subject. Cortical thinning in areas that regulate emotion and cognitive stress response may thus be a familial trait marker for vulnerability to MDD. The first large-scale study to develop a platform for biomarkers using MRI, electroencephalography, behavioral tasks, and genetics to predict treatment response to MDD using selective serotonin reuptake inhibitors was initiated in 2011. Other promising areas for depression research include studies of circulatory levels of peripheral/serum growth factors and cytokines, which are altered in patients with MDD and which may be normalized or reversed with antidepressant treatment. There is agreement that a single biomarker approach may not be useful. The development of biomarker panels that profile a diverse array of peripheral/serum growth factors, cytokines, hormones, and metabolic markers may provide better coverage of the biologic abnormalities in MDD.

There are numerous studies on the efficacy of both medications and psychotherapy for depression. Treatment can hasten remission, may reduce suicide risk, and, if continued, can prevent relapse. Many of the pharmacologic agents with effective antidepressant action amplify serotonin or neurepinephrine signaling by inhibiting reuptake. There are also several evidence-based psychotherapies developed for MDD. They target the distorted thinking of depression (cognitive therapy) or stressful life events (grief, disputes, transitions) that trigger an episode (interpersonal psychotherapy). Drugs and psychotherapy in combination have been shown usually to have the best outcome, but many patients do not have access to, cannot afford, or do not want both. Both classes of treatment need to deal with the delayed response rate (3 to 4 weeks) and the high recurrence rate. Continuation or maintenance therapy (drugs or psychotherapy) is usually indicated.

Myrna M. Weissman and Ardesheer Talati

Advances in molecular biology have led to the ability to systematically inactivate the genes that control the expression of proteins that make up receptors or neurotransmitter/neuromodulators in the central nervous system using the gene knockout approach. Notable positive results with gene knockout studies in mice have focused on knockout of the μ opioid receptor, which eliminates opioid, nicotine, alcohol, and cannabinoid reward in mice (Contet, Kieffer, & Befort, 2004). Selective deletion of the genes for expression of the dopamine D_1 and D_2 receptor subtypes and the dopamine transporter has revealed significant decreases in activation and reward produced by psychomotor stimulants. Although developmental factors must be taken into account for the compensatory effect of deleting any one or a combination of genes, it is clear that D_1 and D_2 receptors and the dopamine transporter play important roles in the actions of psychomotor stimulants (Caine, Gabriel, Berkowitz, Zhang, & Xu, 2002).
